Acerca de este libro

Esta es una copia digital de un libro que, durante generaciones, se ha conservado en las estanterías de una biblioteca, hasta que Google ha decidido escanearlo como parte de un proyecto que pretende que sea posible descubrir en línea libros de todo el mundo.

Ha sobrevivido tantos años como para que los derechos de autor hayan expirado y el libro pase a ser de dominio público. El que un libro sea de dominio público significa que nunca ha estado protegido por derechos de autor, o bien que el período legal de estos derechos ya ha expirado. Es posible que una misma obra sea de dominio público en unos países y, sin embargo, no lo sea en otros. Los libros de dominio público son nuestras puertas hacia el pasado, suponen un patrimonio histórico, cultural y de conocimientos que, a menudo, resulta difícil de descubrir.

Todas las anotaciones, marcas y otras señales en los márgenes que estén presentes en el volumen original aparecerán también en este archivo como testimonio del largo viaje que el libro ha recorrido desde el editor hasta la biblioteca y, finalmente, hasta usted.

Normas de uso

Google se enorgullece de poder colaborar con distintas bibliotecas para digitalizar los materiales de dominio público a fin de hacerlos accesibles a todo el mundo. Los libros de dominio público son patrimonio de todos, nosotros somos sus humildes guardianes. No obstante, se trata de un trabajo caro. Por este motivo, y para poder ofrecer este recurso, hemos tomado medidas para evitar que se produzca un abuso por parte de terceros con fines comerciales, y hemos incluido restricciones técnicas sobre las solicitudes automatizadas.

Asimismo, le pedimos que:

+ *Haga un uso exclusivamente no comercial de estos archivos* Hemos diseñado la Búsqueda de libros de Google para el uso de particulares; como tal, le pedimos que utilice estos archivos con fines personales, y no comerciales.
+ *No envíe solicitudes automatizadas* Por favor, no envíe solicitudes automatizadas de ningún tipo al sistema de Google. Si está llevando a cabo una investigación sobre traducción automática, reconocimiento óptico de caracteres u otros campos para los que resulte útil disfrutar de acceso a una gran cantidad de texto, por favor, envíenos un mensaje. Fomentamos el uso de materiales de dominio público con estos propósitos y seguro que podremos ayudarle.
+ *Conserve la atribución* La filigrana de Google que verá en todos los archivos es fundamental para informar a los usuarios sobre este proyecto y ayudarles a encontrar materiales adicionales en la Búsqueda de libros de Google. Por favor, no la elimine.
+ *Manténgase siempre dentro de la legalidad* Sea cual sea el uso que haga de estos materiales, recuerde que es responsable de asegurarse de que todo lo que hace es legal. No dé por sentado que, por el hecho de que una obra se considere de dominio público para los usuarios de los Estados Unidos, lo será también para los usuarios de otros países. La legislación sobre derechos de autor varía de un país a otro, y no podemos facilitar información sobre si está permitido un uso específico de algún libro. Por favor, no suponga que la aparición de un libro en nuestro programa significa que se puede utilizar de igual manera en todo el mundo. La responsabilidad ante la infracción de los derechos de autor puede ser muy grave.

Acerca de la Búsqueda de libros de Google

El objetivo de Google consiste en organizar información procedente de todo el mundo y hacerla accesible y útil de forma universal. El programa de Búsqueda de libros de Google ayuda a los lectores a descubrir los libros de todo el mundo a la vez que ayuda a autores y editores a llegar a nuevas audiencias. Podrá realizar búsquedas en el texto completo de este libro en la web, en la página `http://books.google.com`

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

THE
Electrical Engineer.

VOL. XIII. JANUARY 6, 1892. No. 192.

THE BUILDING OF PERRET DYNAMOS AND MOTORS.

I.

FEW developments in the electrical domain of late years have been more rapid and more interesting than those which pertain to the electric motor industry. The practical utilization of electric power may be said to date from the International Electrical Exhibition of 1884, but it is only within the last two or three years that motor building has taken prominent place among the electric arts, opening up a field of activity and usefulness the limits of which no man can set. It is said by some observers that already the production of generators to furnish current for motors is larger than that of generators for lighting; and while this may not be true, it is evident that when the employment of lighting generators during daylight hours for power purposes is taken into account, the motor is even to-day well abreast of the lamp as a consumer of current. This state of affairs is in many respects matter for congratulation, and the double demand for current cannot but hasten the coming of the time when electric mains will ramify as universally and be availed of as freely as are water mains at this moment.

The popularity of electric power has, as readers of THE ELECTRICAL ENGINEER are well aware, called various types of motors into existence, the majority of which were of the high-speed type, a feature against which no small portion of the public raised objection on the very natural ground that such high speeds rendered it difficult to effect feasible and satisfactory combinations between the driving and the driven mechanism. One of the very first inventors and designers to give attention to the production of "slow speed" motors, was Mr. Frank A. Perret, and his ideas enlisted so much support that the Elektron Manufacturing Company was formed and a large factory started in Brooklyn, N. Y. Owing to the rapid growth of the business, larger quarters became necessary, and after the inspection

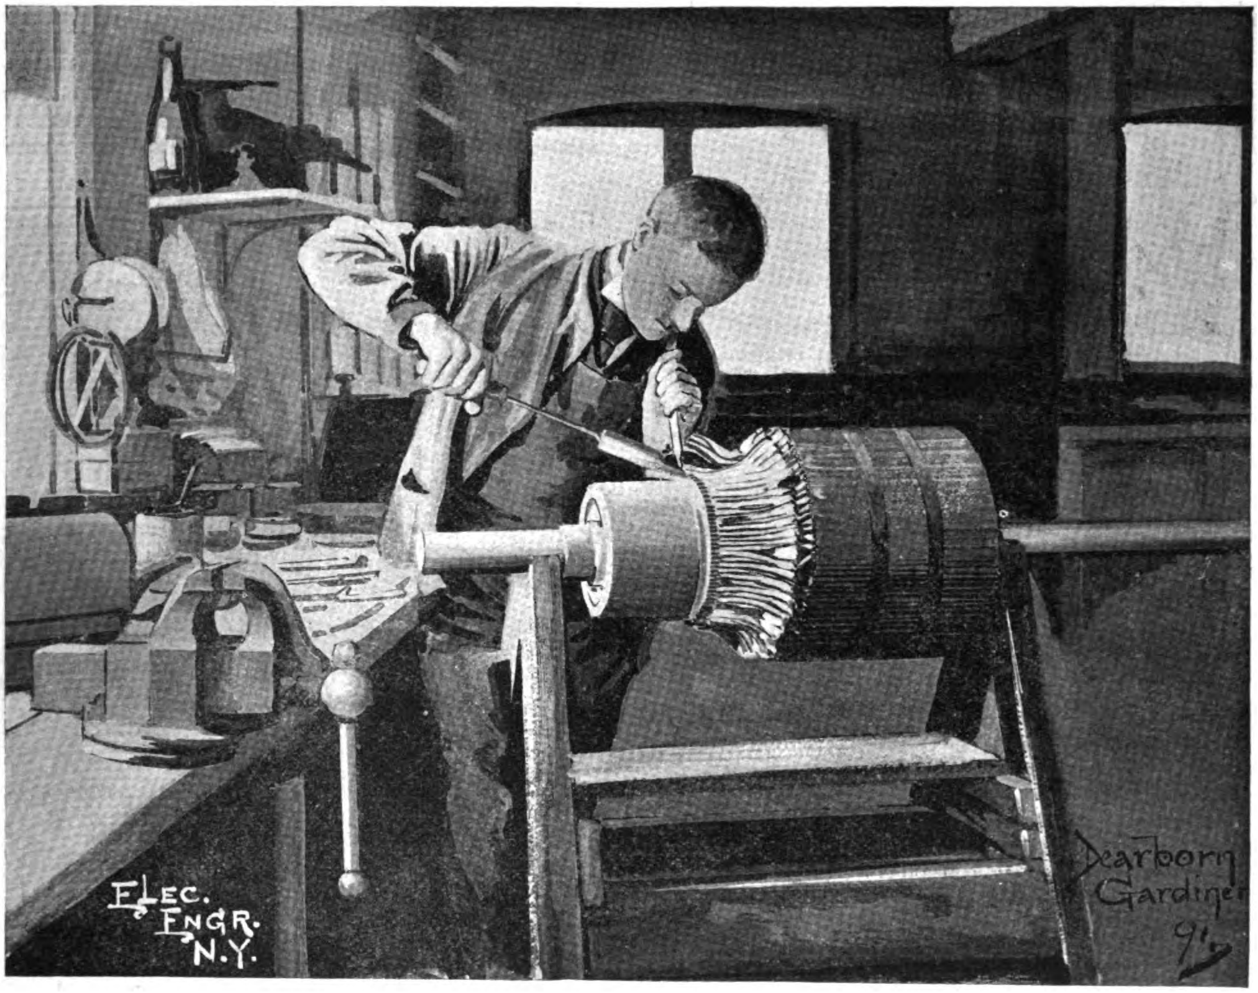

FIG 9.—CONNECTING ARMATURE COILS WITH COMMUTATOR IN A PERRET MOTOR.—(See page 6.)

of a number of properties, choice was made early last year of a fine manufacturing building at Springfield, Mass., whither a removal was made during the summer. The new factory is now in full swing, and the various processes and ideas there illustrated are so important, interesting and ingenious that no apology need be offered for making here an extended description of them, setting forth standard methods of motor manufacture in America.

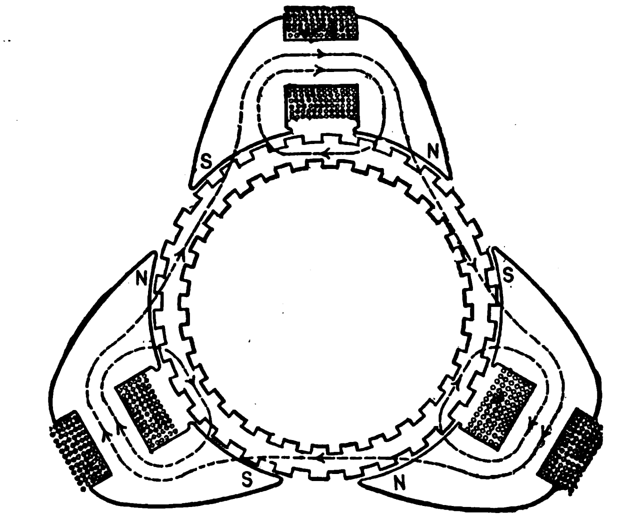

FIG. 1.—PERRET MULTIPOLAR FIELD.

II.

Before entering into a description of the method of manufacture adopted in the Perret motors, it may be well to touch briefly upon the reasoning which led Mr. Perret to design the machine as we find it. He had long recognized that the speeds at which the original types of bi-polar motors were operated were such as to lead to inconveniences and additional care in attendance at the motor, and necessitated as a rule the employment of counter-shafting, which always involved an additional expense whenever such a high-speed motor was installed. He had, therefore, started out at once with the problem of producing a slow-speed motor; that is to say, not to wind an armature to run slowly, but to design a machine for low speed which should have as high an efficiency as those of the high-speed bi-polar type. But how was this to be accomplished? Mr. Perret argued that in the ordinary two-pole machine the armature conductor crosses the magnetic circuit and cuts all the lines of force twice during a complete revolution, viz., where they enter the armature core at one pole and where they leave it at the other. Now, if we so dispose the magnetic circuit as to cause the lines of force to enter the armature core at one point, to leave it at another, to enter it again at a third point and to leave it at a fourth, it is obvious that the conductor will cut all the lines at four points in each revolution, and that it will, therefore, generate the same E. M. F. at one-half the original speed. If we increase the number of poles to six, we shall obtain the same effect at one-third the speed, etc., etc. This, then, is the principle of construction by which low speed is secured.

Fig. 1 is a diagram of the magnetic circuit of the Perret machine. As will be seen, there are but three magnets, each being isolated magnetically from the others excepting through the medium of the armature core, and completely isolated from the frame-work of the machine. They are formed of plates of soft sheet-iron, which are punched to the required shape and strung together on non-magnetic bolts by which they are secured to their supports. A single magnetizing coil forms two salient poles, and as each magnet is built of a large number of plates a uniform magnetic conductivity is secured. By this method of construction all danger of any inequality in the strength of the poles is avoided, and a magnetic circuit without joints and of the lowest possible resistance is secured. It is understood, of course, that in all cases the number of ampere turns on each magnet must be equal.

III.

The works, a view of which is given in Fig. 2, are situated on Wilbraham street, beside the New York & New England railroad, from which a side track is run in. The main building is of brick, 40 feet by 55 feet, and four stories high. It has a long three-story wing, 125 feet by 40 feet. In this wing the workrooms are located. A brick engine and boiler-house, 45 feet square, is situated north of the main building, with a 15-foot passageway between. The 16-inch leather belt, by which power is transmitted from the engine to the main shafting, passes above this driveway in a covered bridge.

The plan upon which the machinery and the works at Springfield, Fig. 2, have been laid out is such as to effect the greatest economy in time, both as to the manipulation of the raw material and the assembling of the finished parts. In the reception of the raw material the works are peculiarly fortunately situated by having the New York and New England railroad beside them, so that the raw material can practically be unloaded directly from the cars into the shop basement floor. This first floor is a little below the level of the street and constitutes the heavy machine-room where the heavy lathes, planers and drilling machines, are situated. In this department, among other things, the rough castings are finished off and a number of special tools are employed to insure accuracy in the pro-

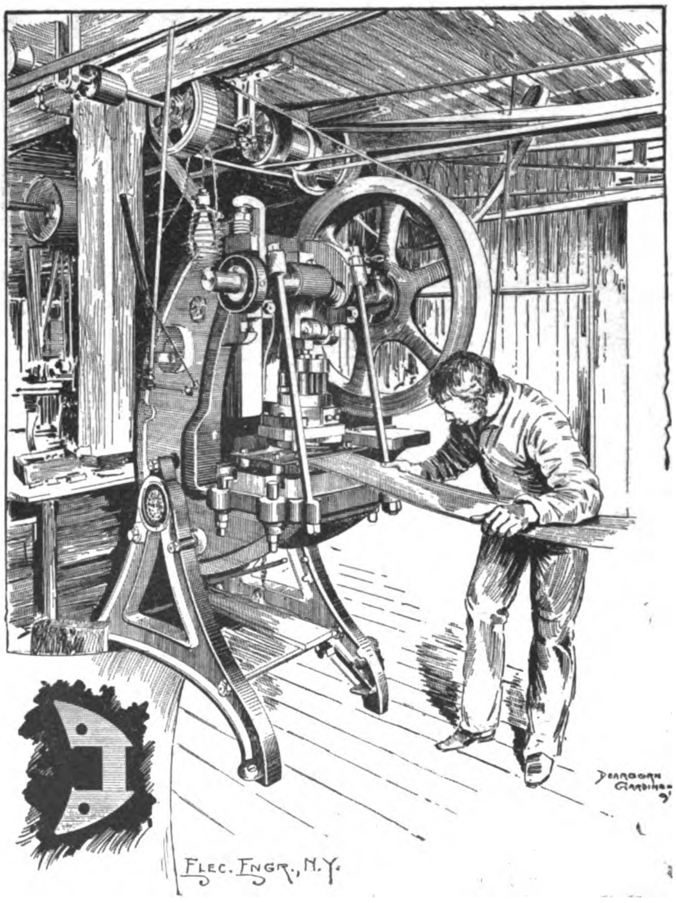

FIG. 3.—STAMPING OUT LAMINÆ FOR FIELDS.

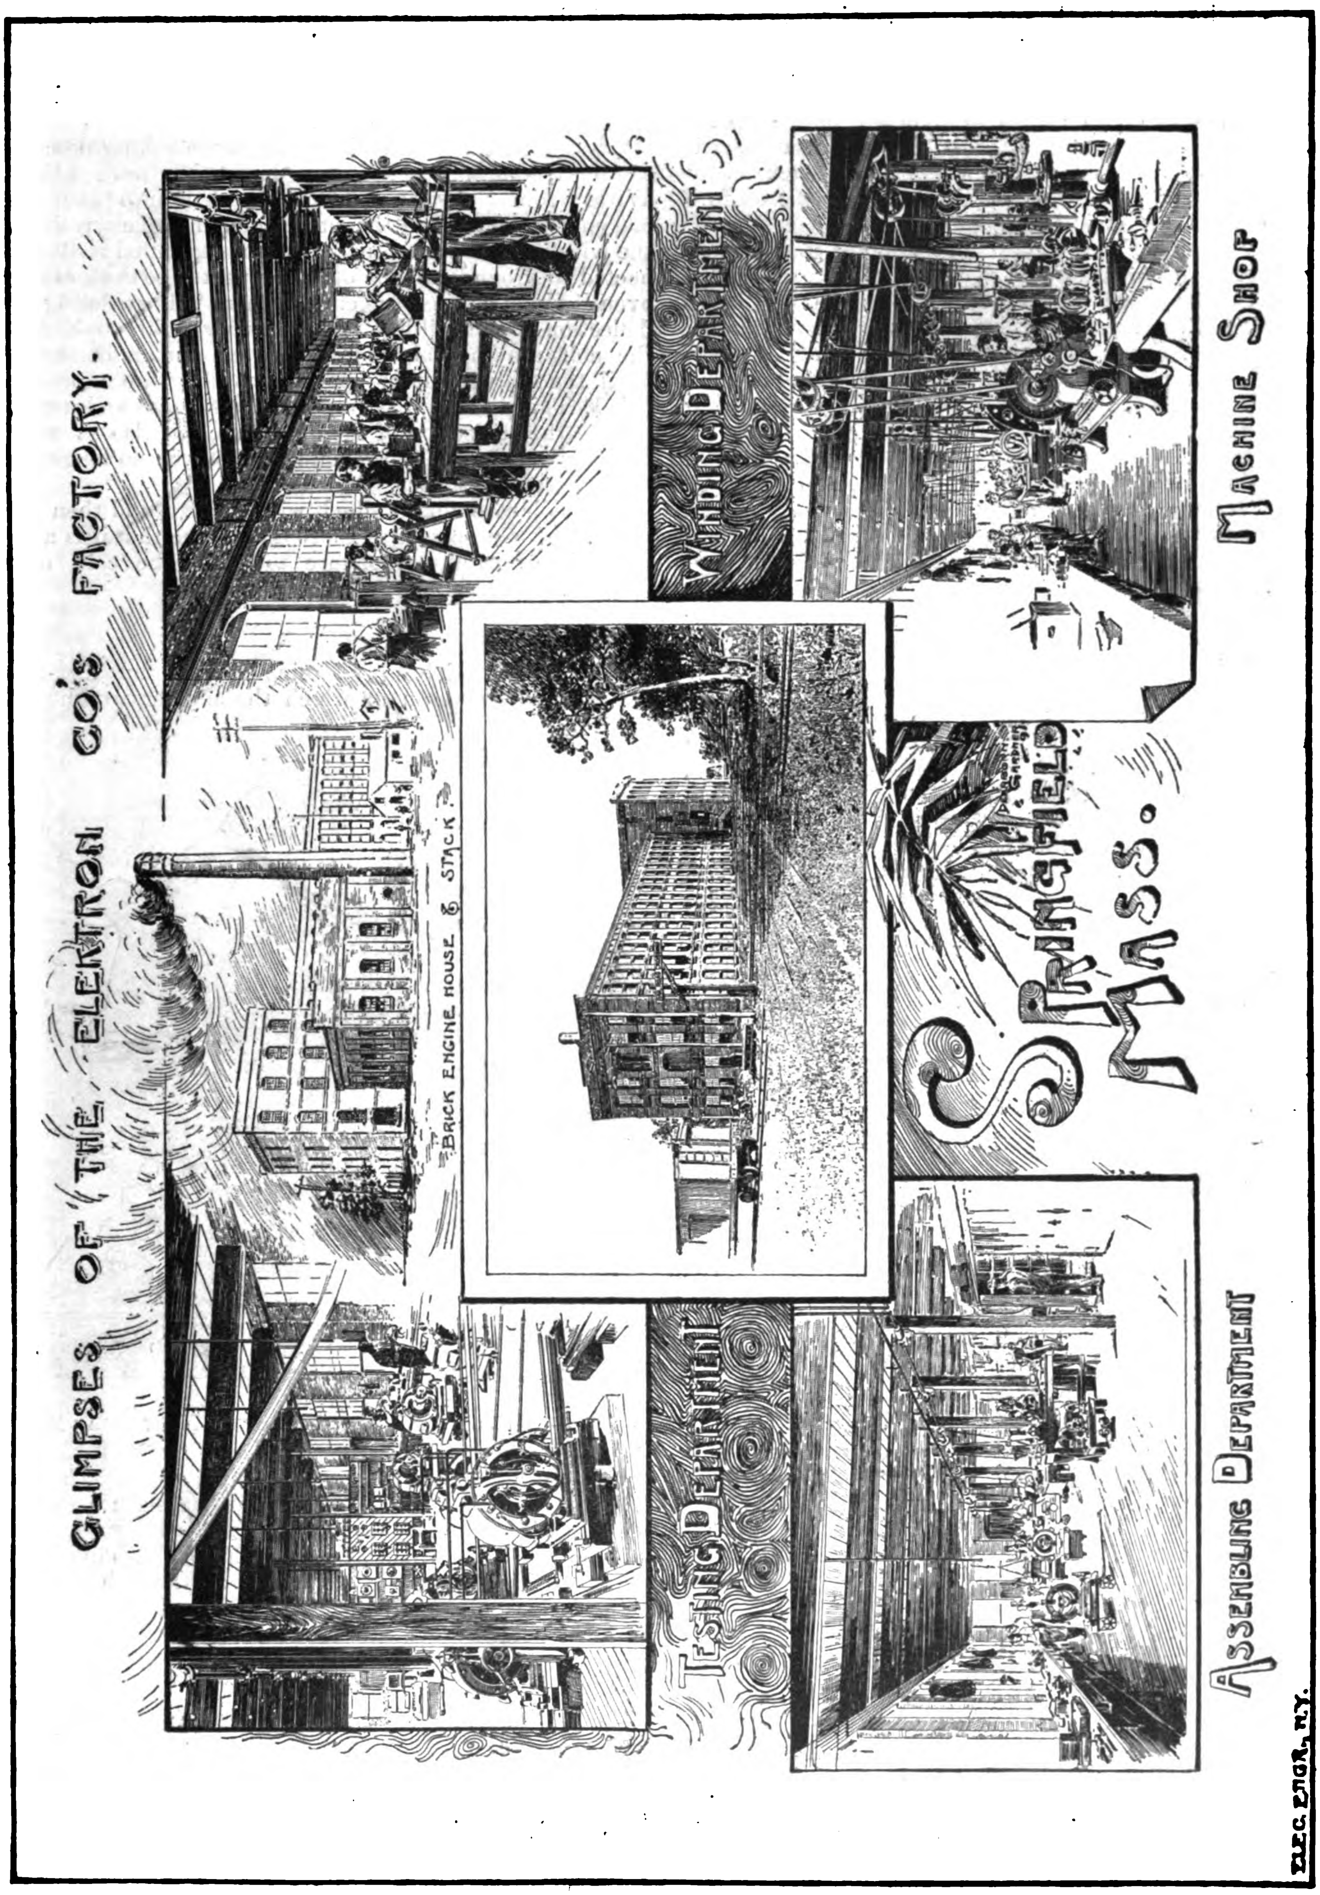

FIG. 2.—TESTING, WINDING, ASSEMBLING AND MACHINE DEPARTMENTS, ELEKTRON FACTORY, SPRINGFIELD, MASS.

ducts, as well as speed in their production. Notable among these is a special turntable "monitor" lathe, built by the Jones & Lamson Machine Works, of Springfield, which is able to take the heaviest cuts from stock and to screw thread shafts up to two inches in diameter in one operation. This machine alone performs practically automatically the work of a number of ordinary lathes attended by machinists, and on a size of work never heretofore attempted, with, of course, a large saving in time.

The engraving, Fig 2, shows the section of the machine shop devoted to the lathes and planers. On this floor also are situated the heavy presses for stamping out the sheets from which the armature and field magnets are built up. Our engraving, Fig. 3, shows one of these presses, which are able to stamp out the largest sized sheets required, and in the lower left-hand corner is shown the single stamping of the field magnet. The presses are placed close to the windows and the iron is dumped from the cars directly into a chute through the windows of the shop on to the floor. Here it is first cut up into suitable strips and then fed into the presses. Only the softest decarbonized steel is employed for this purpose, which has been rolled and pickled, and this quality of iron is used for both the armature and the field. Here we also find a well-regulated tool-room and a fireproof tool vault where the expensive dies and other standard jigs and gauges are stored, by which the work is constantly standardized in its progress and the tools kept to their correct size by comparison with the originals. The basement floor also contains the stock room where all raw material, such as castings, iron, brass, sheets, fibre and drop forgings, are kept in quantity and drawn from as the demand warrants.

Close beside this we find the room devoted to nickel plating and dipping, which the company has installed in order to avoid the delays frequently encountered in having this work done outside, and here also the polishing of the finished parts in brass is carried out. The freight elevator which passes up through the entire height of the building has its lowest landing on this floor, and is so arranged that trucks bringing in raw material back right up and deliver their goods directly upon the elevator platform, whence they are raised to the floor desired without further handling.

IV.

We will now ascend to the top floor of the building and trace the course of the work as it steadily proceeds towards the assembling-room below. This floor is devoted to the construction and winding of the field magnets and armatures.

The first operation in the construction of the field magnets is to punch the plates from the softest sheet iron that can be possibly obtained, which operation has just been described. The round holes through these plates are very carefully located and a number of the plates are then clamped together by bolts through the holes and with nuts on the same to form a field magnet, shown in Fig. 4. This constitutes one of the distinguishing features of the Perret machines, namely, that the magnets are built from plates of sheet iron instead of being made from a solid casting or forging.

The magnets thus constructed are then sent to the insulating-room where the magnet heads are applied and the magnet core and heads are thoroughly insulated by several thicknesses of canvas and tough paper prepared especially for this purpose and thoroughly shellacked.

The magnets thence pass to the winding-room where they are mounted between centres and revolved, the wire being wound on insulating and fire-proof spools, being guided by an attendant. This operation is well shown in the engraving, Fig. 4, which shows a coil almost completed.

After the magnets are wound, they are placed in a steam box and baked at a temperature of over 250 degrees until the shellac has been perfectly dried in place. Much inconvenience has been experienced in motor work, and, indeed, not a few troubles have developed, from the fact that the condition of the coils to be dried was not ascertained while the coil was in the oven. In order therefore to have an absolute means of ascertaining when the baking process is complete, the following arrangement has been adopted: Wires from the testing-room are led into the oven, one end grounded and the other touching one terminal of the wire coil. In the testing-room, one terminal is also connected to ground and the other connected to the coil in the oven. Upon closing the circuit there will evidently be a deflection if the coil has not been thoroughly baked, and the coils are thus always allowed to remain in the oven until the galvanometer shows that they are thoroughly dried. This method leaves no room for doubt and not only insures the perfection of the operation, but also saves time by allowing the coils to remain in the oven no longer than is absolutely necessary.

The coils are finally filled with shellac and then again dried. This process is so thoroughly done that it is almost impossible for any moisture to enter the coils of the magnet.

V.

While this work has been going on in the winding-room, the cast iron frames upon which the magnets are mounted have been finished in the machine department. These end frames carry the bearing in which the armature shaft revolves, and are plainly shown in Fig. 5.

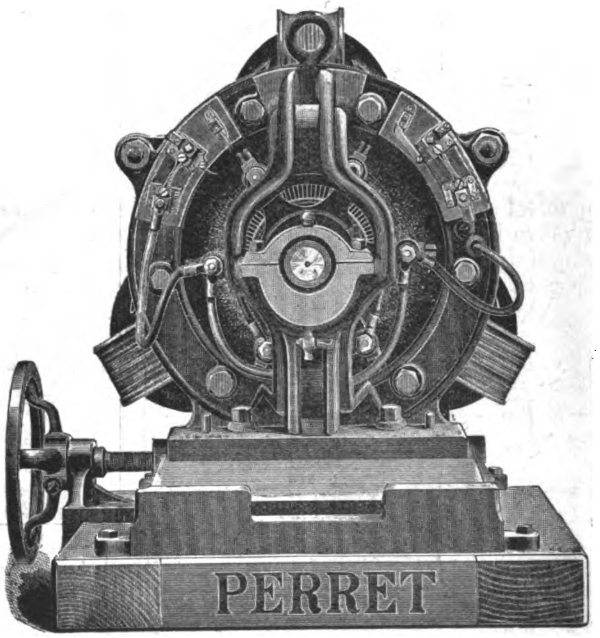

FIG. 5.—END VIEW OF PERRET LOW SPEED MULTIPOLAR MOTOR.

The same bolts which pass through the plates of the magnets binding them together, project through holes accurately located and drilled through the end frames and thus the field magnets are supported in perfect alignment with the armature.

There are three field magnets arranged at equal distances around the periphery of each armature. A bolt passes through the polar portions of each field, making two bolts to each magnet, six to each machine. The ends of these bolts are plainly seen projecting through the frame in the end view, Fig. 5.

The cast iron end frames are now bolted upon a cast-iron base which has been prepared to receive them. This base is so constructed that it slides in two cast iron ways or tracks which are bolted upon a wooden-base frame. The hand-wheel and screw are designed to force the machine in either direction on these tracks in order to loosen or tighten the belt which runs on the pulley of the machine.

The bearings of each machine are provided with a simple device by which they oil themselves. It consists of a brass ring of larger diameter than the shaft and which hangs upon the shaft inside the bearing and dips down into a chamber filled with oil. When the shaft revolves the ring revolves slowly and keeps the shaft constantly oiled. The only attention required is to change the oil every week or two.

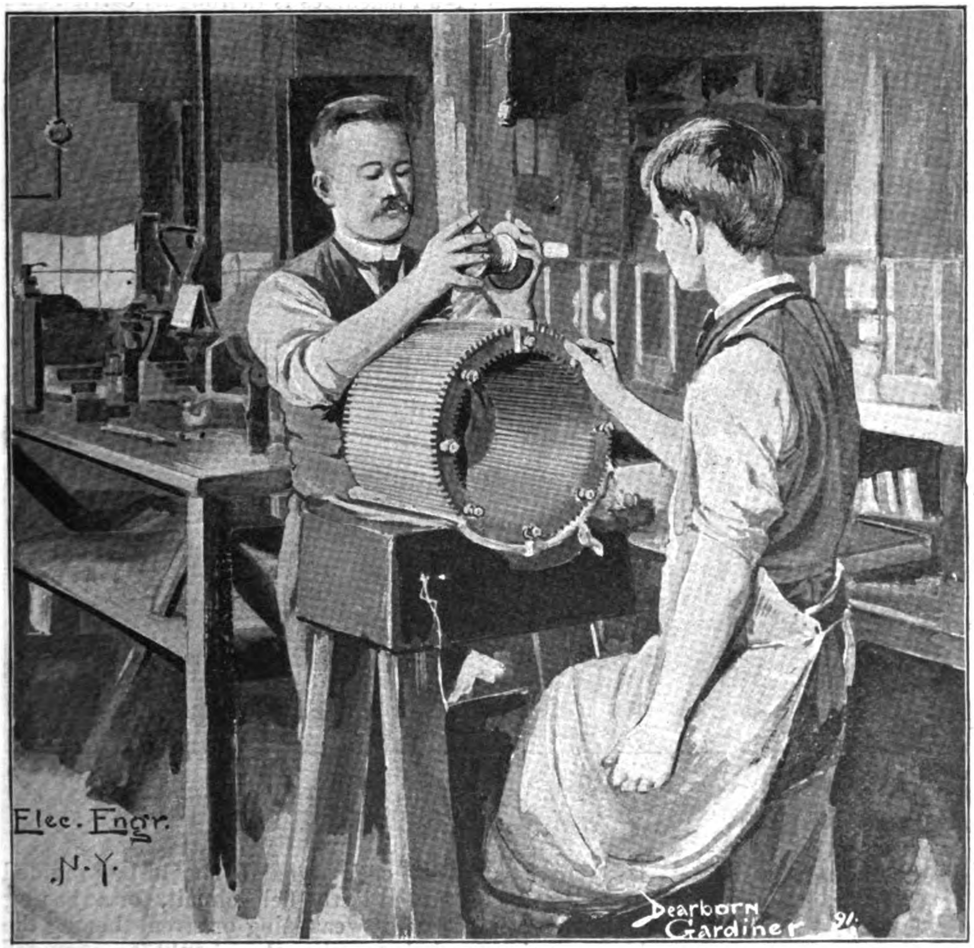
Elec. Engr. N.Y.

Fig. 4.—Winding a Perret Field Magnet.

VI.

The armature, that most important part of every dynamo-electric machine or motor, receives the most careful consideration in the Elektron Works. Its construction is commenced by cutting off a round bar of best quality steel to the proper length for the shaft and then carefully turning it in a lathe to the proper diameter; after this, key-ways or slots are cut in it by which the armature proper and the commutator may be mounted upon it. The plates are then punched out with which to build the armature core, being punched from the same quality of sheet iron as the field magnet plates. In order that the machines may be very efficient it is necessary that this iron should be of very high magnetic permeability.

The armature plates are ring-shaped with teeth on both the outside and inside of the ring. The appearance of the armature core after being built up from these plates by bolts passing through them is shown in Fig 6, and the channels formed in the periphery of the core by the teeth on the plates may also be clearly seen. The plates are held together and formed into a cylinder by screwing up nuts firmly on the ends of the eight insulated bolts which pass through them; and these same bolts serve also to attach the armature to the shaft by means of a disc or "spider" of gun metal at each end. Each spider is bored out to fit the shaft and has eight holes bored to fit the eight bolts.



Elec. Engr. N.Y.
Dearborn Gardiner 91.

Fig. 6.—Winding a Perret Armature.

The armature core is now ready to be insulated and wound. The insulation is very simply effected by means of what may be called a trough of insulating material which is slipped into each channel on the outside and also on the inside of the ring, after which a spool of magnet wire is taken and the winding is commenced. For each channel on the exterior of the ring there is a corresponding channel on the inside, and the depth and width of these channels are just right to contain the proper number of turns of wire.

The method of winding is clearly shown in the illustration, Fig. 6, one man drawing the wire through on the inside and the other pulling it over on the outside until the channel is filled. After filling one channel the end of the wire is passed onward to the next.

It is of the utmost importance in electrical machines that the wire shall be of sufficient size to carry the full current without heating and that it shall be so perfectly insulated that there shall be no contact between adjacent wires or with the iron core of the armature. Also that it shall be held so rigidly that it cannot be shifted out of place by any strain that may be thrown upon it. This is all facilitated by the plan of winding the wires in channels instead of winding on a smooth round periphery as is sometimes done. After the winding of the armature is completed it is dried, shellacked, and dried again, the same as in the case of the field magnet.

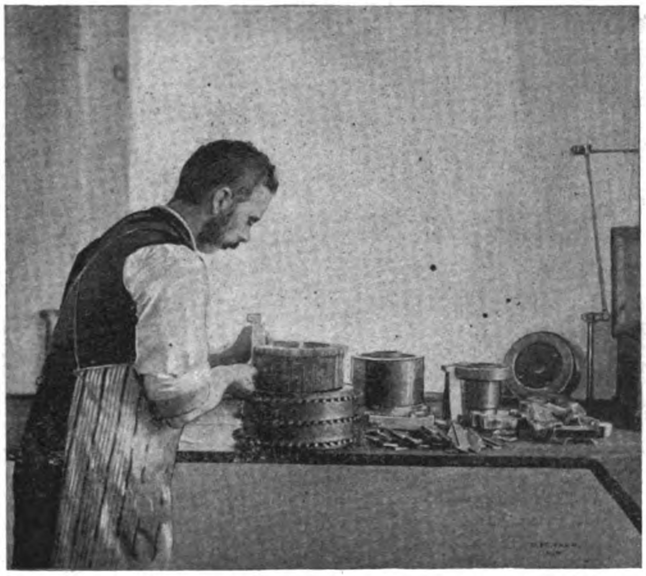


FIG. 7.—BUILDING UP A COMMUTATOR.

In order to mount the armature upon the shaft one of the spiders which we have previously described is bolted to each end of the armature ring by means of the same bolts that pass through the core and clamp the plates together, and the whole is then slipped upon and keyed to the shaft. The commutator is then slipped upon and keyed to the shaft.

VII.

The construction of the commutator, the tender spot in every continuous-current machine, is an operation requiring the greatest care. A single error, which might not appear on the surface, might be enough to cause serious trouble in the working of the machine. The method here adopted is illustrated in Fig. 7, showing the process of building up a commutator from the copper segments, a pile of which may be seen on the bench at the workman's right. Each of these segments must be set in its exact place inside the ring-shaped fixture, and it must be thoroughly insulated by a solid layer of best quality mica from every other section and also from the two end discs between which it is clamped. When all put together the commutator has the appearance shown in Fig. 8, which shows it mounted on a mandril undergoing its final turning in the lathe. The segments are all formed of the purest copper, and are provided with lugs which are slotted to receive the armature coils. Fig. 9 (page 1) shows the armature of a 20 h. p. motor and commutator for the same mounted on the shaft, which is supported upon a "horse," while the workman is engaged in soldering the armature coils to the commutator segments, an operation requiring considerable care and skill.

One of the most interesting features of the Perret machines lies in the fact that for all sizes of the machine between 4 and 20 horse power, but one diameter of armature, namely, 14 inches, is employed, the various sizes being built up by increasing the length of the armature; and in a like manner increasing the width of the pole-pieces by adding more sheets, according to the length of the armature. The great economy effected by this method of construction is so obvious as to need no further pointing out, and it will also be conceded that the designing of the teeth to meet the requirements of the space required by the various sizes of wire with which each machine is wound shows the highest skill in the design of the machine.

VIII.

We now descend to the floor below, where we find the assembling department. Here the heavy parts of the machine are brought up from below, and the magnets and armatures brought down from the floor above, where they are assembled, the parts being fitted together and bolted into place. Upon these operations our engraving, Fig. 10, shows a workman engaged, fitting brasses to the bearings of the motor. After this fitting it only remains to place the armature in position, connect the wires and start up the machine.

The motor is now ready to be transferred to the testing department, which is also situated on this floor, and a view of which is shown in Fig. 2. This testing department still employs, as a generator, the first 15 h. p. multipolar Perret machine built, and its continuous active service is probably as good a proof as could be found of the general excellence, both in design and workmanship, of this machine. Here the testing of all machines is thoroughly carried out, not only electrically, but mechanically. For the latter purpose an Emerson power scale is employed and every machine is put through a continuous run of several hours at more than its rated capacity before it is allowed to go out of the works.

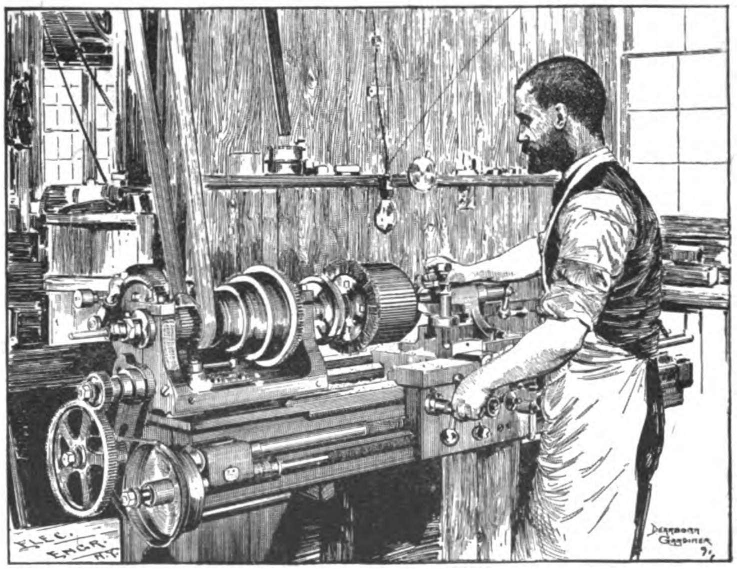

FIG. 8.—FINISHING COMMUTATOR IN LATHE.

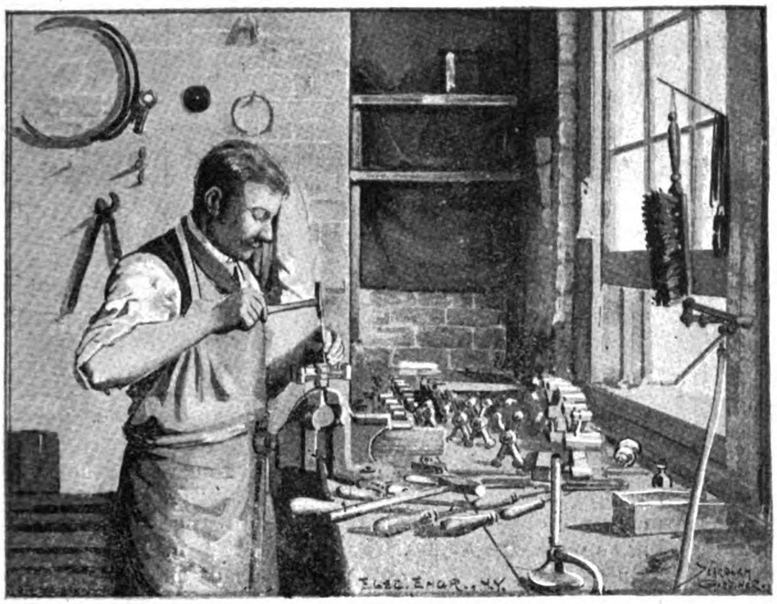
IX.

It is necessary that each dynamo should be provided with a rheostat connected in the field circuit, for adjusting the electromotive force by weakening or strengthening the field magnetism, and that each motor should be provided with a rheostat or starting box in the armature circuit to prevent an excessive rush of current on starting up the machine. The construction of these rheostats has been the subject of special study in order to provide an apparatus which should be absolutely incombustible. The necessity of this is evident when it is considered that machines are frequently placed in the care of ignorant persons, and rheostats intended to be placed in circuit for a few moments only, are left with the full current turned on for hours. As a result of this experience, the Elektron Co. make all their rheostats and starting boxes entirely of non-combustible material. The resistance coils are of German silver or galvanized iron wire, which are supported in the iron box by porcelain bushings, and the contact plates are of brass on a slate base. The engraving, Fig. 11, shows the method of conducting these rheostats, which have now become one of the standard products of the Elektron Co.



ELEC. ENGR., N.Y.

FIG. 10.—FITTING A MOTOR BEARING.

X.

A very important point in connection with all dynamo machinery is the brushes, and this has also engaged the special attention of Mr. Perret. Instead of using a solid carbon block a series of carbon pencils are employed, where the work to be effected is light and intermittent in its nature. For heavy and constant work, however, Mr. Perret has found the carbon block to be most efficient, when certain precautions are observed. Principal among these is the securing of a good connection between the carbon and the circuit wire. For this purpose the carbon brush is connected directly to the terminal wire by a short length of flexible cable, so that, having free movement under the influence of the springs, it forces itself against the commutator, the spring and the holder in which the carbon slides not being called upon to carry any of the current. The result is that the heating noted at the brushes where the latter take their current from the holder direct is practically overcome. Where the voltage is under 110 volts and heavy currents are to be carried, Mr. Perret still prefers the copper brush.

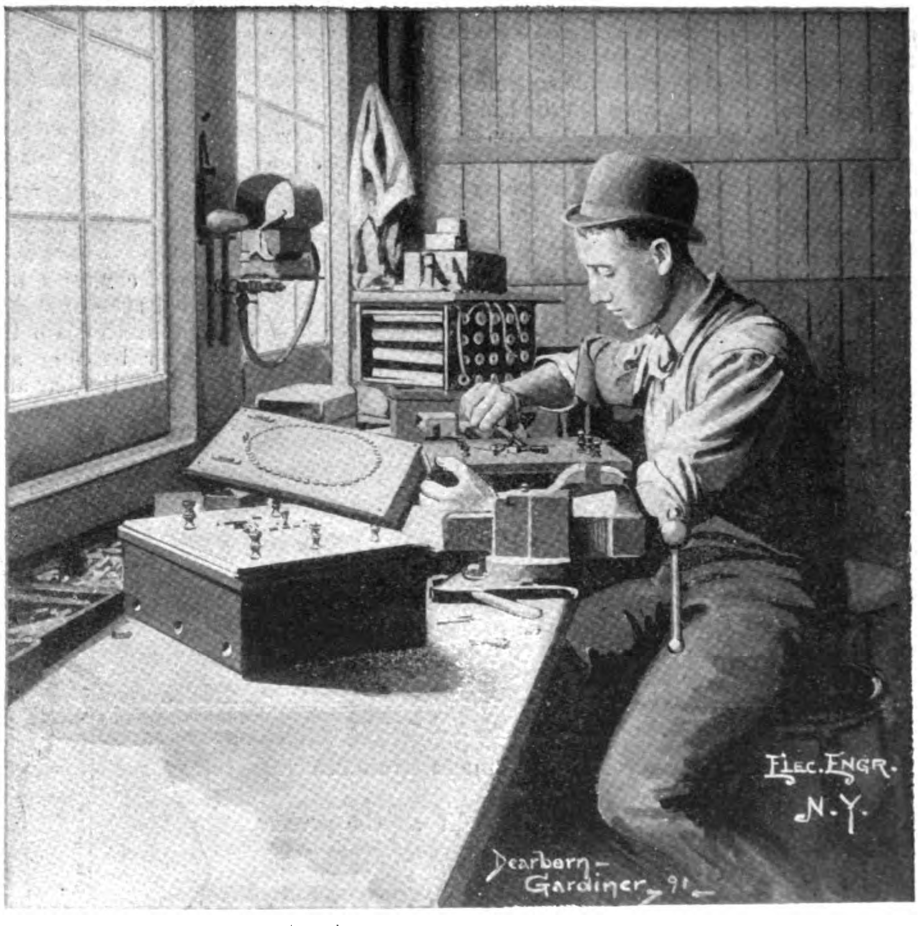


FIG. 11.—BUILDING AN ELEKTRON FIREPROOF RHEOSTAT.

XI.

The engravings, Figs. 5 and 12, show the standard Perret multipolar dynamos and motors, as at present constructed. In all essential points the construction is the same as that of the first machine which was brought out about two years. The only changes which have been found necessary have been in the minor details of the frame. In this respect the machines are quite remarkable and are a constant testimony to the genius of Mr. Perret as a designer.

The production of the company consists very largely of these multipolar machines and during the past year the demand for them has been rapidly increased, not only for use as motors but also as dynamos for isolated plants, for which purposes they possess unusual advantages by reason of their high efficiency, perfect regulation and the small attention required. In these machines the reduced speed is obtained without increase of weight or of space over the ordinary, and for this reason the dynamos are in great demand for places where economy of space is important, as on shipboard.

One of the most important attributes of any machine, whether used as a dynamo or as a motor, is its regulating qualities. For incandescent lighting the desirability of closest regulation is obvious, and on the other hand, an electric motor whose speed is not uniform at all loads does not fill the requirements for most purposes. Perhaps the best way of demonstrating the regulating qualities of the Perret machine was that embodied in a test shown to the writer at the works of the company during a recent visit. The machine in question was coupled direct to a steam engine, the plant, illustrated in Fig. 13, being intended as a marine electric lighting plant. At the writer's suggestion the machine was loaded to its full capacity and the main switch opened and closed successively. In neither case could a variation of more than a small fraction of a volt be detected upon a Weston voltmeter. This type of marine plant will shortly be installed in a number of yachts and steamships, and it is safe to assume that it will form an important branch of the business of the Elektron Company. Certainly every one noting such a test must be impressed with the perfection to which the regulation of dynamos and motors has been brought at the present time.

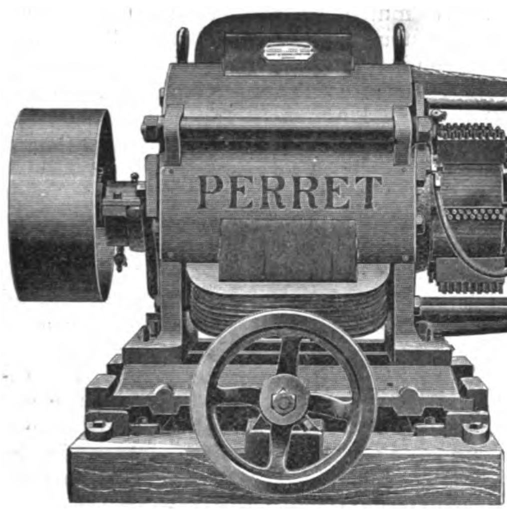

FIG. 12.—SIDE VIEW OF PERRET LOW-SPEED MULTIPOLAR MOTOR.

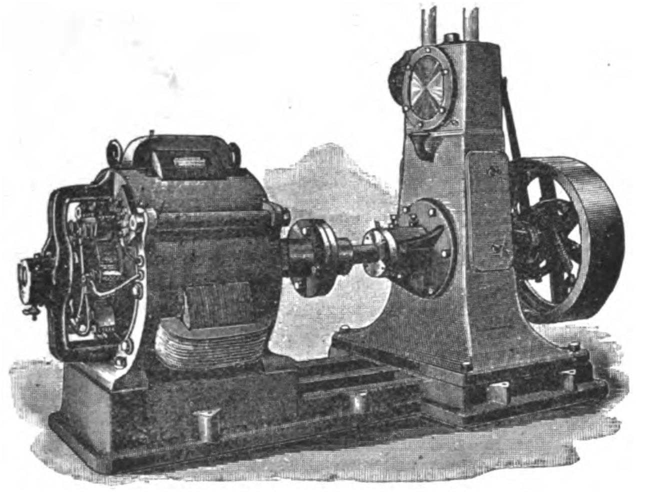

FIG. 13.—DIRECT CONNECTED PERRET SHIP LIGHTING PLANT.

XII.

There are many situations in which a machine developing from ¼ to 2 h. p. is required, and for this purpose the type illustrated in Fig. 14 has been designed and is regularly built at the Elektron Works. It is of the bi-polar type and, like the multipolar machines, has both its field and armature built up of soft laminated iron.

Not a little attention has been bestowed by Mr. Perret upon the design of motors for small powers, such as the driving of fans, sewing-machines, jewelers' lathes, etc.

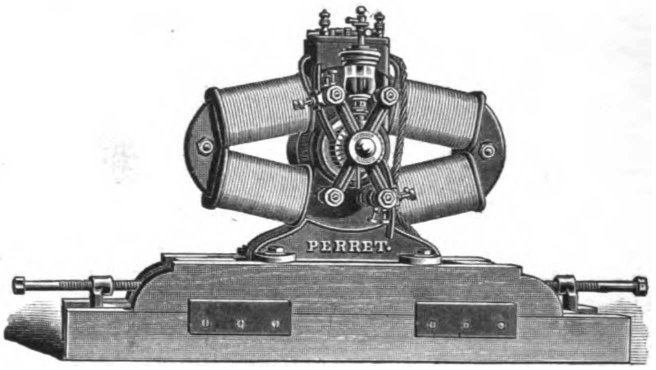

FIG. 14.—TYPE OF ¼ TO 2 H. P. PERRET MOTOR.

The same principles which have led to success in the larger machines are also embodied in these. Fig. 15 shows the manner in which the field magnets of these pygmies are built up and Fig. 16 shows a Perret ⅛ h. p. fan motor mounted on a base. Special methods of manufacture are employed in the construction of this type. For the small size of commutators employed on the fan motors, the dovetailed type of segment is not employed. In its place the commutator is built up by placing the segments on a hard rubber bushing and driving in brass pins at the ends through the bar and into the fiber. This holds the segments securely, and largely reduces the cost of manufacture. One of the features of the armatures of these machines is the peculiar spiral form given to the grooves in which the wires are wound. The pitch of this spiral is so

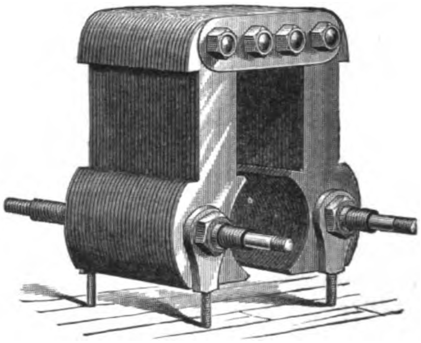

FIG. 15.—FIELD MAGNETS OF SMALL MOTOR.

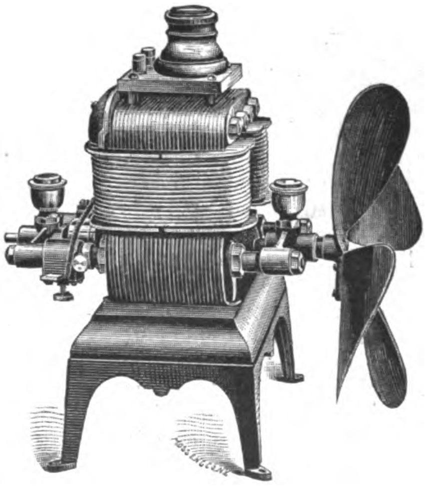

FIG. 16.—⅛ H. P. FAN OUTFIT.

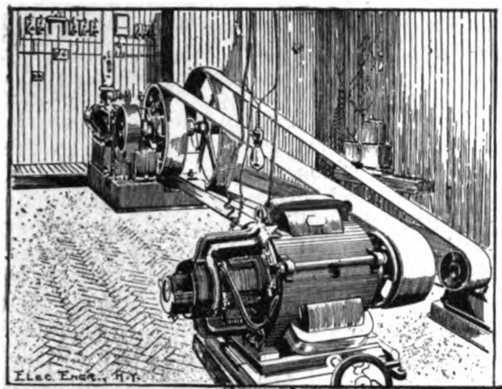
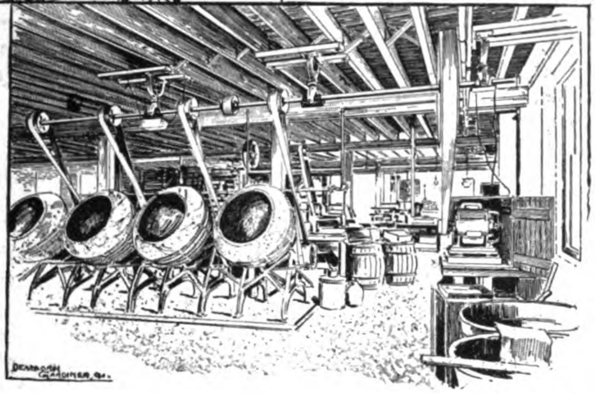


ELEC. ENGR., N.Y.



arranged that the end of one tooth leaves the edge of the pole-piece at the instant that the beginning of the next comes under it. In this way the lines of force emanating from the pole-piece are not broken abruptly, as would be the case if the teeth were parallel with the edge of the pole-piece, and as a result the action of the motor is smooth, heating of the pole-pieces is avoided, and a great deal of noise dispensed with.

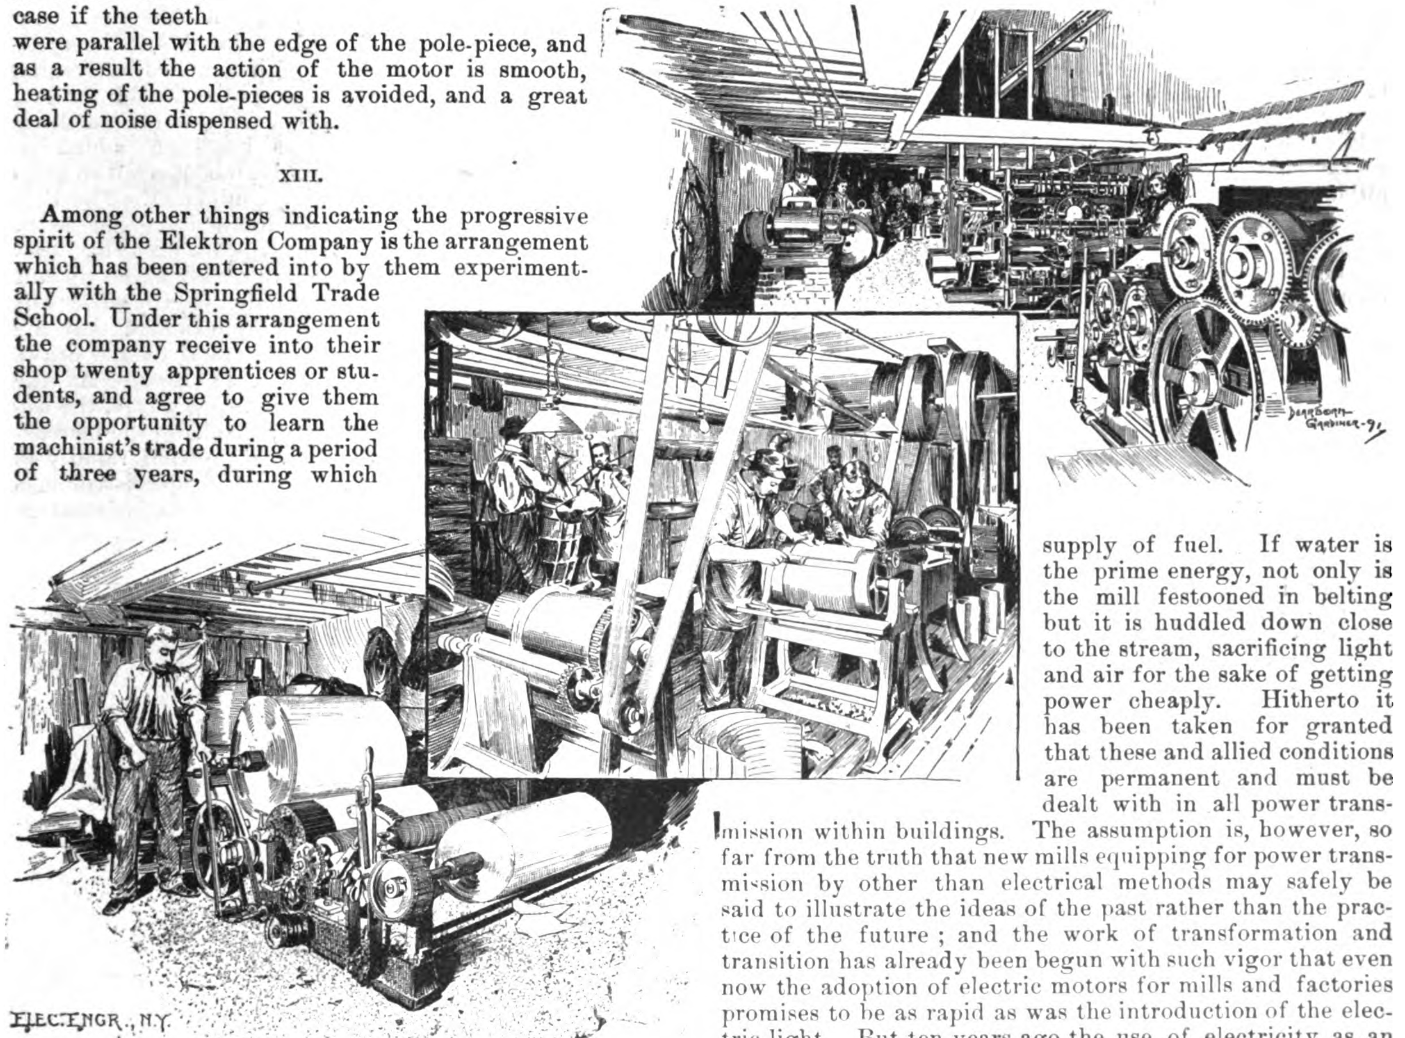
XIII.

Among other things indicating the progressive spirit of the Elektron Company is the arrangement which has been entered into by them experimentally with the Springfield Trade School. Under this arrangement the company receive into their shop twenty apprentices or students, and agree to give them the opportunity to learn the machinist's trade during a period of three years, during which the young men work in the shop one-half time and devote the other half to a special course of study in such branches as would be of most service to them in the mechanical line. The students are grouped into two divisions, one of which works one day in the shop and the other the next day and so on.

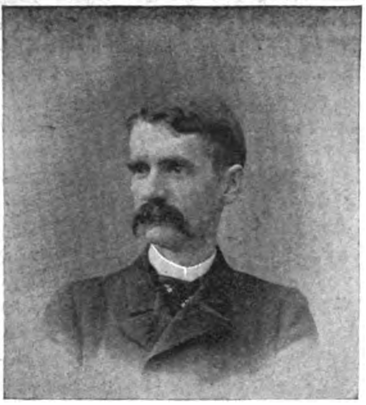
It has been a cause for regret that there has seemed to be in our present industrial system nothing to take the place of the old apprentice system which has practically passed out of existence, but this arrangement at the Elektron shops, if it proves successful, and it now appears so, will prove a solution of the problem. At all events the scheme is creditable both to the managers of the Elektron Co. and to the school. Of course the number of students at work at one time must of necessity be confined to a small percentage of the whole number of the employees, as it is not practicable to do a very large proportion of the work by students. But this new departure seems to us one of the most hopeful that has been made of late years in regard to the training of artisans, and we think it will be closely watched by economists of all schools.

XIV.

Two features are conspicuous in the construction and operation of nearly all American mills and factories at the present time. If steam is the means of distributing motive power, long and heavy lines of shafting obtrude themselves upon the eye, combined with an endless maze of belts; and the mill itself hugs closely the railroad from which it derives its supply of fuel. If water is the prime energy, not only is the mill festooned in belting but it is huddled down close to the stream, sacrificing light and air for the sake of getting power cheaply. Hitherto it has been taken for granted that these and allied conditions are permanent and must be dealt with in all power transmission within buildings. The assumption is, however, so far from the truth that new mills equipping for power transmission by other than electrical methods may safely be said to illustrate the ideas of the past rather than the practice of the future; and the work of transformation and transition has already been begun with such vigor that even now the adoption of electric motors for mills and factories promises to be as rapid as was the introduction of the electric light. But ten years ago the use of electricity as an illuminant in a mill was still a decided novelty, not a little scouted and frowned down upon. To-day it is without a rival in popularity. A similar course of events may be looked for with regard to the use of electricity for power



FIGS. 17 AND 18.—A NEW ENGLAND CANDY FACTORY, AND THE PRESS ROOMS OF NEW YORK COMMERCIAL ADVERTISER. OPERATED BY PERRET MOTORS.



W. D. Sargent.

transmission, except that the stages of advance will be the more rapid because in a great many instances the existing circuits for lighting are of capacity enough to carry ample current for motors also.

The work of the Elektron Company furnishes more than one example of this peaceful revolution now going on, and that which we here illustrate in Fig. 17 is typical in many respects. The cut shows the factory of B. H. Douglass & Sons, at New Haven, Conn. The business of this company is the manufacture of confectionery. The entire factory is operated by electric power, the plant being installed by the Elektron Company, from the plans and under the superintendence of Mr. George G. Grower, electrical engineer, of Ansonia, Conn. One of the views here given shows the 25 h. p. steam engine belted to a Perret generator, which is compound wound for 110 volts and supplies current to the Perret motors located in various parts of the works. The dynamo and the motors are all of the six-pole, low-speed type. The 4 h. p. motor on the first floor operates the elevator. A 2 h. p. on the second floor drives blowers and machines used in the manufacture of fruit tablets, which are here made in great quantities. On the third floor a 4 h. p. motor drives two cocoanut grinders; another 4 h. p. motor is used for stirring candy in the steam kettles; while the 7 h. p. motor shown in our other view is used to rotate what are called the plum pans, seven in number, although only four of them are included in the engraving. This plant has now been in operation about nine months, with a marked saving in coal consumption, and with a keen appreciation of the many advantages that electric power brings with it.

E. H. Cutler

XV.

So interesting and important is this work of electric power distribution that we may be forgiven if we direct attention to another striking plant installed by the Elektron Co., who have the honor, unless we are greatly mistaken, of being the only motor builders whose machine prints a great metropolitan daily newspaper. Our illustration, Fig. 18, shows the press rooms of the *Commercial Advertiser* of this city, where a 20 h. p. slow-speed Perret motor runs a large portion of the establishment. Early this year the idea occurred to Mr. Harold Godwin, then editor of that century-old evening paper, that it would be an advantage to use electricity to run his presses, and he did the editors of THE ELECTRICAL ENGINEER the honor of consulting them on the subject. Encouraged by the advice and information he received, Mr. Godwin lost no time in making his arrangements, and on taking possession of a large new office he installed the Perret motor, together with a Corliss engine of 50 or 60 h. p. which was to operate the supplementary apparatus and to answer as a reserve. The electrical plant was put in last April, and was started almost immediately. The equipment of the pressroom comprised a large Hoe perfecting press, capable of throwing off 25,000 copies an hour, two Cottrell presses, capable of printing 15,000 an hour each, and one wetting machine, all these being on one floor in the basement, in Park Row, and driven from a main shaft directly from the motor, without the intervention of any countershafting. Besides these heavy pieces of mechanism, there were on the floor above an outfit of regular stereotyping machinery and a 48-inch ventilating fan, all run by the same motor.

Frank A. Perret.

This Perret motor was put in by Mr. Godwin to run the single Hoe perfecting press, but it tackled that load with such a light heart that the two Cottrell presses were added. On a sudden emergency, when no steam was available, the wetter, stereo-machines and fan were also heaped on its sturdy back, but it shouldered the whole so satisfactorily that the practice has been continued. Shortly after this plant was started, Col. Cockerill bought the *Commercial Advertiser* and started the *Morning Advertiser* which has already secured so firm a footing among the popular morning dailies of New York, and for a time the motor printed both the morning and the evening editions. But the success of the morning paper soon outran the old facilities and lately a big new Hoe press has been added to which the spare Corliss engine has been connected so as to get the full benefit of the existing equipment. The Perret motor has, however, made a most striking success in keeping with the progressive journalism that it has been called upon to aid; and it is believed that at no distant date electric power will handle not only the *Advertiser* but other large dailies in this city. It may be added that the motor is on the regular 110 volt Edison circuit and draws current from the old mains along Park Row. As the readers of THE ELECTRICAL ENGINEER are aware, the use of electric motors in printing offices, thanks to the increasing availability of electric current, is growing rapidly in the larger cities of the Union, a fact which speaks volumes for the motor, in view of the delicate and difficult nature of the work, which compares in many respects, and especially in its rapid variations of load, with street railway work.

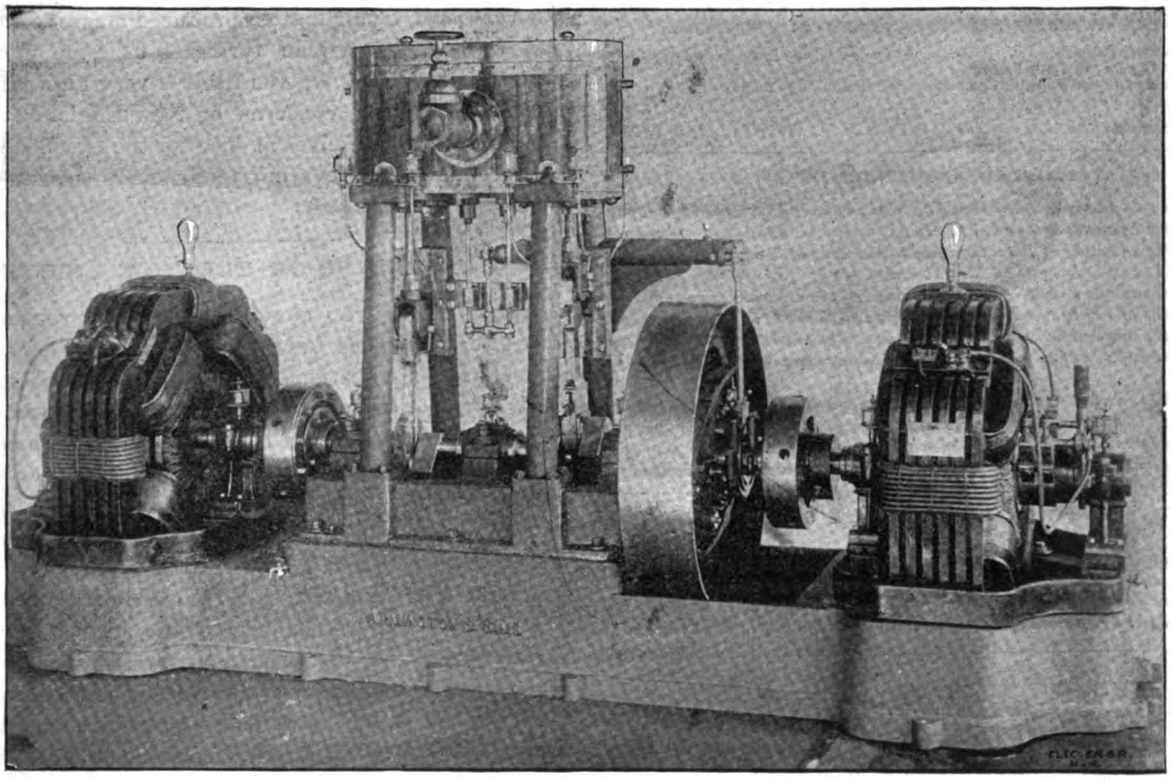
XVI.

A word by way of conclusion may not inappropriately be devoted to the personnel of the management of this progressive company, and we are glad to present here portraits of the leading officers. The president, Mr. W. D. Sargent, is not only an old telegrapher, but a pioneer telephonist, and is actively connected at the present time with the telephone companies of Long Island and New Jersey. Mr. E. H. Cutler, the treasurer and manager, has been associated with the company from the inception, and the same is true of Mr. Frank A. Perret, its electrician and electrical engi-

Leon J. Harley.

neer. Associated now with these gentlemen is Mr. Leon J. Harley, as general superintendent, a position for which a long training in the manufacture of small arms qualifies him in a special manner. The company have as selling agents, J. U. Burkett & Co., in Washington; George Baquie, in New Orleans; the Electrical Engineering Co., in Chicago; F. J. Renz, in St. Paul, and the Pennsylvania Machine Co., in Philadelphia. They have also large offices in New York under the care of Mr. Robert Watson, among whose installations may be named one of 185 lights in the building on Liberty street, where his headquarters are established, and through whom the company now have orders on hand for the equipment of a number of steamships with dynamo and engine coupled direct on one base.

The number of Perret motors now in operation in all parts of the country will figure up to several thousand and they are used for every conceivable purpose. Most of these machines are shunt wound for giving constant speed in cases where this is an important requirement, but there are many in operation that are wound to suit special work.



NEW THOMSON-HOUSTON DIRECT-CONNECTED MARINE PLANT, WITH ARMINGTON & SIMS ENGINE.

NEW THOMSON-HOUSTON DIRECT-CONNECTED MARINE PLANT.

WE illustrate in the accompanying engraving the combination of the Thomson-Houston multipolar marine dynamo with the double upright Armington & Sims engine, connected directly to the armature shaft by an insulated flexible coupling. This combination has, it is claimed, in the opinion of the Naval Board of Electrical Experts, shown greater efficiency than any other combination of the kind they have ever tested. Over sixty of these plants have been constructed which have been illustrated and described from time to time in the ENGINEER. A slight change has, however, been made from the single to the double dynamo in the steamer "Fairfax" of the Merchants' and Miners' Transportation Co.

The object of the builders was to furnish a plant as compact as possible, and the preliminary test indicated that the departure had been successful. The floor space covered by the engine and dynamos is three by ten feet, a saving of nearly one-half as compared with steamship plants previously furnished. This economy of space was gained by coupling two dynamos to one engine.

The dynamos are of the Thomson-Houston multipolar marine type, 110 volts, and each has a capacity of 10,000 watts. Both dynamos will be in service when it is desired to call into use the entire capacity of the ship, and in addition to lighting the vessel, they will supply a search light of 4,000 candle-power which is automatically operated from the pilot house. By the search light, buoys can be located from three-fourths of a mile to a mile, and the lights can be seen at a distance of fifteen miles from the vessel.

The dynamos are driven by a seven by five inch double upright Armington & Sims engine, which has a speed of five hundred revolutions a minute. The entire marine plant, which weighs seven thousand pounds, is a duplicate of those furnished the Navy Department for the new cruisers, one to three of which were placed upon each vessel. There is this difference, however; the Government engines have one dynamo connected to each engine by a flexible coupling, while the electric plant of the steamer "Fairfax" has a dynamo directly connected to each end of the engine shaft. This plant has been installed and is now in successful operation.

THE ELECTRICAL UTILIZATION OF WATER-POWER AT MARBURG.

A PROJECT is on foot, suggested by the success of the Lauffen-Frankfort experiment, for conveying 600 h. p. by electricity from Marburg to St. Lorenzen, a distance of 18 miles. A head of water, over 200 ft., is available at the former place.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JANUARY 6, 1892. No. 192.

It cannot be impressed too forcibly, both upon the student in mechanics and upon the workman, that accuracy of measurement is essential for good and efficient workmanship, and that it tends to economy in all branches of manufacture.—Sir Joseph Whitworth.

THE ART OF MOTOR BUILDING.

THE electric motor industry is still in its first decade, but it has made enormous strides and to-day constitutes one of the most active, popular and progressive fields of work in the whole domain of electricity. An evolution, strictly, of dynamo design and construction, it has yet developed many special features and principles of its own, the importance of which is daily proved in the highly ingenious and successful machines that furnish power to hundreds of different industries throughout the length and breadth of the land, either taking current from central stations or else constituting a part of some concentrated factory system of power distribution.

The art of motor construction is therefore to-day a new story, and the chapter of it presented in our description of a recent visit to the new works of the Elektron Co., at Springfield, Mass., brings out many points of great interest. The region in which these works are located is famous for the perfection of its small arms, and in various respects the electric motor belongs in the same category of fine work, intelligently designed and skilfully turned out. The motor industry, in fact, bears with its right on the sewing machine and small-arms branches of industry, and on its left is in touch with the heavy engineering of compound steam engines, and this range is one of its largest elements of promise.

A special point of interest in our article will be found in the description given of the manner in which the Elektron Co. has allied itself with the Springfield Trade School, so as to admit a limited number of students into its works for technical and mechanical training. This is an admirable departure—one, indeed, so new and novel that we do not quite see where it is likely to end. It is certainly a very ingenious and laudable attempt to give us the new system of apprenticeship of which this and every other manufacturing country so sorely stands in need; and we are glad to know that so far it is working successfully. Nowadays we hardly expect any one to go through the old seven years of drudgery that belonged to apprenticeship; but that hard, trying system produced magnificent artisans; and if the Elektron plan furnishes us some more of the old breed it will have given itself a very high rank among the manufacturing concerns of New England that have distinguished themselves at once for the excellence of their product and the elevating tendency of their social influences.

CONDENSERS IN ELECTRIC LIGHTING.

AMONG those who closely watch the progress of the times, the increasing importance of the condenser in nearly all electrical applications must have attracted more than usual attention during the last few years. This early adjunct to telegraphic apparatus has already vastly changed telegraphic methods and increased their scope, especially in submarine work; and it now bids fair to have a not unimportant bearing upon the future methods of electrical distribution of light and power. It is some years ago that Mr. S. D. Field and Mr. C. E. Fritts, in this country, and Doubrava, in Austria, called attention to the availability of condensers as direct-current transformers, at a time when the alternate-current transformer was fast occupying a field which it has now made peculiarly its own. But while thus early recognized in connection with direct-current distribution, recent developments indicate unmistakably that associated with alternate current distribution the condenser will find its more immediate and perhaps extended application. In view of this, the discussion of the condenser as a transformer of electric energy is eminently timely, and we therefore give the conclusions arrived at by Mr. Jas. Swinburne in an analysis of the subject. But besides their employment as pure converters, the important functions which they perform in alternating-current apparatus involving a lag of phase, such as we meet in the new types of alternating motors, give them an immediate interest of the highest order. If to this we add the possibility hinted at of obtaining the direct currents necessary for energizing the field magnets of alternating machines by means of condensers, and without a commutator, then indeed it must be admitted that the condenser is worthy of the most serious consideration. Nor must we forget the important part it is destined to play in the beautiful and almost ideal method of illumination of Mr. Tesla, whose experiments as detailed in his now famous lecture before the American Institute of Electrical Engineers show some of the difficulties met with in employing condensers at high potentials and frequencies. In this respect the condenser transformer will, without doubt, be made to conform to the most recent practice adopted in connection with the iron transformer, in that air will no longer be used as the insulating material, giving place in its stead, to oil. The cost of condenser apparatus for the various purposes alluded to, will to a certain extent be governed by the potentials employed, as this will determine their size, but the advantages which the use of the condenser will bring with it will probably offset this consideration in a large measure.

LOW-TENSION ALTERNATING CURRENTS FOR ISOLATED LIGHTING.

One of the earliest methods employed for isolated lighting purposes was the operation of low-tension alternating-current machines, a type which was adopted at the time principally for the reason that the machines were simple in construction and were claimed to give very good regulation. Our readers will remember that among those machines, the Ferranti-Thomson obtained considerable prominence about ten years ago. At present, however, this method machine is used for low tension. That there appears to be has been entirely discarded, and the continuous-current good reason for seriously reconsidering this method at the present time was, we think, well brought out in the interesting article by Mr. Horry appearing in our last issue. Mr. Horry, in fact, advocates the adoption of the low-tension alternating machine for isolated lighting, especially in view of the fact that we have now placed at our disposal a simple way of regulating the intensity of illumination in the lamps by means of a device which consumes no energy. While there may be those who doubt the value of this particular quality in a lamp installation, there can be no question as to the simplicity of the alternating machine and its excellent regulating qualities.

ELECTRICAL FAKES AND FRAUDS.

The paper by Mr. A. A. Knudson read by him before the New York Electrical Society last week, on frauds in the electrical business, touched an amusing and interesting subject that, as far as we are aware, had never before been handled at a gathering of the kind. The pity is that it is not possible to reach a larger audience or body of readers with it than is the case, where all to whom it is addressed are familiar with the questions involved and are not likely to suffer from imposition. Mr. Knudson makes an exposé for instance of the Scott electric hair brush; but we take it for granted that no electrician or electrical engineer uses Scott's brushes or the other fellows' belts or any other swindles of that character. As to what may be termed "frauds," namely, attempts to plunder the public through the medium of new "inventions" of alleged merit and value, it is evident that in this respect also the desideratum is to get the ear of outsiders. No electrical engineer loses his money in such a fraud as the Friend electric sugar refining, but a good many of us know people who are prejudiced against electricity because they have been big enough fools to invest without investigating. There are remedies against these fakes and frauds, and it becomes the duty of every informed man to make an exposé of such deceit wherever and whenever he encounters it, either through the ever-open columns of the scientific press, or better yet, with the help of such useful functionaries as district attorneys and such bodies as the grand jury. It is, perhaps, significant that Mr. Knudson's paper was read at Columbia College. It is to the influence of our seats of learning and of the educated men they turn out that we must look for the greatest protection and advance. A large number of people like to be humbugged and need no sympathy with their peculiar manifestation of weakness of mind; but not a few other people suffer sorely in mind, body and estate from these predatory swindlers, who take advantage of the popular belief in the ability of electricity to do anything and everything.

Cheap Street Railway Track.

It would certainly seem as if the most limited amount of common sense might by this time have taught our horse railway managers the unprofitableness of making use of the most costly kind of motive power for no better purpose than that of banging their cars to pieces against the unevennesses of a weak and flimsy track. Yet one may see to-day a new track in process of being laid in West street in this city—a location in which, to say nothing of the heavy legitimate wear, it is subjected to the incessant pounding of a never-ending procession of heavy freight trucks—in which the superstructure consists of a light side-bearing rail spiked upon longitudinal wooden stringers.

Iron in Central Station Construction.

Mr. A. E. Braddell writes us this week with regard to a point of special interest in central station construction, namely, the use of iron particularly in roofs. He states that some of the stations he has visited as an insurance inspector have suffered from the dropping of moisture from their iron roofs like a heavy dew, creating a condition of danger in the short-circuiting of the apparatus, etc. Two remedies suggest themselves. One is the construction of an inner roof of wood immediately under the iron; the other is the erection of slight sheds or awnings just over the engines and dynamos. Further and better remedies than these should lie within reach, and we shall be glad to hear from our readers on the subject. Iron is pre-eminently a material to employ in central station construction, with brick and stone, and we are slow to believe that solid or lasting objection can be found in the troubles to which Mr. Braddell calls attention.

What Shall We Do with Our Mules?

The mule is not a thing of beauty, although his efficiency is very high, and his capacity great, and when his field of labor in the lower walks of life is suddenly closed to him his usefulness is gone. When electricity usurped the place of animal power on street railways, an opportunity was afforded the horse to turn his attention to nobler things, but when canal boats are towed, and plows driven, electrically, as described recently in our pages, the mule suffers, while his manufacturers are fain to go into the motor business.

NOTES ON ELECTRIC STREET RAILWAY CONSTRUCTION.—I.

BY

A. K. McCay.

WHEN electric railroads were first introduced, the methods of different systems were quite at variance. There has been very generally, of late, a weeding out of the older and cruder methods, and nearly all systems have adopted, more or less, the good points of their rivals. So that to-day there is a similarity, and, in fact, nearly an identity, in the best railroad practice.

Beginning with the generating station, we will endeavor to refer briefly to some salient points of construction and arrangement of a successful railroad plant. If the road is to be a small one, say under ten miles, a high speed, quick-governing engine is to be preferred; as the load is very likely to vary from zero up to full load in a few moments. The engine which is generally recommended is one that has fly-wheels especially heavy, and an automatic governor sufficiently sensitive, so that variations of load are quickly compensated for. The best practice strongly recommends the use of a simple engine where condensing is not used. If water be convenient and cheap the first cost of compounding and condensing is far outweighed by the saving in coal, very often amounting to 25 per cent. In larger plants some form of Corliss engine is very generally adopted, although the writer infinitely prefers a triple or even quadruple expansion engine directly geared to the dynamo. This latter engine, usually of a vertical type, is being rapidly introduced on ocean steamers, where economy of coal means economy of operation, just as it does in an electric light or railway plant. The latest tests of this type of engine in England give a little over 1 lb. of coal per horse-power hour, so that no doubt the large railroad installations of the future will seriously consider such an engine before introducing one less economical.

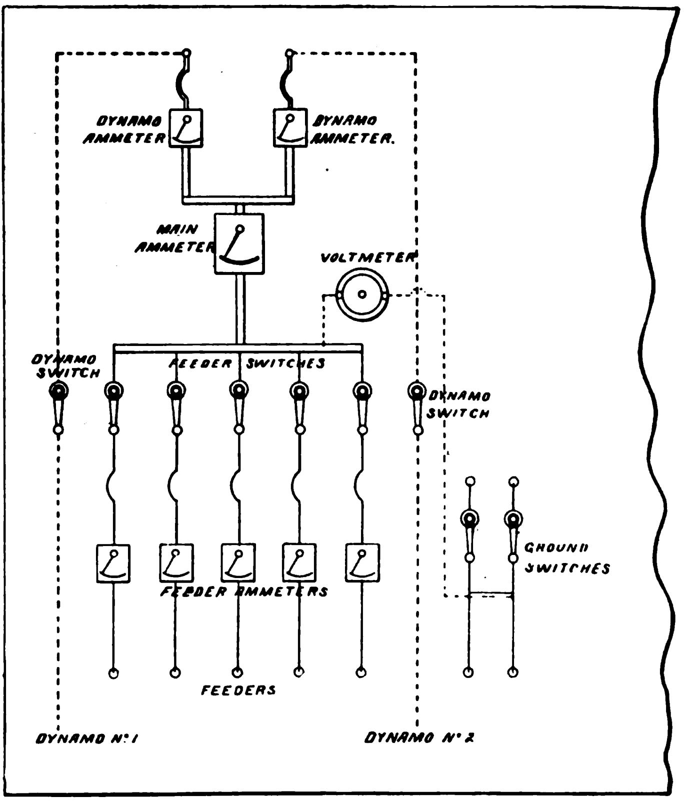

FIG. 1.—SWITCHBOARD FOR ELECTRIC RAILWAYS.

As to the dynamo, general practice has evolved a very efficient machine of the compound type, whose voltage is practically constant, and whose life is only measured by the care bestowed on it. The writer was in a large railroad plant a short while ago, and saw dynamos which have been running some eighteen months, and which are at rest just *forty-five minutes* each day, and yet the commutators were as bright, and just as large in diameter as when they began running. The application of the carbon brush practically extends the life of the dynamo indefinitely, if not heavily overloaded.

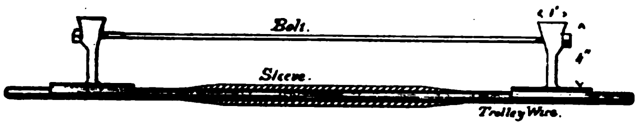

FIG. 2.—METHOD OF RELIEVING STRAIN ON TROLLEY WIRE JOINT.

Passing from the machine to the switchboard, we would recommend this to be of slate, set well away from the wall, at least four feet; and so placed as to be easy of access and perfectly safe from fire. In small stations the solid brick wall may be used; small, neat strips of wood being nailed to the wall, on which the bus bars and instruments may be secured by porcelain insulators. Fig. 1 shows the general type of a board for two dynamos. It will be noticed the main ampere meter registers the joint load when both machines are running, and checks the reading of each dynamo ampere-meter when running alone. On each feeder there is placed a fuse, a switch and an ampere-meter, so that an account can be kept of the amount of horse power required for a certain route. The wires should be brought under the floor in conduits to the switchboard and be brought from the back out to the front of the board. On installing, the board should be sufficiently large, so that additional dynamos may be connected as the business grows, as grow it will.

Passing from the switchboard to the line, we will first notice the poles. If these are of wood they should be at least 25 feet long and 7 inches in diameter at the top, and either of cedar or chestnut. In setting the poles great care should be exercised. The holes in soft dirt should never be less than six feet, while in rock formation five is permitted. Before being placed in the hole, the lower end of the pole should be coated with tar, as this will be found to materially lengthen the life of the pole. Great care should be used in setting poles. The bottom should be braced with heavy stones thrown into the hole and well rammed. The poles on a 30-foot street (between curbs) should rake some 9 inches away from the centre of the street; on a 50-foot street 14 inches will not be found too much. Special attention should be given to corner and end poles. The heaviest and stoutest poles should be chosen for these positions, and from 2 to 6 inches additional rake should be given them. Too great care cannot be given to ramming and setting

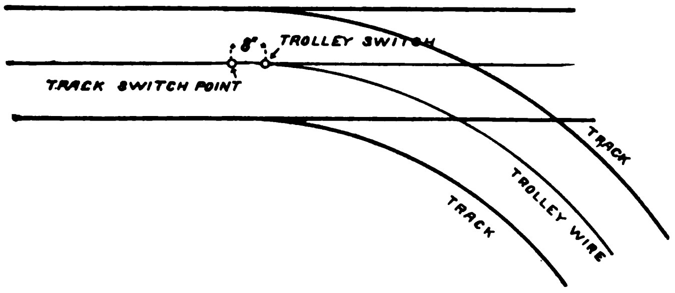

FIG. 3.—LINE CONSTRUCTION AT SWITCHES AND CURVES.

these important poles, as the life of the line and the efficiency of the service will greatly depend on this portion of the work being well done. Iron and steel poles are not given so much rake as wooden ones, because they are stiffer, and their bases are practically immovable. In setting these, care should be taken to see the concrete well rammed and that it is fresh and not set before being put around the pole.

When the poles are well set, the span wire should be strung. Modern practice is rapidly discarding the ratchet for the turnbuckle, which, to the writer's mind, is a very sensible move. Larger wire is also being used; some advocate ⅜ inch diameter, which, while to my mind it is excessive, is certainly safe. The trolley wire will probably give no trouble except at the joints. The constant passing over of the joint by the trolley wheel seems to crystallize the solder and render it brittle. If the line is stretched taut, the cool nights of the fall and early winter contract the wire, and bring a great strain on the joints, causing the wire to break at these points, entailing delay and sometimes accident. The writer has used with good effect a device shown in Fig. 2 to prevent this; and, in fact, partially to relieve the joint. It consists of two pieces of brass, whose lower part is cast to receive the trolley wire, like a bell hanger; but whose upper part is heavy enough to have a ½-inch bolt pass through it. This bolt is usually some 16 inches long and extends from one brass piece to the other; both being soldered to the trolley on each side of the sleeve. This bolt takes the strain somewhat off the sleeve, and has been found to practically overcome the trouble of the trolley pulling loose at the sleeve.

Line switches can give a great deal of trouble if not properly placed in reference to the track switch. Fig. 3 shows the relative position and the distance between the point directly below the line switch, and the point of the track switch is given as 8 inches, a distance which has been found to give excellent results. At this distance the car is well around the curve before the trolley wheel reaches the line switch. This causes the trolley wheel to bear well over in the direction the car is taking, and the trolley wheel takes the switch without fail. With these points well adhered to, little trouble and minimum expense will be found in the operation of these branches of an electric street railway plant.

A SIMPLE HELIX TELEPHONE RECEIVER.

BY

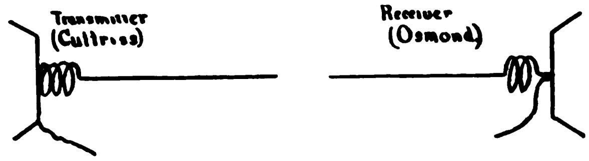
J. Thornton Osmond

Mr. Cuttriss described, in The Electrical Engineer of Dec. 16, 1891, a telephone transmitter of decidedly novel and very simple construction, and possessing superior qualities as a transmitter. I would like to call attention to a point concerning its action which he appears to have overlooked, and also to describe a very simple and mechanically similar receiver which I made in 1886, and found to have superior articulation.

In his description, Mr. Cuttriss speaks as though he regarded the action as due wholly to the change of resistance of carbon with change of pressure. I think that there is another principle which, if secondary to that named, is important in the action. I refer to the electro-dynamic action of currents in neighboring conductors. When the slight increase in pressure due to a vibration of the plate causes an instantaneous increase of current, this increasing current in the coils draws them together and thus adds to the pressure and so to the current strength. This electro-dynamic action will contribute largely to the strength of the whole action.

Perhaps I should not attach so much importance to this point but for the following experiments: In 1885, in trying to form a system for classifying telephones, it occurred to me that among the various principles of electrical action which might be used to convert the energy of the current into mechanical vibrations of similar "form," the electro-dynamic action of currents, as in a helix, had not been used. It seemed to me doubtful whether the electro-dynamic action could control the natural periodicity of the helix, and its inertia.

To test this, I made, in the early part of 1886, a rude apparatus of a bored block of hard wood, clamping a tin-type diaphragm with one end of a helix soldered to the centre. The wire was bent sharply back and then off at a right angle, as shown in the illustration. The transmitter used was sometimes the Bell (Berliner-Blake), and sometimes the Reis "bored block." It required a good deal of trial, different springs, tension, etc., to get articulate speech. Sound and pitch gave no trouble at all. But occasionally, when everything was just right, words were received with great clearness and strength.



The Helix as Receiver and Transmitter.

Of course, both Mr. Cuttriss' helix and mine, when a current passes, form magnetic fields varying with the current and acting on the diaphragm. But I found that it was possible to connect the end of the helix to the diaphragm by six or eight centimetres of silk thread without material change in the action. The proof seemed to me complete that electro-dynamic action of currents could be applied, as in a helix, for the telephonic receiver.

THE BERLINER PATENT AND THE HUNNING TRANSMITTER.

BY

Albert Stetson

The granting of Berliner's patent of November 17, 1891, seems to have called out a great deal of discussion and the expression of a variety of opinions. Some have maintained that its granting after so long an interval was an injustice, and one that would be remedied by the courts. To the writer there seems no injustice, in fact it seems entirely in accordance with the rules of the Patent Office, and its being kept in the office appears the only possible way of keeping within the spirit of our patent law. If the patent is so basic as is claimed, a great injustice would have been done by its issuance previous to the final decision by the Supreme Court on the telephone cases. Drawbaugh claimed to be the original inventor of the telephone, and while his claim was unadjudicated, it would not have been right to issue so broad a patent. How just the action of the office was, is shown by the fact that three out of seven of the Supreme Court judges were disposed to recognize Drawbaugh's claims. Whether the patent to Berliner should have been kept in the office from that time until its issue, is a question better decided inside the Patent Office than out. At all events the Commissioner seems to deserve great credit for getting it out of the office so soon after entering upon his new duties.

If it is wrong, as is urged, for patents to remain tied up so long in interference proceedings, then the remedy is not growling over specific cases, but an earnest attempt to reform some portions of our generally admirable patent laws. This would have to be done through an act of Congress, and the real friends of our patent laws would shrink from attempting any reform from fear that in reforming one pillar of the building we may pull the edifice down upon us.

Some claim that there are certain foreign patents issued to Berliner which will limit the life of his American claims to a very short period, if they have not already expired. This may be so, and in the absence of an extended search, it is impossible to say how much weight should be given to this objection. That will be a question for the courts to decide. In the absence, however, of any such test, it is well for those who expect on the expiration of the Bell patents, to reap fortunes in the telephone business to let their feet be guided somewhat by the lamp of experience.

In view of the magnificent business management that has characterized the commercial and legal conduct of the Bell Company's affairs, the idea would naturally suggest itself that the attorneys of the Bell Company were as well aware of the existence of the alleged foreign patents as any outsider could be. Looking back over the past records it will be difficult to find any great number of instances in which Mr. Storrow has been caught asleep. Many a time opposing counsel have found him very much awake, really too much so, and their clients' pocketbooks (if opposition telephone companies ever paid their bills) have suffered severely from their error of judgment as to the ease with which the Bell monopoly could be overthrown. Before venturing too far, and expending too much money, would-be telephone investors will do well to carefully examine the alleged defences.

To the writer the easiest, and apparently only safe, attack upon the telephone field, after March 7, 1893, seems to be through the Hunning patent, No. 246,512, of Aug. 30, 1881. This patent having been taken out in England on Sept. 16, 1878, will become public property on Sept. 16, 1892, and it would seem that any one will then be free to use "carbon in a state of fine loose powder, not in any way compressed or consolidated." I cannot think the Berliner patent will be possibly interpreted broadly enough to cover this use of carbon. As to the efficiency of the Hunning transmitter, Preece & Maier, in their book, "The Telephone" (page 88) say, of transmitters of this class: "It was certainly the most powerful instrument tried in England." The so-called long-distance instrument of the Bell Company is based upon the use of carbon in a free and loose state, and all know the excellence of that apparatus. With respect to the patented improvements embraced in that instrument, there are likely to be some interesting developments in the near future.

With such reliable instruments in the hands of the public as the Hunning transmitter and the Bell receiver, it would seem to be a matter of indifference whether the last Berliner patent were sustained or not.

MAGNETIC PROPERTIES OF LIQUID OXYGEN.

PROF. DEWAR recently made a highly interesting communication to the Royal Society. He sought to determine what effect a temperature of 180°C. would have upon the behavior of liquid oxygen in the magnetic field. Having previously ascertained that liquid oxygen does not moisten or adhere to rock crystal, and consequently maintains in contact with that substance a perfect spheroidal condition, he poured the liquefied gas into a shallow saucer of rock crystal, and placed it between the poles of the Faraday electromagnet. On the magnet being excited, the whole mass of liquid adhered to the poles until dissipated.

FRAUDS IN THE ELECTRICAL BUSINESS.[1]

BY A. A. KNUDSON.

THIS subject unfortunately is one of such wide scope that to cover it fully would mean the publication of a good-sized volume. For a paper of the ordinary length therefore I shall only touch upon the various branches of electricity in which impostors have left their tracks, and relate a few instances as they have come under my notice during the past few years, which will show some of their methods. We wish it understood that in speaking of impostors or "fakirs" in this paper we mean only those who, knowing an invention to be worthless, or of but little value, will attempt by false statements to induce people to put money into the same. Neither do we wish to include under this head those inventors who, honestly believing they have discovered something new and original, seek to interest capital, although their scheme may finally prove to be impracticable or previously patented.

We will now consider one or two fakir methods in the galvanic or storage battery line which as we all know has proved in the past an inviting field for that class of men. The first will be the primary battery with the electric motor. Some years ago before the advent of the dynamo, when electric motors had to depend upon the primary battery for current, a French gentleman appeared in New York with alleged new and useful improvements in both battery and motor. He had induced a relative of mine (since deceased) who was an officer in one of the savings banks to invest in the same, and had been given the use of an unoccupied room above the bank for the purpose of exhibiting the apparatus. I was asked to call and examine this "wonderful invention," for, according to the inventor, it *was* one of the greatest scientific productions of the day. The motor did not differ in principle from those already invented and published, such as that of M. Froment or of Davenport on this side of the water. In fact it was not only the same in principle as that of Froment's but nearly the same in construction.

The battery, the inventor said, was a secret, and he would not explain it. The method of demonstrating the efficiency of both motor and battery was by lifting a weight of a few pounds to the ceiling by means of a pulley and rope, the rope being wound around a drum secured to the shaft of the motor. The battery although a secret, disclosed itself soon after the motor was started, in the strong nitric acid fumes it gave out, and the active manner in which it boiled. When spoken to about the strong odor from the battery which was enough to choke one, the explanation would generally be (with an attempt to smell): "You smell anything?" Our report as you will surmise, was not favorable and we strongly warned the banker to go no further, but he had actually become so wedded to the scheme that he would believe nothing against it and all I got for my pains was a self-satisfied smile and the remark, "Well, I can believe my own eyes when I see that weight going up to the ceiling."

You will anticipate the outcome. I left them to themselves and to their own eyes; and after several thousand dollars had been sunk in the attempt to make the scheme practical, it was finally abandoned. The banker frankly acknowledged afterwards that he believed the whole thing was gotten up with the deliberate intention to deceive. So much for that wonderful motor, and the battery that was a secret.

Another case, and this will illustrate how people will sometimes put their money into a scheme, and afterwards seek advice in regard to it, was one which came under my notice a few years ago where the primary battery played a conspicuous part (although concealed in the cellar), and was, like the one in the previous case, a secret. It had for its object the production of an electric light. The gentleman who employed me to investigate this case, had, I was informed, already invested something like $20,000 in the scheme. Knowing this I certainly expected to find something at least worthy of an invention. It is a singular fact, however, and one that I have often come across, that instead of getting full and reliable advice before embarking in a venture, people will often invest their money and then afterwards, when a sense of doubt and insecurity dawns upon them, will fly to an expert.

The object of this invention, as already stated, was the production of an electric light. It was exhibited in a room ordinarily used as a dining-room in a private house. There were three or four lights placed on the chandelier and when the current was turned on, they did make a brilliant and steady light while it was being shown. It consisted of two small carbon rods placed inside a glass tube, the point of contact between the carbons being about midway between the ends of the tube which was about six inches long with a bulb at the centre. The wire from the battery connected with the carbons, and that was practically all there was to the invention. The inventor succeeded even before any patents were obtained, with his exceeding plausibility (and he was a remarkably good talker) in inducing these gentlemen to put in this large sum of money. Why, to hear this man talk was enough to deceive the very elect if they were not posted, and to show how easy some men are induced to invest in worthless enterprises of an electrical nature when in the hands of a good talker, I will give an example of the way he talked—"Edison was nowhere. For years Edison had been trying to accomplish what he had already just perfected. In Edison's system enormous capital was required in the construction of central stations, besides the cost of running expenses for fuel, labor, etc.; but in his system all of this was done away with, and for a few cents per night a whole house or store could be illuminated, and the battery would run indefinitely," and so on, ad infinitum. All of this time he was careful to conceal the fact that he was using in the battery in the cellar electropoion fluid by the barrel and zinc by the square yard in order to produce the three or four lights for comparatively short intervals of time. He told the gentlemen present and myself that there were but four cells of battery in circuit; this to me was surprising for the amount of illumination given. By a series of cross-questions we finally found out just what he had. The four cells of battery consisted of four enormous earthenware crocks, holding about 25 gallons each. Across the top of each jar or crock was placed a bar of wood to which was secured various plates of carbon and zinc running down to the bottom of the jar, so that instead of four cells or galvanic pairs in circuit, there were actually nearer 40 of very large size and the beautiful and brilliant electric light on the chandelier was duly accounted for. I do not suppose that the gentlemen who had invested their money in this scheme thought it worth while to even inquire about the battery. They saw the light, and like the banker in the former case, when he saw the weight go up and heard the inventor talk, they thought they could believe their own eyes. After the exposure was made, there was no more money invested in that scheme.

---

[1] A paper read before the New York Electrical Society, Dec. 30, 1891, at Columbia College.

I could give many other instances where the impostor has manipulated the galvanic battery to his own profit; but as they would be almost repetitions of those just stated, we will pass on and look into some of the fakir's work in the electric and acoustic telephone business. I presume there is no electrical business of late years which has been so thoroughly worked by unprincipled men as the telephone business, and in order to have a better understanding of the methods of telephone sharpers, we will give a short résumé of the telephone situation as we understood it a few years ago. Where important lawsuits have been going on, the amount of fraud occasionally practiced in the attempt of one company to secure an advantage over another, would, if made known, be surprising. Bribery and false swearing has often been resorted to in some of the telephone patent suits in past years. Witnesses, experts, lawyers, and even the judge on the bench have not been entirely free from the baneful influence. I will give an instance: You may have heard of the man who was an examiner in the electrical department of the Patent Office at the time the Bell patent was issued, and who in later years for a certain sum of money made an affidavit in favor of the Bell Company setting forth certain alleged facts which occurred at that time, and who not long afterward accepted a fee from another company and made another affidavit setting forth alleged facts entirely contrary to the first sworn to. It often happens in patent suits where large amounts of money are involved, the temptation is strong to mislead and deceive, wherever such deception will be of advantage. Especially was this the case in the legal telephone fight during the attemps made to overthrow the Bell patent by attempting to show that the Reis telephone would articulate. It was well known that if the telephone invented by Reis in Germany (which ante-dated the Bell by several years) could be proved to have talked, and to have actually produced articulate as well as musical sounds, it would mean death to the Bell patent. Or if a telephone made exactly on the principle of the Reis could be shown to articulate in court, if only for five minutes, it would in all probability upset the Bell patent, the advantages of which would thus revert to public use. Hence there was abundant reason for the opponents of the Bell Company to prove if possible one thing or the other, and the utmost exertions were put forth. Germany was ransacked for relatives and those who had been acquainted with Reis during his lifetime, and affidavits and witnesses were obtained by the score, attempting to prove when, where, and how the Reis telephone talked; without doubt many of these affidavits were drawn from mistaken imaginations, while others were but partial truth. On this side of the water numbers of inventors were at work struggling for the prize in their efforts to make the thing articulate. I well remember the experience Mr. Mailloux and myself had in that direction. Night after night we worked at our homes in Brooklyn with varying success. Sometimes we would succeed in making it articulate, but our experience was, it seemed impossible to make it stay in that condition. We finally came to the conclusion that it was possible to make a Reis telephone talk, but it could not be depended upon to stay in a talking condition from one minute to another, and so far as my knowledge extends of this subject no telephone made exactly after a Reis pattern has ever been able to articulate for any length of time. When they did articulate it was probably on account of either an extremely delicate adjustment which was only temporary, or the oxidation of the contact points, thus for the time creating the variable resistance which is the life of articulation. But we could not trust it to remain in that condition over night; often did we lay it carefully one side after working for hours at night, feeling, that at last we had it, and in the morning find it as dumb as an oyster, and finally we abandoned the attempt entirely.

There was one party, however (and this is more in line with my subject in speaking of frauds) who claimed to have produced a constant talking Reis telephone, and to the consternation of the Bell Company actually showed it in a good talking condition; there could be no fault found with the articulation; it did talk and talk well, and things for a time looked blue on the Bell side of the house, until one of their experts, more observing than others, discovered a carbon button concealed in the box and in the circuit, so that it was not a genuine Reis telephone that produced the articulation, but one with the necessary modern improvement.

I once had a telephone case to investigate which will show to what extent a fake scheme will sometimes go before it finally reaches its end. There were but two papers furnished me to examine, one a copy of the patent (there was but one patent), and the other a copy of the prospectus. The claims of the patent were exceedingly limited, but the prospectus was broad enough to make up for any deficit in that respect. One clause in the patent set forth that this invention was based on the undulatory current principle, while a clause in the prospectus stated that the invention was not based upon the undulatory current theory but upon the make-and-break principle—a square contradiction on its face.

In point of fact it did not differ only in construction to the Bell telephone. The parties to whom I reported did not invest in the scheme, but other parties did, and a company was started. Their method of doing business was to manufacture the telephones here in New York, sell State rights on the patent, and establish local companies in cities and towns wherever they could, and supply them with telephones. In this way they earned in course of time sufficient money to pay a dividend on the stock and the stock advanced (a good deal of it being sold) and everything went on swimmingly; about this time I was asked by the party for whom I reported if I had not made a mistake, and they pointed to the fact that a dividend had been paid by this company. I said I thought not and advised them to wait a little longer. The Bell Company through the slow process of the courts finally reached them, and they were blotted out of existence.

A similar experience as we all know happened to a large number of other companies who attempted to compete with the Bell Company. In the acoustic telephone business it seemed at one time as though it was infested with fakirs. There seemed to be stronger inducements in the acoustic field for this class of people even, than in the electric, especially after the Bell patents had been sustained by the courts. I presume one reason was, there was no difficulty in convincing people that there was no infringement on the Bell patent, it being easy to show no electricity was used to carry the voice, and another reason was that an acoustic telephone when first put up for exhibition purposes generally worked surprisingly well. The voice could usually be heard from 10 to 20 feet away from the instrument, and the promoter would not be slow to exaggerate these advantages and almost always to characterize it as fully as important and valuable as the Bell telephone. They would say nothing about the difficulty of constructing the wire and of keeping it in repair, and in most cases those investing would hardly inquire if there were any wire at all, when in point of fact the wire is the most important part of the whole business of an acoustic telephone line. The difficulty of maintaining it is well known. In this respect this case would be similar to those above mentioned where people saw a weight go up, and saw a beautiful electric light. They thought they could believe their own eyes and when some people listened to the remarkable performances of the acoustic telephone they thought they could believe their own ears. The acoustic telephone has its place in the commercial world and in its place is most useful and convenient; but in the past it has been badly misrepresented by being exaggerated by men whose only ambition was to sell stock in fake companies

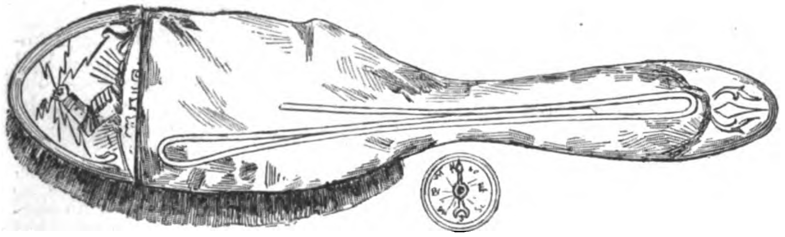
We will now leave the telephone business and pass on to the consideration of telegraph frauds. Some years ago a French Canadian appeared in Hartford, Conn., making a great stir about a new multiple telegraph system which he claimed to have invented. According to his story he could send and receive upwards of 40 messages over one wire. The duplex and quadruplex were but child's play in comparison, and so plausible were his other assertions concerning it that he succeeded in interesting some parties and finally obtaining from them a considerable sum of money for an interest in the scheme.

For a complete swindle in every detail this beat all I have ever heard of in the electrical business. It was an ingenious swindle and in order to describe it more fully I will refer to the diagram on the blackboard. A few instruments only are shown but they will be sufficient to illustrate the scheme. Several Morse sets of instruments were placed at each end of a room and a wire loop was run to New Haven, in which wire the main battery was placed. From the ends of this loop, wires were branched to one of the two binding-posts of the instruments; from the other binding-post ran a wire to all appearances to the ground, but it did not go there at all for it was purposely broken inside of the insulating covering and the ends pulled apart. Another very fine wire, however, was connected to the bottom of this same binding-post at each instrument, carefully concealed, and led to the side of the room where it was hidden entirely from view behind the paper on the wall. These fine wires all connected with the opposite instruments in their respective pair at the other end of the room. The wire in the long loop to New Haven, as you will observe, simply acted as a return ground, or one side of a metallic circuit. Under such conditions the multiple scheme, as you would expect, worked perfectly, and with any number of instruments. After the inventor had absconded with his money, which he did shortly after he got it, the instruments were removed from the room, and in doing so the fraud was discovered, for there were the wires all carefully concealed behind the wall paper.

Electrical frauds have visited the United States and plied their vocation from most every country on the face of the earth, but this man was from Canada, a country one would hardly expect to produce such a clever electrical swindler, and he showed a surprising nerve by going right into the heart of Yankeedom, in the State of Connecticut, where the people's reputation for shrewdness is so well known that it has been said, in order to dispose of some of their products such as wooden nutmegs, etc., they are compelled to go outside of the State to do it. During my sojourn in Canada for the past four years I have met but one or two who could be termed electrical fakes and they came from the States. Another phase of electrical frauds may be illustrated in a recent exhibition of a scheme in Boston.

The inventor showed a battery of peculiar construction; to the zinc pole of which was attached a wire leading out of doors to a lightning rod a short distance away. The wire from the other pole of the battery went somewhere, but supposedly to go to the ground.

The object of the scheme, according to the inventor, was to produce a constant and unlimited supply of electricity from the air. To show the practicability of the scheme a motor was placed in circuit and it ran as though it would burst; an ordinary Morse sounder was tried and that worked as though it would be torn to pieces. Mr. Frank Pope examined the scheme but was not allowed to look into it thoroughly and he said he couldn't tell just where the fake was, but it was there somewhere, and he advised the capitalist who was with him and who was in the electrical business to get some of his electricians to try and duplicate it if they could. I am sorry this scheme was not unearthed, for I believe it would prove an important addition to this paper.



Scott's "Electric" Hair Brush, with Steel Wire Exposed.

As a conclusion to this list of electrical fakes we will now consider the medical part of the business. Here we find among the so-called electrical appliances, such as belts, hair brushes, corsets, etc., gross imposition is practiced under the name of electricity upon the public and has been for years. There is hardly a complaint in the human calendar of diseases that these things, according to flaring advertisement and circulars, will not cure. To show to what an extent this imposition is practiced at the present day I will read an extract or two from a full-page advertisement taken from one of the most highly respectable magazines in this country:

> Disease is the result largely of depleted nerve force and demagnetized blood. These electro-magnetic corsets (the maker's name is here mentioned), belts, insoles and appliances have been demonstrated to be the best agency yet discovered for preventing this depletion and demagnetization as well as restoring such forces when lost. These garments are unlike any other device for electrifying the system or charging it with magnetism. As a force it is self-supplying, retaining its virtue for years and invariably benefits. These appliances so electrified can always be relied upon.
>
> These appliances promptly annihilate those weak and languid feelings, exterminate rheumatism from the system, and promptly cure the above-named disorders. They are light and comfortable to wear, and are guaranteed to imperceptibly generate a mild continuous current of electro-magnetism, all-healing in its effect. They differ from the so-called electric and galvanic belts which are usually worthless and which create sores on the body, leading to blood-poisoning. Beware of them and see that you get this one (our special make) with silver compass free. Ours are truly electro-magnetic, as any tyro in electric therapeutatics will inform you, and are absolutely reliable.

You will note the attempt is made here to work in magnetism as a curative property. Except where steel magnets are concealed of which I shall speak later), there is not one particle of magnetism produced by the action of a so-called electrical appliance of this class.

This is a point to which I wish to call special attention. Electricity properly controlled and applied is capable of wonderful effects in the relief and cure of a large number of diseases, and its legitimate use is increasing daily in the practice of the most enlightened and scientific practitioners of the age. In fact, hardly a practicing physician of any repute can be found who has not his medical batteries, some of them costing hundreds of dollars, with all kinds of electrodes, some of which are as ingenious in construction as they are humane in purpose.

It is just this point that the swindlers of to-day lay hold of and turn to their own purposes. They designedly confound electricity and magnetism, and by a skillful interchange of terms they encourage in the public mind the same confusion. In many cases where they claim that magnetism is generated by their appliances there is no magnetism at all; and in others where they claim that there is electricity there is magnetism. But this magnetism is not the result of any inherent virtue, it is the result of a smart piece of chicanery, in which the concealed magnet and the compass needle play the principal part. I claim, therefore, that in any event it is wrong and misleading to attempt to confound magnetism with the curative properties of electricity.

I have yet to learn the first case where magnetism, either strong or weak, has ever produced any effect either beneficial or detrimental upon the human system. Night after night for months I have been in the presence of the most powerful dynamos (as have thousands of men in the many electric light stations all over the world) where magnetism of the strongest kind permeates every bone and fibre and tissue of the body, and yet, so far as any effect either good or bad on the system goes, one would never know he had been in the magnetic field, and he would not notice it unless he found his watch stopped. To the best of my knowledge and belief there is absolutely nothing in the human anatomy that can be acted upon by a magnet. Of course, if a child swallows a mouthful of tacks or a paper of needles, there is something inside of the child upon which magnetism will act, but not otherwise.

What physician of any reputation has ever been known to attempt to apply magnetism, or to recommend the use of electric belts or the like? On the contrary every reputable physician with whom I have talked on the subject has denounced them as worthless. Let us go a little further into this subject, and see how some of these things will bear the light of an investigation. We will first consider the so-called electric hair brush. I have thought best to purchase one of these brushes so that we can just see how they are made and to prove the assertion that so far as any curative property is concerned they are no better than any ordinary hair brush. I will first read an extract or two from the directions pasted in the box in which it comes:

> Cures headache in five minutes; cures neuralgia in five minutes; restores the hair, prevents baldness. The "Odic force" can always be tested by moving the brush near a compass. This power is so strong that if the compass is placed upon a thick book or table and the brush is moved in a circle beneath the same the power will pass through the intervening table or book and cause the needle of the compass to rotate rapidly. A silver compass of considerable value accompanies each brush.

Now this brush I have does deflect the compass needle just as stated, but the real cause is very different from the ostensible one, and instead of any Odic force (whatever that may be) or any electricity having anything to do with its deflection, the statement is false, as I shall prove. I have taken pains to dissect the back of this brush and we find just what we expected to find. Embedded in the material of which it is composed is a steel magnet. That, and that alone, is the cause of the compass needle moving towards the brush when brought near it. When I purchased this brush I was told that the movement of the needle proved that the brush was charged with electricity, and I have no doubt everybody else is told the same thing that buys one. You will notice this magnet is made of a piece of steel wire in the form of a double loop and extends nearly to the end of the handle. The only electrical effect possible that can be produced by the use of this brush is static, and even under favorable conditions of the atmosphere, the greater part of such very small amount of static electricity as might be generated while the brush was being used would imperceptibly pass off the earth through the hand and arm and body of the user, leaving them no more benefited by its use than if they had used any other hair brush.

Electric corsets are another deception. How is it possible, I ask you, for such a thing to be of the slightest use electrically to the wearer when they are not even worn next the skin. The magnetizing of the steel ribs as is often done is of no use whatever as to any beneficial effect upon the wearer. Another of these precious frauds is the electric garter. I have seen advertisements, as no doubt many of you have, where the use of electric garters are guaranteed to give a more shapely form to the limbs of ladies. The absurdity of such an appliance is too apparent for comment but it is really too bad to disappoint and deceive the ladies in a case like that. What swindle under the name of electricity will not be attempted next? Why don't they get up an electrical hat band guaranteed to supply a lack of brains or furnish new ideas to those that wear them, yet would not such a thing be just as reasonable as some I have stated?

As an answer to some of the reckless statements which appear in advertisements and circulars, some of which I have mentioned, in regard to electric belts and other appliances I will quote an authority and read some extracts from De la Rive's "Treatise on Electricity." De la Rive was at the time of writing his work a member of the Academy of Sciences, and also of Medicine, of nearly every large city in Europe, so that he is an eminently qualified authority to pass judgment on these appliances. After explaining the construction of the electro-galvanic chains and belts of Golberger, and of Pulvermacher, he says:

> We do not very well understand the effect of this arrangement by virtue of which the current is scarcely to circulate in the chain without traversing, at least in a very sensible manner, some part of the body. For not even a derived current can be obtained on account of the imperfect conductibility of the skin. Moreover, no very positive fact has proved the efficacy of this later mode of application, upon which experience has not yet decided. And again, We do not deny that there may be a production of currents in these apparatus; even the galvanometer indicates their presence; but they are very feeble currents; and we do not see what advantages can be presented by these arrangements which at the very basis rest on false ideas of the electricity of contact.

My wonder is that the electrical journals have not been more outspoken in showing up these frauds upon the public. The public would naturally look to such a source for information of this kind, and these journals are not handicapped as others are by being paid for fat advertisements, for it is the uninformed public on electrical matters that they desire to reach; so they use the daily press and weekly and monthly publications to make known their wares. In summing up this whole matter of electrical appliances, it seems singular that they have been allowed to exist so long, especially the hair brush; one reason may be that the "public love to be humbugged"—but there is a limit to all things, and I predict, as electrical knowledge is being more and more disseminated by such institutions as Columbia College, it will not be long before people will understand the truth in regard to them.

Although I have touched upon but a few frauds and deceptions as practiced in the electrical business, I am aware of there being many more which would prove interesting were it not for the risk of tiring your patience. I have no doubt there are those in this audience who remember the electrical sugar refining frauds of a few years ago. Also the motors of Paine, which for many years continued to deceive people. Also much might be said of the tapping of telegraph wires leading to race courses, and the ingenious electrical devices and methods for supplying stock quotations to bucket shops in Wall street. Also some of the so-called telegraph schools, where young people are induced to pay their money with the promise of a situation as soon as competent. This class of fraud cannot be too strongly condemned.

In concluding this paper I cannot refrain from expressing a few words as to the position of the capitalist or investor in regard to new electrical inventions. In the few instances cited I have endeavored to illustrate how easy an investor may be deceived. It may be fairly asked by some, "Has the investor then no protection from the designs of a dishonest promoter, or from the mistaken though honest inventor?" I answer, he has. There are plenty of good, honest and capable engineers, in this and other cities, who, for a reasonable fee, will investigate and report upon any new scheme if they are only applied to. Some of these engineers are peculiarly fitted to give advice and opinions in certain branches of this business by reason of their long experience in such branches, while others have had experience, more or less, in all of them. Besides these individuals, there are now lately established in this city electrical firms composed of men of unquestionable reputation and standing, who make it their business to investigate and report upon any electrical invention; and I claim that there is now no excuse of an investor being deceived where such facilities exist for obtaining correct information upon electrical subjects. Would a man afflicted with disease undertake to cure himself if he knew nothing of the study of medicine, or would a man having an important lawsuit on his hands undertake the management of his own case if he knew nothing of the practice of law? On the same principle, then, an investor takes a large risk if he depends on his own judgment while placing his money in alleged new electrical enterprises. On the other hand, the judicious investment of capital in electrical enterprises has brought large returns to a great many people, and in very many cases handsome fortunes have been realized. As an evidence of this fact, we have but to point to the marvelous success of the Bell telephone, also the electric light (both arc and incandescent), also the electric railway. Besides these great industries, there is no end of less important schemes varying in value according to their commercial usefulness, and almost every day something new in the electrical line is being discovered.

In this paper I have endeavored to interest you by pointing out the methods of unprincipled people in the electrical business, and I have also attempted to make clear the importance of investors seeking good advice before placing their money in electrical schemes. If I have succeeded in these two points then the prime object of my paper is effected.

The paper was followed by a very interesting and amusing discussion, in which Prof. Crocker, Dr. Laudy, and Messrs. R. W. Pope, T. C. Martin and G. H. Guy participated. Several frauds and fakes were named, and Mr. Guy, as secretary, read a letter from one innocent who was being imposed upon by some persons advertising under the name of the society, and who recited a long list of swindles of which he had been the willing victim.

THE PROBABLE FUTURE OF CONDENSERS IN ELECTRIC LIGHTING.[1]

BY JAMES SWINBURNE.

It is always difficult to foretell the future in electrical engineering work, but it is sometimes interesting to try to see in what direction developments are like to take place.

The first idea of the use of condensers was to employ them like storage batteries, and mention is frequently made by the early electric light patentees of their proposed use in this way. It is needless to remark that these inventors had not the most remote idea of the vast electrostatic capacities needed for storing by the hundred ampere hours.

The project of using condensers instead of transformers is by no means dead. It has been recently taken up on scientific principles by Mr. Doubrava. As soon as a condenser is charged and discharged rapidly enough its size becomes manageable, and Mr. Doubrava is therefore working out a system in which condensers take the place of converters. This development is in good hands, and need not be discussed further. One great difficulty is in charging condensers with direct currents. A condenser of the capacity of a farad charged with one volt contains, if the expression be allowed, only half a joule. If a condenser is charged by being connected to leads at one volt half a joule is wasted over resistance and the other half is stored. The only way of charging the condenser without loss is to connect it with an electromotive force which is gradually rising. Similarly, in discharging, the electromotive force must fall gradually. This condition is not at all difficult to attain.

The greatest development of the use of condensers will probably be in connection with alternating currents. It is doubtful whether ingenuity will ever design an arrangement of condensers that will take the place of transformers in practice. In one sense there is better material to work upon. A transformer is always inefficient on account of hysteresis. The loss by "soaking in" may be taken as analogous to the loss by hysteresis, but it is infinitely less in comparison. For instance, a condenser that takes 2,000 volts and 10 amperes has a loss which is too low to measure—that is to say, it is less than 5 or 10 watts. This loss is proportional to the size of the condenser, so that small sizes are just as efficient as large. In transformers this is not the case. A 100,000 watt transformer has a loss of from somewhat less than 1,000 up to about 5,000 watts, according to the design, and if the 100,000 watts is made up of a number of small transformers the loss is much greater.

The uses for condensers are already developing. In the first place, they can be used to supply magnetizing or exciting currents to all sorts of machinery, and also to apparatus that takes lagging currents. It must be remembered that the magnetizing current in any receiving apparatus means a demagnetizing current in the generator. As an example that will soon be common, and is also striking, we may take that of running arc lamps off 100-volt circuits with choking coils in series with them. As far as the lamp is concerned, there is no better arrangement than running it off a 100-volt circuit with a choking coil in series with it to reduce the terminal pressure to about 30 volts. If such a lamp takes 10 amperes, the apparent power taken is 1,000 watts, but the real power is probably less than 300 watts. The dynamos at the station have thus to supply large "idle" currents. These not only lead to armature heating, but also demand extra excitation. If many arc lamps are used, more dynamos become necessary, as no machines will stand three times their normal armature currents, even though they are out of step with the electromotive forces. Such currents, therefore, lessen the plant output, or, as it is often loosely called, the "plant efficiency." To overcome this trouble all that is necessary is to place condensers in shunt to the choking coils and lamps, or in shunt to the high-pressure leads. The last arrangement is best, as it admits of arranging the condensers at the central station. In addition to this, condensers for 2,000 or 1,000 volts are easier to make than those for 100 volts. Condensers for such low pressures cost too much in tinfoil, and are somewhat bulky, because the dielectric has to be made thick in proportion, to make certain of the absence of flaws. At present comparatively few arc lamps are run in this manner, but that is because nearly all the alternating current systems now in use have small transformers in houses and high-pressure mains about the streets. It is probable arc lights will be run off 100-volt circuits with choking coils, and condensers will be required at the stations. Of course there is no reason why arc lights should not be run off high-pressure circuits by means of constant-current transformers. This system has never come into use in this country, probably because the low cost of this method is not generally appreciated.

---

[1] Abstract from *Industries*.

It may be well to give some idea of the size of a condenser. One cubic foot of condenser will take about 2,000 volts and 5 amperes, or 10,000 apparent watts. With higher pressures the volume necessary is slightly less, and with low pressures the size increases. Below about 500 volts the bulk increases rapidly, as the volume of tinfoil is greater. The cost, therefore, increases too. It is possible to make condensers very much smaller than this; but while they are new it is best to allow a large factor of safety. Choking coils and constant-current transformers for arc lamps are not the only things requiring exciting currents. Transformers, especially if made with open iron circuits, take "idle" currents, and this can be supplied in the same way. Nearly the whole of an open circuit exciting current can be supplied by condensers. There is always some left over, because the electromotive force never varies exactly harmonically. Even if it did, there is some loss in the iron, so the no-load current cannot be reduced to nothing. In a closed circuit transformer the no-load current is less to begin with, but the active component is much greater, so that it cannot be reduced so much by condensers. It can generally be about halved.

The next use, which is analogous to those already described, is in connection with motors. Of course it is a little difficult to say what the alternate current motor of the future will be like. If it is a synchronizing machine, with the magnets excited by a direct current, it may take a leading or a lagging current, or one in step with the pressure. If it has field magnets excited by an alternate current it will take a lagging current, and condensers will be necessary. Nearly all the multiple-current motors take large exciting currents, so condensers will be necessary in their case. Take the case, for instance, of the Dobrowolsky 2 h. p. motor, as it is the only case whose figures have been published: at no load it takes 70 volts and 30 amperes at 35 periods per second. This current is presumably in each of the circuits, so that the apparent power is 4,200 watts; at full load it takes 70 volts and 100 amperes in each circuit, or 14,000 apparent watts. It, therefore, requires two condensers to reduce the apparent watts to about a tenth of these values. The enormous exciting current taken by this form of motor is one of its greatest disadvantages. A condenser to supply 14,000 apparent watts at a frequency of 35 would have a volume of four cubic feet. If the frequency is raised to 100 the exciting current increases at approximately the same rate, and so the condenser remains the same size. As there is some difficulty in making large low-pressure condensers, it is best from that point of view to put the condenser on the high-pressure side of the transformer. This, unfortunately, demands that the transformer should be 10 times the size. Thus, a 2 h. p. motor of this type would demand a 20 h. p. transformer at a frequency of 35, or a 60 h. p. at 100 periods per second. The transformers are nearly the same size in these two cases. The enormous size of the transformer is a great drawback to machines excited by alternate currents, and, unless multiple-current motors can be greatly improved, this fault alone will be enough to render them useless for most work.

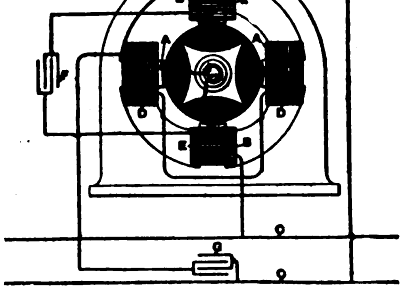


FIG. 1.

So far the condenser has been described as arranged in shunt to the circuit containing self-induction. It has then no effect on the circuit with self-induction, but affects the dynamo. In fact, it supplies exciting current instead of letting the dynamo supply it. The self-induction can, however, be counteracted by arranging capacity in series with it. For instance, suppose the alternate machine is made like one for direct currents, except that the field magnets are laminated. Suppose the machine in question is a 10 h. p. motor for 100 volts. If the field magnets are wound to suit 100 volts on a direct-current circuit, they will be only very slightly excited by the alternating pressure. If the number of turns is much reduced and the diameter increased, full excitation will eventually be reached, but the current will be enormous. For instance, if the magnets take two amperes on a 100-volt direct-current circuit, the loss in copper is 200 watts, but to drive two amperes through the inductive circuit with an alternate current would probably need something like 5,000 volts. If a few turns of large wire are used instead, the full excitation will probably be reached with about 100 amperes. Not only is the exciting current enormous, but the armature current is not in step with the field induction, so the output is lessened from this cause too. M. Leblanc was the first to point out the way to overcome these troubles by the use of condensers. A condenser may be put in series, of such a capacity that at the frequency employed the electromotive force of the condenser is always exactly equal and opposite to that of the self-induction of the magnets. This condition can only be attained approximately, as the pressure does not vary perfectly harmonically. If it did, all the electromotive force of the supply circuit would be spent on resistance, so that the same current would be produced as if the magnets were excited by a direct pressure. The field induction is then in step with the electromotive force, so that the armature current is so also, and the power taken by the motor is found by multiplying the pressure by the current.

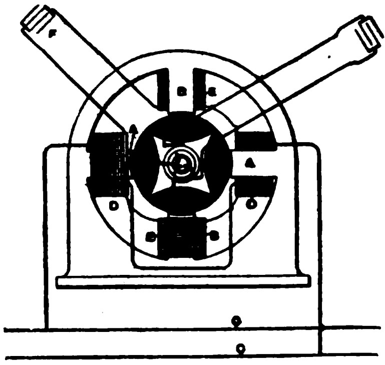

FIG. 2.

Messrs. Stanley & Kelly have designed and worked out a motor on this principle. It is constructed like an ordinary direct-current shunt motor, but has laminated field magnets. A condenser is arranged in series with the magnets. This motor has some drawbacks. In the first place, if the field magnets and armature are on a 100-volt circuit, the pressure on the condenser and on the field coils will be something like 5,000 volts, and this might make the motor too dangerous for admission to private premises. Of course this depends on the size and design of the motor. It may be possible to design a machine with much lower condenser pressure. The loss by hysteresis in the field magnets is also necessarily large; but that is not such a serious matter in a motor as in a transformer, which is on all day and all night. The next trouble is sparking at the brushes. The armature coils are short-circuited just at the time of the most rapid change of field, so that there is a large current in the short-circuited section. I would suggest that this trouble can be overcome by winding the armature with two separate circuits in parallel. The brushes then collect from both, but never short-circuit any of the sections.

The Tesla motor, as is well known, demands two or more currents differing in phase. Two currents differing a quarter of a period will do. At first special dynamos with double armature circuits were used as generators, but several arrangements involving condensers have been proposed. The first experiments of this kind were probably made by Prof. Ayrton and Dr. Sumpner. They had a small Tesla motor some years ago, but made up some arrangement with self-induction and capacity so as to split the single into a double current. The experiments have not been published, so I do not know what the exact arrangement was. Mr. Tesla has designed numerous arrangements himself; but the most complete investigations have been made by Messrs. Leblanc and Hutin, and those interested in this subject will do well to read the able articles in the *Lumière Electrique* which have been appearing recently at short intervals. These authors have gone most carefully and exhaustively into the whole subject of alternate-current motors of all sorts, and their papers are very suggestive. Fig. 1 shows a very simple arrangement due to them. One field magnet circuit E E has a condenser in series with it. Its current and induction are therefore in step with the pressure, and the wire used is the same as for direct currents under the same pressure. The other magnets A A, however, are wound with few turns of low-resistance wire B B, and take a large current, which lags practically a quarter of a period behind the pressure. In all practical cases the lag can be adjusted to a quarter of a period by using a condenser of the right capacity in the first circuit.

It is to be feared that there will be great difficulty in work-out this system to be right at various loads. As the load increases, an active current should flow in both circuits. The circuit with the condenser in series with it cannot take its load current, so that the full load output of this form of motor may be little more than half that of a double-current motor of the same size. It is probable, however, that the ingenuity of Messrs. Hutin and Leblanc in France, or Mr. Tesla in America, may overcome this drawback. A multiple-current motor is, however, thus obtained, which will work on ordinary supply circuits Only one of the sets of magnets takes a large "idle" current; but to avoid troubles from this a second condenser G in shunt to the mains C C or to the transformer that supplies the motors is advisable. This condenser is of the same cubical contents as the first, but unless arranged on the high-pressure side of the transformer it is designed for a much lower pressure and for a correspondingly larger current. By this means a self-starting motor can be obtained which has no brushes, which works on an ordinary supply circuit, and which gives full torque on starting. It has, however, the same drawbacks as the type first described. The dangerous pressure on the field coils of the first circuit may be reduced by arranging the magnet coils in small portions alternately. If the fields take 5,000 volts to drive the exciting current through, say, twelve coils, the coils and portions of the condenser may be arranged alternately, so that the maximum pressure is just over 400 volts due to the condensers. The fall over the resistance of the circuit is out of step with this, and may therefore be neglected. Mr. Tesla has also patented an arrangement on the same principle as Messrs. Hutin and Leblanc. He uses one field circuit partly as a transformer to transform up, and then places the condenser F in the secondary circuit D E D E. This seems rather to increase the difficulty arising from the very high pressures resulting from arranging condensers and induction coils in series. His arrangement is shown in Fig. 2. He has also put a condenser in the armature circuit, but it is difficult to see the inventor's object in this. Whether this form of motor is the motor of the future or not is difficult to say; but if it is, the number of condensers required will be considerable, so we are justified in discussing it at some length in this article.

There is still another possible use for condensers, and that is for exciting dynamos. An alternate machine may be regarded as made up of two elements. One has constant induction, and is called the field magnet; the other is variable, and called the armature. The field magnet may be excited by a direct current round it, or by an alternate current in the armature which is direct relatively to the field, because the armature changes position while the current changes its direction. As far as copper in the machine goes, it is cheaper to excite the fields by arranging the machine so as to have considerable armature reaction, and exciting by means of a condenser. Suppose when the field has its own coils the current density and weight of copper is the same in the field magnet and armature; if the field coils are removed and the condenser applied, the armature copper need not be doubled; it will carry the current at the same density as before, if the copper is increased in the proportion $\sqrt{2}:1$. The total power wasted is then less than before; in fact, if the armature copper is not increased at all; the loss of power in the armature alone when the condenser is used is the same as that in the armature and field magnets together, with separate excitation. By the use of a condenser, cheapness, or higher efficiency, or a compromise of these can be obtained. The condenser itself is generally much cheaper than an exciter, and is of course very much more efficient. An alternate machine with a condenser follows practically the same laws as a shunt-wound dynamo, but it has only one copper circuit, and no commutator.

Perhaps enough has been said to show that condensers may have a large future. New possibilities are appearing every day, and there is no saying what combinations of capacity, self-induction, and resistance may be invented during the next few years.

CALENDARS FOR NEW YEAR.

We have received a number of fine calendars for the New Year, and are making an æsthetic and effective disposition of them in our offices. Among them we may mention one from Mr. H. T. Paiste of Philadelphia, who, it will be remembered, has issued some very choice examples of time literature. We have also two calendars from the Commercial Cable Co. and the Direct United States Cable Co. The former is large, with a sheet pad; the latter has a leaflet pad, one leaf for each day. Pettingell-Andrews Co., of Boston, issue a large sheet calendar with big figures. The Bubier Publishing Co., of Lynn, is more modest in the proportions of its calendar, which is ornamented with a chromolithographic snow scene. The Ashton Valve Co., of Boston, have published a very tasteful calendar prepared for them by John A. Lowell & Co., who have put on it one of the finest "smooth" etchings. The Standard Paint Co., of this city, have sent us some charming little calendars for the pocket. They are printed in gold on tortoise shell, and are as useful as they are dainty. They are certainly "P. and B."—being both pretty and beneficial.

Letters to the Editor.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted, will oblige by mentioning the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

THE HUM OF MOTORS.

FOR the benefit of Mr. Binney, I will somewhat further elucidate my theory of the cause of humming in motors.

Sound, as any one at all acquainted with physics knows, is a mode of motion produced by a peculiar vibratory movement of matter, and is transmitted by any conducting medium to the drum of the ear, and thence by auditory nerves to the brain where it is recognized as sound; and not, as Mr. Binney says, "set up by some force or forces other than those derived from motion."

I made the statement in my article that the movement in the armature was a progressive, undulatory movement of the iron; I should have said a progressive, undulatory movement *around* the circumference of the ring, not a progressive movement of the *iron;* that is, the iron does not progress, but simply has a *progressive movement*, as on waves of water the water does not progress, simply the movement. Mr. Binney seems to be unaware that all wave motion is progressive.

The intensity of attraction on any particular spot of the circumference of the ring, as it is revolving, is constantly varying, producing a vibratory movement of the iron and a progressive wave-like motion around the ring. The vibratory movement of the iron produces also a vibratory movement of the air surrounding it, which air transmits the vibration to our ears and we recognize it as sound. The wave-motion *around* the ring is undulatory and transverse to its line, or direction of propagation and is *not* sound (and I never claimed it was); whereas the vibratory movement of the iron transmitted by the air is longitudinal to its direction of propagation and *is sound.*

If Mr. Binney doubts the slightness of vibration being able to produce the sensation of sound, it would be well for him to notice the phonograph in which the little glass diaphragm appears motionless, and yet we know it vibrates and produces sound. Perhaps it would be easier for Mr. Binney to understand the action if he would imagine the poles to revolve about the armature, which would produce the same result.

I should be pleased to know what the "more admissible theories, already somewhat numerous," are.

CHAS. J. HAYES.

DETROIT, MICH., Dec. 24, 1891.

MR. STUART AND REACTIVE COILS.

THE letters by F. L. P. and Prof. Elihu Thomson, in your issue of the 16th inst., both take me to task for saying, in my article on "Reactive Coils," that Prof. Thomson first stated that if a magnetic field cut or is moved across a conductor, a current of electricity will be generated in the conductor.

Regarding the references to Faraday's "Experimental Researches" made by F. L. P., all I have to say is, that the "principle" is not stated therein. But I am aware that the principle was *known* many years ago. I do not remember that I have ever heard it *stated* except by Prof. Thomson. However, I am willing to be corrected by such eminent authority as Prof. Thomson, and the matter cannot, probably, be better stated than in his own words: "Any one who is familiar with the work of Faraday and others will understand that the principle was known many years before I was born, and is a fact so self-evident that no statement of it would be required," etc.

Concerning Prof. Thomson's next point I desire to say, first, that I am aware of the nature of his patent, No. 428,647; secondly, that I knew of the apparatus he mentions he had in his house in Lynn, and have myself operated the same; and thirdly, that I was aware of the "problematical" efficiency, so called, of reactive coils when used for such purposes.

Prof. Thomson's patent does not describe such a device as the Ries regulating socket. The device used by Prof. Thomson in his house in Lynn was not such a device as the Ries regulating socket. Nor was I considering *who* was the original inventor of the device.

In my opinion the Ries regulating socket is one of the most interesting applications of the reactive coil. I first saw this socket at the Montreal Exhibition last September. Since then I have seen it tested, and I was surprised to find its efficiency so high. My remarks on it were made because I desired to name an application of the reactive coil of the most general interest and usefulness.

The patentability of the Ries regulating socket is a matter of opinion which I will not attempt to discuss. It seems to me as worthy of a patent as many other patented devices—as worthy, for instance, as some of the regulating coils of the Thomson Electric Welding Co.

OTIS K. STUART.

PHILADELPHIA, PA., Dec. 28, 1891.

IRON ROOFS FOR LIGHT AND POWER STATIONS.

WHEN building an electric light or power plant, one of the objects in view is to have its construction as fireproof as possible. In order to secure this I know of four stations where iron roofs have been placed. These answer very well in the warm weather, but as soon as it becomes cold, very rapid condensation is the result and if not remedied very serious troubles may be caused by the water falling on machines, switchboards, etc. I know of one lighting station in particular which I visited during cold weather and found that wooden sheds had to be built over the machines in order to run them. I would ask through your numerous readers the best means of obviating this trouble, as it appears to me to be one of no little importance.

It may be a little difficult with the so-called "iron bridge" roof, but by placing a light woodwork under the rafters I should say it would answer the purpose with the least expense. Trusting you will give this a space in your valuable columns,

ALFRED E. BRADDELL,
Electric Inspector, Underwriters' Asso'n., Middle Dept.

PHILADELPHIA, Dec. 29, 1891.

REACTIVE COIL IN A KEYLESS SOCKET.

I have read with interest the various articles in regard to the reactive coil as used with a socket for the regulation of an individual lamp. It may be interesting to note that in the early part of 1889, when manager of the Gardner (Mass.) Electric Co. the writer made a small reactive coil and attached same to a keyless socket. This device was attached to the wires in the house of the vice-president of the Co., and turned down and up a lamp screwed into the socket. Owing to other work pressing this was laid aside to await a more favorable opportunity for placing it on the market. The opportunity never arrived however.

EUGENE T. CARPENTER.

FORGE VILLAGE, MASS., Dec. 26, 1891.

Society and Club Notes.

PROF. J. P. BARRETT BEFORE THE CHICAGO ELECTRIC CLUB.

A paper was read by Prof. Barrett before the Chicago Club on January 4, on "Electrical Exhibits at the Columbian Exposition." With regard to electric light and power, he stated that about 25,000 h. p. will be utilized in the shape of current in the building and grounds. He said that an important part of the electrical exhibit would be the original models and apparatus of some of the greatest inventions. As to prizes and awards, he remarked:

"It is not contemplated by the National authorities of the Columbian Exposition to offer awards which would have so great an intrinsic value as to attract exhibitors, but it is contemplated to make the standard of excellence so high that the bare acceptance of an exhibit by a department will be a lasting and distinguished honor. In the Electrical Department, the space available for exposition purposes will be so small as compared with the demand, that the greatest judgment will have to be brought into play to decide what exhibits are worthy of a place and what will have to give way. It will be impossible to accept all. Therefore the presence of an exhibit in the Electrical Building will be a testimonial of its unusual merit. The awarding committees have determined to have full and exhaustive tests made of all machinery in competitive exhibition, by the juries of the different departments, and to publish these tests and the jury findings, at the close of the exposition, under the authority of the National Commission."

NATIONAL ELECTRIC LIGHT ASSOCIATION.

WORK is being actively pushed for the convention at Buffalo next month, and there is promise already of good papers and a large attendance. One of the gentlemen who will contribute to the proceedings is Mr. Erastus Wiman, whose subjoined circular letter explains itself:

"Having had the honor of being especially designated by Mr. C. R. Huntley, president of the National Electric Light Association, to address the next convention at Buffalo, on the special subject of the financial side of electric lighting, I am desirous of all the help I can get to make a careful and strong presentation of the merits of this class of property. There is believed to be in the public mind, and especially in financial circles, a growing prejudice adverse to securities based on electrical properties. It would seem important at this juncture that as clear a view as possible should be had of the real facts of the case. Hence, it would be very desirable if I could be placed in possession of instances of successful companies, with particulars of the amounts of their stock, the length of time before dividends were paid, and the amounts regularly realized, cost of maintenance, and such other facts as can be readily got together. Some special instances of very successful concerns are particularly wished for, and the history of companies which have not at first been successful, but which have since been rescued from insolvency by good management; also any facts relating to combinations between gas and electric light companies, and how best it can be promoted.

"If you happen to have anything of that kind and can send it for me to Mr. George F. Porter, 136 Liberty street, New York, I shall be much indebted."

NEW YEAR'S EVE AT THE NEW YORK ELECTRIC CLUB.

THE entertainment at the New York Electric Club on New Year's Eve was voted a great success by all who participated in it, and the club house between 7 P. M. and 1 A. M. was visited by about 150 members. A most interesting and eloquent address on various features of journalism was delivered by Mr. Joseph Howard, Jr., a member of the club, and one of the most celebrated correspondents in the country. The address abounded in reminiscences of the elder and younger Bennetts, Horace Greeley, Henry J. Raymond, Henry Ward Beecher and others, and bristled with anecdotes and epigrams as well as with many well-directed criticisms on the less admirable aspects of modern newspaper work. Mr. Howard was listened to for over an hour with the deepest attention and received a warm tribute of applause.

The musical part of the entertainment was begun by Mr. Alfred Grünfeld, Imperial Court pianist of Vienna, Austria, who rendered a fantasia on the themes of Lohengrin and Tannhauser. The delicate touch of Mr. Grünfeld in the piano and pianissimo passages and the feeling and expression infused throughout his rendering were remarkable, and called forth well-merited applause. He was followed by his brother, Mr. Heinrich Grünfeld, Imperial Court violoncellist, of Berlin, who played a "Romanza," composed by Mr. Alfred Grünfeld. In response to a hearty encore, Mr. Grünfeld played the "Golden Wedding," by Gabriel Marie. In response to the continued and unremitting applause, Mr. Grünfeld rendered the "Guitarre" of Moskowsky. As a violoncellist Mr. Grünfeld undoubtedly ranks among the best who have thus far been heard in this country. One of the most characteristic performances of the evening was the rendering of the "Hungarian Rhapsody," composed by Mr. Alfred Grünfeld, in which he portrayed with masterly skill the peculiar intonations and effects of the Hungarian national instrument, the cymbal.

The vocal part of the programme was inaugurated by Mrs. Anna Lankow, the well-known alto concert singer and vocal teacher, who sang the celebrated aria from Gounod's "Mignon" with most consummate finish. As an encore Mrs. Lankow sang the alto aria from "Samson and Delilah." The programme was brought to a close by Sig. Victor Clodio, tenor in Gilmore's orchestral company and now of the Italian Opera Company, who sang Tosti's "Rosa" with excellent effect, his high B, *sostenuto*, calling forth enthusiastic applause. Mr. Friedberg, the well-known pianist, played the accompaniments to Mrs. Lankow and Sig. Clodio in the most finished manner.

After the regular programme had been gone through, Steward Reynolds filled the club punchbowl and served a collation. A few minutes before midnight Mr. George H. Guy played "Auld Lang Syne" on both the pianos in the club parlor, and his music was ably seconded by a large gathering of those who had lingered to see the New Year in. Steward Reynolds is entitled to much credit for the success of the arrangements in the club and for the excellence of the table d'hote dinner and later collation.

CHICAGO ELECTRICAL ASSOCIATION.

AT the regular meeting of the Chicago Electrical Association, Dec. 22, Mr. A. H. Adams read a paper upon "Chimneys and Chimney Draughts"; Mr. L. G. Bassett read a paper upon "The Speed of Electricity." The following officers were elected for six months, to begin Jan 12: President, E. G. Hovey; vice-president, J. I. Connor; secretary, F. R. McBerty, No. 227 So. Clinton Street; treasurer, Albert Scheible. This association meets the second and fourth Tuesday evenings of each month at No. 169 E. Washington street, Chicago.

GRAND RAPIDS, MICH., ELECTRICAL EXHIBITION.

GRAND RAPIDS is about to have an electrical exhibition under the auspices of the Electromathean Society. Space will be granted to manufacturers and dealers in electrical goods, for simply the payment of the expenses pertaining to their own exhibit. Some new and attractive features are promised. Mr. Eugene B. Palmer is chairman of the Committee on Advertising and Solicitation, and will be glad to furnish information to any one interested.

NEW ENGLAND ELECTRIC CLUB.

GENTLEMEN interested in the New England Electric Club have elected the following-named officers: President, Mr. Ferdinand A. Wyman; vice-president, Mr. E. A. Record; secretary, Mr. Lynn M. Hays; treasurer, Mr. A. O. Smith; board of directors, Mr. Charles C. Pierce, Mr. Maybin W. Brown, Mr. Elmer P. Morris. The officers, with Mr. E. R. Tilton and Mr. James E. Cotter, were appointed a committee on constitution and by-laws and also to take all necessary steps toward obtaining a charter, and to investigate, consider and report in regard to obtaining quarters for the club. The club starts off with a membership of 110.

Obituary.

GEORGE W. COSTER.

IN the death by pneumonia, at Schenectady, N. Y., of Mr. George W. Coster, district manager Rocky Mountain District, the Edison General Electric Company has lost one of its most faithful, efficient and zealous officers. Mr. Coster was educated at the United States Naval Academy, graduating from that school in 1867. He remained in the Navy until 1880, when he resigned and went into business. While in the Navy he acquired a thorough knowledge of discipline and of the handling of men under him, which he afterwards utilized to good purpose in civil life.

Mr. Coster was connected with the Edison interests for the past six or eight years, and his ability as an executive officer had been thoroughly demonstrated. He possessed to a marked degree the ability to surround himself with able assistants, men peculiarly fitted for their positions, and to secure from them the most devoted loyalty. His entire office was permeated with a loyalty to, and enthusiasm for, the interests of the company, which he himself served so ably and so well. Mr. Coster is not only a great loss to the Edison General Electric Company, but to his many intimate friends connected with the electrical business, who remember his warm friendship and genial manners, his death comes as a severe personal loss.

Personal.

MR. R. G. BROWN.

THE many professional and business friends of the above-named gentleman will be greatly interested in the news of his marriage to Dr. Lucy M. Hall, of Brooklyn. Mr. Brown, who is at present connected with the Interior Conduit and Insulation Co., has had an active career in telephonic and telegraphic fields in this country and abroad. Dr. Hall-Brown is a well-known and popular practitioner, vice-president of the medical alumni of Michigan University, secretary of the Department of Health, of the American Social Science Association, and has been in many positions of importance and influence.

Legal Notes.

INCANDESCENT LAMP LITIGATION—THE UNITED STATES ELECTRIC LIGHTING CO. vs. THE EDISON LAMP CO.—IV.

ARGUMENT OF GEORGE H. CHRISTY FOR THE UNITED STATES COMPANY.

But defendant had said further that so much of the invention as was of any practical utility, was Maxim's and not Weston's, and that all manufacturers in this country were using what was spoken of as the "attenuated-gas" treatment. Mr. Christy read Shallenberger's explanation of the attenuated-gas treatment, showing that a deposit within the pores and a deposit upon the surface went together as the inevitable result of the passage of a current through the carbon filament in the presence of hydrocarbon gas. What were the substantial marks of identity of the process? Weston's claim called for the carbon pencil, filament, illuminant; for the passage of a current to raise it to a proper temperature, and a surrounding envelope of hydrocarbon liquid or gas. With reference to what? Why, the "building up" of the carbon, by putting into it, or on to it, or both, a deposit of carbon from the surrounding carbonaceous envelope. This attenuated-gas treatment they were talking about, had every element of the Weston claim, working in the same way, with reference to the same end, and producing identically the same result. Clarke the defendant's expert, had admitted that the use of hydrocarbon vapor was a part of Weston's original invention. The point was that the use of hydrocarbon vapor constituted part of Weston's invention, whether attenuated or not. Yet defendant had tried to argue that attenuated gas—lighter gas and less of it—did not come within Weston's invention. But to go a step further, it was a fact that the oil never touched the highly heated body anyhow; it was always surrounded with vapor. If you stuck a red-hot poker into water the poker would not come in contact with the water; the heat would generate an envelope of steam around it; so it was with the red-hot carbons in oil. Although oil was one of the materials mentioned in the patent, as a matter of fact the work was actually done by hydrocarbon vapor or gas.

There was another singular fact in this case; his brother Betts had conceded that Maxim had done nothing of consequence, except perhaps making one lamp. down to 1880; that he made one lamp and took some patents. Defendant had nevertheless gone to the expense of bringing Maxim from England to examine him. In his testimony in 1891 Maxim magnifies this process; claims the credit of it himself and says that he worked it practically and publicly in 1878 But his testimony in the old interference case in the record, squarely contradicts his 1891 testimony and showed that everything he did down to 1880 had been purely experimental, and had been so admitted in his previous testimony. But Maxim, their own witness, had said that between a little less than one atmosphere and a highly attenuated atmosphere, the difference was simply a difference of degree and not of principle, exactly as he (Mr. Christy), had contended, for reasons set forth in Shallenberger's testimony. Moreover defendant did not use attenuated gas, and it did not lie in their mouth to say that something else than oil was better. They had used oil, and so far as the proof went it was the only thing they ever did use.

Referring again to defendant's brief, Mr. Christy said he had already shown that it contained erroneous statements of fact. He thought it also contained some bad statements of law. Under the heading, "Rules of Law Here Relied Upon," was this passage: "It is a fundamental principle of patent law that to entitle an alleged inventor to protection by a valid patent, it must appear that he was the first in this country to reduce the invention to a fixed, positive and practical form. That was not the law, said Mr. Christy, and it never was. The rule had been well settled by repeated adjudications, especially in this circuit, that the party who first conceived an invention, provided he used reasonable diligence in adapting and perfecting it, was the party entitled to the patent, and it made no difference who came in between. Mr. Betts' next proposition was: "Mere speculations of a party, or experiments incomplete and inconclusive in their nature, or the production of drawings or models, are insufficient to sustain the issue of prior invention when the burden is upon him to prove it. That was about as bad law as the other. Judge McKennan had said, that the first inventor might by drawings, sketches and models, carry back the date of his inception, and if he had meantime used reasonable diligence, he could thereby establish priority. The third proposition was equally objectionable and for the same reasons. There had been no citations of authorities in support of those propositions.

(To be continued.)

A QUESTION IN FIRE INSURANCE.

A CASE of much interest to insurance and electrical companies has been brought at Salem, Mass., before the Superior Court.

On the 26th of October, 1890, the night employees in the power station of the Lynn Gas and Electric Light Company discovered fire in the tower or monitor cupola over the engine-room. Attempts were made to extinguish the flames, but before it could be done the tower was charred and the main light wires burned off.

The result was a quick short circuiting of the station. So big a load was taken off the engine that it began to race, and in a very short space of time the big fly wheel was hurled in fragments through the solid brick walls of the building, carrying havoc everywhere. The station was pretty well wrecked.

It was insured for $9,000 against fire in 23 companies.

The companies refused to pay their policies because the damage and loss was from the racing of the engine, as they claimed, and not from fire.

The Lynn Electric Light Company brought suit on the ground that the damage was from fire, and that fire was the first cause, as but for the fire, the burning of the wires and the release of the engine the latter would not have run away and there would have been no explosion.

MR. R. W. POPE, secretary of the American Institute of Electrical Engineers, delivered an interesting lecture on Dec. 18, at Fitchburg, Mass., in the city hall, under the auspices of the Fitchburg Board of Trade. His subject was: "Electricity: Its Past, Present and Future."

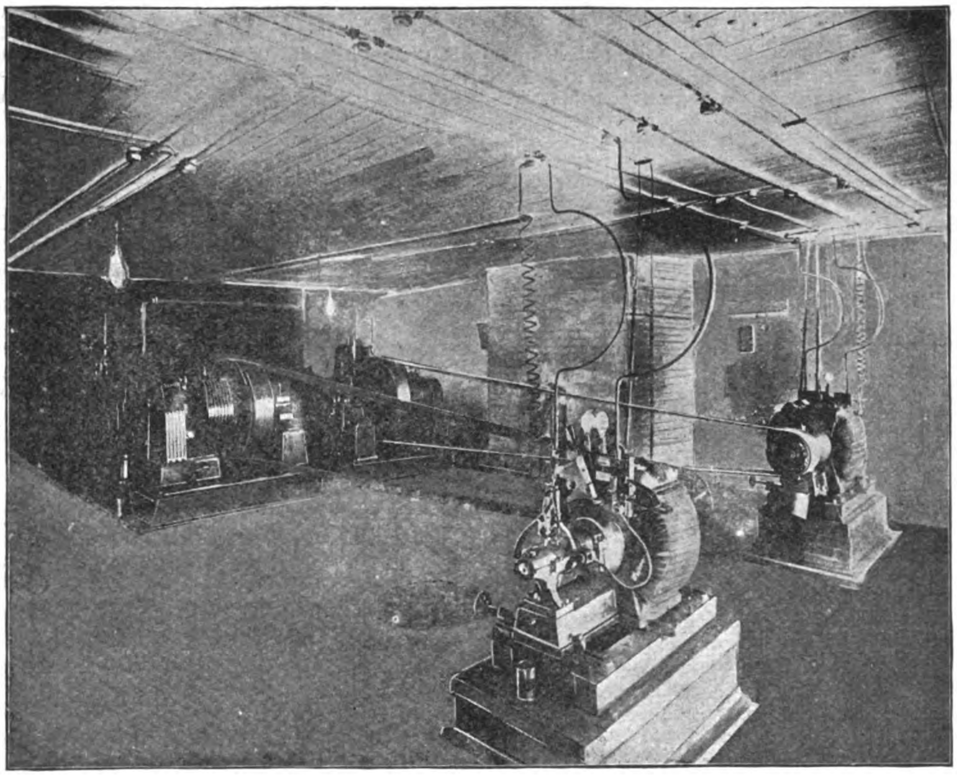
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

The man who doesn't advertise is soon out of circuit or grounded.

A "C. & C." LIGHTING PLANT IN THE ST. NICHOLAS HOTEL, CINCINNATI, O.

THE illustration on this page shows the dynamo-room of the St. Nicholas Hotel, Cincinnati. The two generators have a capacity of 300 lights each and are of the standard "C. & C." type. The fields of the dynamos are compound wound and the entire machine is constructed with a view to attaining the highest possible efficiency. The armature shaft revolves in self-oiling bearings, and the whole machine rests upon a sliding base, which can be adjusted to tighten the belt. This installation was made by the "C. & C." Electric Motor Company, New York, about a year ago, and the dynamos have been in constant service since then. The fact that a 40 K. W. dynamo of the same type has recently been added to this plant to furnish current for an increased number of lights, gives evidence of the satisfaction which these machines have given.



"C. & C." LIGHTING PLANT IN THE ST. NICHOLAS HOTEL, CINCINNATI, O.

THE EQUITABLE ENGINEERING AND CONSTRUCTION CO.

THE Equitable Engineering & Construction Co., Drexel Building, Philadelphia, announce that on the 1st of January their company will go into liquidation. Their business for the past year has been a profitable one, but the active members of the concern wish to get out of the construction business.

Mr. S. Ashton Hand has accepted a position as superintendent of the Detroit Electrical Works, Detroit, Mich.. and Mr. W. A. Stadelman wishes to devote his time for the present to his interests in Bristol, Tenn., which consist of the Bristol Belt Line Railway and the Bristol and East Tennessee railroad, in both of which he owns a controlling interest.

The company retires from business with every debt paid and a good balance to be distributed as a dividend to the stockholders.

WESTERN ELECTRIC COMPANY—MORE FACILITIES?

WHEN, some eight years ago, the Western Electric Company purchased its extensive property in South Clinton street, Chicago, and erected a large building upon a part of it, it may well have been thought, even by the company itself, that abundant provision for its Western manufacturing and for its general offices had been made for a generation. Several extensive additions to the building have since proved requisite until the entire ground has been occupied, and yet more space is required for the company's constantly augmenting business. It is now reported that a purchase has been made of a block of ground adjoining the factory on the south, and known as the Collins and Burgie property, the ground measuring 300 by 200 feet.

Inquiry at the New York office of the Western Electric Co. fails to secure a confirmation of the report, and we have been unable to learn whether it is the intention of the company to erect extensive factory buildings upon the property at once, or not. It is the well-understood policy of the Western Electric Co. to maintain its manufactories within cosmopolitan cities, rather than in suburban locations near such cities, or in smaller towns. In accordance with this plan its manufacturing business is, at present, compactly located and organized in Chicago, New York, Antwerp, Berlin and in Paris.

It is also worth noting that the company has always refrained from premature announcements of its policies and intentions, preferring to await the completion of its facilities and extensions before notifying the world of them.

The report can hardly be without some foundation in fact, though we are not apprised of the purchase price of the real estate. The property includes several buildings erected by Collins & Burgie, who have conducted a foundry business on the premises for 30 years. The property can be worth scarcely less than half a million dollars, situated as it is, near the central business part of Chicago.

As the Western Electric Company has never been known to speculate in real estate, nor to undertake any piece of business just for the fun of the thing, it seems reasonable to infer that it is about to construct an extensive addition to its present Chicago factory.

F. P. LITTLE & CO.

THE above enterprising firm of electrical engineers of 141 East Seneca street, Buffalo, N. Y., have just closed a contract with William H. Walker & Co. for the installation of a 250 light Thomson-Houston incandescent dynamo and a Rice engine, for their new eight-story building on Pearl street, that city.

"P. & B" INSULATING COMPOUNDS.

A letter was recently sent by Mr. George P. Low, electrical inspector for the Pacific Insurance Union, 307 Sansome street, San Francisco, Cal, to the Paraffine Paint Co., San Francisco, who manufacture the "P. & B." insulating compounds on the Pacific coast, and for the territory west of the Rocky Mountains. The letter contained among other things, the following:—

"Permit me to express appreciation of the inestimable benefit you have conferred upon the electrical industry in perfecting and bringing out your "P & B." electrical compound. I know of nothing in the way of an insulating paint for all-around work that is compared to it."

The Pacific Insurance Union controls the entire insurance work of the Pacific coast, and early this year, Mr. Low made tests of all the insulating materials offered for sale on that coast to determine the safest insulation for the wiring of buildings. Severe tests of the compounds were made, the "P. & B." standing the tests better than anything else, and it is now compulsory that "P. & B." be used in all electrical work which comes under the control of the Pacific Insurance Union. The Pacific Postal Telegraph Cable Co. are painting their bare wires, on the Pacific coast, with "P. & B.," it having been demonstrated that wires so painted have worked perfectly during the heaviest rains, and the densest fog, while through the unpainted wires, not a tick could be heard at such times.

The Paraffine Paint Co. is the Western branch of the Standard Paint Co. of No. 2 Liberty street, this city.

THE THOMSON-HOUSTON CO. IN THE WEST.

The Chicago office of the Thomson-Houston Electric Company has just closed a contract with the Benton-Bellfontaine Railway Company, St. Louis, for the equipment of thirty cars with two motors each of their latest improved type, known as the W. P., or waterproof. The contract includes the furnishing of three 333 h. p. compound-wound generators of the Thomson-Houston manufacture, and it is understood that the railway company will do everything that is required to make this installation a model, complete and perfect in every respect.

The Thomson-Houston Company have their electric railway equipment in exclusive use in St. Louis on the following roads: St. Louis & Suburban, Union Depot, Mound City, Missouri Railroad, Suspension Bridge and East St. Louis, and it is now believed that St. Louis has more T.-H. electric railway apparatus in use than any other city in the United States, with the single exception of Boston.

ENGINEERING EQUIPMENT CO.

Facts "talk." These are facts, reported under date December 18th by the Engineering Equipment Company, of 143 Liberty street, New York. Recent shipments of Anderson's electric railway specialties—2987 "Ætna" insulators; 150 "Boston" trolleys, complete; of Anderson pull-offs, 536; terminals, 405; tree insulators, 925; hangers, 1,595; also miscellaneous shipments in considerable quantities of other Anderson specialties. All of the above were additional to direct factory orders Besides these shipments the Engineering Equipment Company report the following: 310 clips, 1,500 eye-bolts, 7,500 rail bonds, 400 turn buckles, 500 bond clamps, 625 trolley ears, 150 curve insulators, 430 trolley bells, etc. These and other materials not mentioned have been supplied to important electric railways in Massachusetts, New York, New Jersey, Pennsylvania, Georgia, Tennessee, Ohio, and in Canada.

The Engineering Equipment Company are the authorized sales agents for Messrs. A. & J. M. Anderson's reliable line apparatus and "Boston" trolleys.

OTIS K. STUART.

The above-named engineer has now established himself at the City Trust Building, Room 21, Philadelphia, where he will not only act as agent for the Germania Electric Co. in the Southeastern district, but will handle such electrical supplies as dynamos, transformers, lamps, sockets, shade-holders, etc. All who know Mr. Stuart, and are familiar with his activity and versatility will expect for him a prosperous career in his new sphere of labor.

THE BURTON ELECTRIC COMPANY.

At a meeting of the board of directors of the Burton Electric Company, held on Dec. 15 at the Citizens' Bank, Richmond, Va., the following resolution offered by Maj. Chas. R. Skinker, was unanimously adopted:

Be it resolved, That after hearing the favorable report of the superintendent, Dr. W. Leigh Burton, as regards the status of its business, we, the directors of said company, hereby desire to express our entire appreciation and satisfaction to Mr. W. R. Mason, president of the company, for the zeal manifested by him in the management of its affairs, and for his untiring efforts for the advancement of its interests; and to say, further, that we are well satisfied with the success of the enterprise up to this date.

THE SECURITY INSULATOR.

A very pretty and pithy little circular has just been issued by the Security Insulator Co., of 136 Liberty street, on the merits of their insulator, which was recently illustrated and described in our columns. The circular makes a neatly humorous statement of the good features of this insulator, the principle of which is that of the inclined plane. The wire fits snugly into the groove and is then held tightly by screwing the top cap down on it.

BALL ENGINES AT KEY WEST.

The electric light plant being erected at Key West, Florida, is a source of great curiosity to a great many of the natives, who have never seen anything of the kind before. The three large compound engines furnished by the Ball Engine Co., Erie, Pa., are the centre of attraction, the largest engine on the island, hitherto, being an antiquated 6 h. p.

THE CARD ELECTRIC MOTOR AND DYNAMO CO.

The above company, of Cincinnati, O., is now ready for business under its new incorporation. The officers are: J. W. Welshire, president and treasurer; George Bullock, vice-president; C. B. Simrall, secretary; G. B. Wilson, assistant secretary; and O. W. Jantz, electrician and superintendent. The company will push for business more actively than ever, and reports a bright outlook for the coming year.

HEAVY ELECTRIC TRACTION.

It is stated that the Illinois Central Railroad is likely to adopt electric power for the purpose of drawing its heavy trains in and around Chicago, where the smoke of locomotives has become an intolerable nuisance. It is understood that the New York Central has had a similar idea under consideration for its New York terminal tunnel. The Illinois Central has appointed two of its directors, J. W. Doane and Norman Ream, a committee to investigate and report upon the feasibility of having all trains entirely propelled by electric motors.

FACING UP GENERATOR CASTINGS.

A new portable milling machine has been designed by one of tha foremen of the Thomson-Houston Company, at Lynn, for facing up the castings of big generators. The tool is said to do in five hours the work of four days when a planer is used.—*Engineering Record.*

NEW YORK NOTES.

The Easton Electric Company, of Brooklyn, N. Y., lately sold to the Messrs. J. S. & G. F. Simpson, of 28 Rodney street, Brooklyn, N. Y., a six hundred light incandescent plant, consisting of a No. 9 Easton incandescent dynamo and the lamps. The plant includes a number of the Easton arc lamps which are operated on the incandescent circuit. The entire installation was made by the Easton Company and was pronounced a success. The plant is in daily operation on the premises owned by the Messrs. Simpson, and gives entire satisfaction. This is the sixth large plant which the Easton Company have lately installed in Brooklyn. This fact is good evidence that the work of the company is appreciated at home.

Mr. H. Ward Leonard has been called into consultation by the consolidated electric light companies of St. John, New Brunswick. When all the changes that he is to supervise and suggest are made, the company will have 180 arc lights, 5,000 incandescents, and a large power plant for running the street railway.

The Law Battery Co., of 85 John street, issued as a Christmas memento a huge stocking, which typified in a degree their own capacity for receiving orders. The stockings were greatly in demand and none have been returned as misfits.

Mr. F. V. Doty.—The marriage of Mr. Doty, the manager of the Aluminium Carbon Co., of Lancaster, N. Y., to Miss. Frances E. Olmsted is announced for January 14, at the Presbyterian Church, Geneseo, N. Y.

Walter Roach, the bookbinder, Pearl st. and Park Row, has lately put in a 5 h. p. Edison motor to run his large establishment and is more than pleased with electric power.

"A. B. C." GREETING.

WE have received from the enterprising house of Alexander, Barney & Chapin, of 20 Cortlandt st., an extremely tasteful and pretty souvenir of the season, accompanied by greetings for the New Year. It is adorned with portraits of the company's friends and "enemies." The portraits are very faithful, and the expressions will be recognized by everybody as wonderfully characteristic. The brochure is printed in colors and comes from the Bartlett press—a fact which speaks volumes for its typographic and artistic excellence.

STAR ELECTRIX.

THE Star Electrix Co. promise some new things in the way of electric lighting novelties to begin the new year. They will be put upon the market in a few days.

RECIPROCITY IN THE WEST INDIES AND SOUTH AMERICA.

THE new reciprocity treaties with the British West Indies and Salvador admit American electrical supplies and apparatus free of duties into those regions.

WESTERN NOTES.

THE ENGLEWOOD ELECTRIC LIGHT COMPANY are doing a very prosperous business in furnishing incandescent lighting in that section of Chicago, their business having increased 60 per cent. during the past year. Among other work that they have done of late, and which is well worthy of mention, is installing and furnishing current for 300 lamps in St. Cecilia Church, of Forty-fifth and Atlantic streets, for the Rev. E. A. Kelley. This church has been modeled after Notre Dame at Paris, and the lights are arranged one-half around the dome and also around the octagonal portion. On account of the distance of the lights from the station—some three miles—they have employed "boosters," manufactured by the Westinghouse Company, to give the required voltage at the lamps, making it a very interesting plant.

ELECTRIC APPLIANCE CO.—Any one happening into the busy store of the Electric Appliance Company during the last week of December would have wondered at the unusually busy appearance of the place which at no time since the new firm started has been anything but busy. The president of the company, Mr. Willard W. Low, had just returned from a business trip and any one familiar with the personnel of the Electric Appliance Company knows what that means. Mr. Low filled the Electric Appliance Christmas stocking with orders that made holiday week a very restless one for the employés of the company and a merry one for the firm.

ELECTRICAL SUPPLY CO.—Any device that is simple and which contributes to the ease of operating the dynamo is generally welcomed by practical engineers. The Wirt dynamo brush seems to have been a particularly happy design in this respect. The Electrical Supply Co., Chicago, who are the manufacturers, say that they have met with unusual success in introducing it. Engineers who have tried it say that it entirely prevents sparking and the consequent wear of the commutator. Each set is made to order. In this way they are certain to meet the exact conditions of service where used and give the greatest satisfaction.

THE ELECTRICAL SUPPLY CO., Chicago, the Western agents for the well-known "Boston" trolley, report a very marked increase of orders since the announcement of a reduction in price. They keep a full line of complete trolleys and parts in stock. They are also manufacturing a superior grade of raw-hide pinions which are meeting a ready sale. The general inclination of the trade is toward a better quality of supplies, and it is among this class of purchasers the Electrical Supply Co. find their largest buyers.

SOME QUICK WORK has recently been done in connection with the rearrangement of the Chicago Arc Light & Power Company's station recently destroyed by fire. On December 8, this company placed an order with the Chicago offices of the Pond Engineering Co. for a 200 h. p. Armington & Sims engine. The engine was shipped, complete, from St. Louis on the 9th inst. The railroad company delivered it in Chicago on the 14th inst., and on the 17th inst. the engine was ready for operation, and is now regularly driving six 50-light arc dynamos.

MR. F. E. DRAKE is now the selling representative of the Standard Electric Co., manufacturers of arc and incandescent systems of lighting, power generators and motors, at 313 to 317 So. Canal street, Chicago. Mr. Drake is an old telegraph operator, but for a number of years past has been interested in mining engineering in the West, and later in electrical work.

THE ELECTRIC APPLIANCE COMPANY are meeting with splendid success in introducing the New England switch to the Western trade and already report large sales. The Electric Appliance Company have inaugurated what we think a new departure in the electrical supply business; that is, the publishing of a catalogue especially devoted to toys and novelties for the holiday trade. About December first they printed quite an elaborate little catalogue of this character which they have distributed all over the country through the medium of the young people's periodicals, and which is bringing in quite a valuable trade in a small way. The Electric Appliance Company certainly deserve credit for this original idea and in placing before the people in general an opportunity of securing reliable electrical toys and novelties in the electrical line, as heretofore this business has been left to irresponsible dealers and the purchasers have been imposed upon to a large extent.

MR. ERNEST L. CLARK, widely known in electrical circles, has resigned as secretary of the Illinois Electric Material Co. He has organized the Ernest L. Clark Co., which will commence business the first of the year handling poles, ties, cross-arms and all kind of wooden material for electrical construction work. Mr. Clark's many friends will wish him the full measure of success in his new venture, returning as he does to his old line of business in which in the past he achieved an extended reputation and success.

THE RACINE HARDWARE MFG. CO., of Racine, Wis., have just received a second order from the Colorado Smelting and Mining Company, of Butte, Montana, for a 15 h. p. automatic engine for driving an electric lighting plant. This company have had a 10 h. p. of the same make at work for some time and the repeat order is the result of the excellent satisfaction given by this first engine.

MR. GEO. A. MCKINLOCK has returned, with his wife and infant daughter, to Chicago, from his wedding trip around the world, on which he has been gone for more than a year. He will resume his interests in the Central Electric Company and will be back shortly at his desk.

MR. CHAS. E. GREGORY, dealer in standard makes of dynamos, lamps and motors, has leased a floor at 205 So. Canal street. He furnishes machines of all makes and sizes, either new or second-hand, and also pays attention to installing of electrical plants of all kinds.

MR. L. K. COMSTOCK, the Rookery, is doing a general consulting electrical engineering business. He prepares plans and specifications for all kinds of electrical work and supervises the same. Mr. Comstock is meeting with good success here.

THE CENTRAL ELECTRIC COMPANY recently made the heaviest shipments yet in Swan incandescents. They are filling large orders right along, and the large and varied stock they carry enables them to make exceedingly prompt shipments.

CUTTER'S PLUG HAT INSULATOR. One of the odd orders lately received by George Cutter called for "those plug hat insulators that keep the ceiling white." Many who know his E. L. insulator may have other epithets for it.

GEN. C. H. BARNEY, of New York, was a visitor to Chicago, last week, He called at the Western office of THE ELECTRICAL ENGINEER. He was much interested in the progress being made on the World's Fair work.

PROF. D. C. JACKSON, instructor of electrical engineering of the University of Wisconsin, at Madison, Wis., was in Chicago, last week, visiting his many friends among the electrical fraternity.

MR. J. G. BECKERLEY, 229 So. Franklin street, is placing on the market a noiseless back-pressure valve for exhaust steam-heating purposes. It is a very simple and effective device.

THE CENTRAL ELECTRIC COMPANY are sending their friends their handsome calendar for 1892, and shall be glad to hear from those who are not supplied, so that they can be furnished.

THE CENTRAL ELECTRIC COMPANY have ready for distribution a handsome lithographed circular of the Bryant specialties, which have earned such a well-deserved reputation.

MR. C. A. BENTON, manager of the railway department of the Detroit Electrical Works, was a welcome visitor to Chicago last last week.

MR. N. P. SENAT, formerly connected with the *Street Railway Gazette*, of Chicago, has accepted a position with the *Chicago Herald.*

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.

VOL. XIII. JANUARY 13, 1892. No. 193.

AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—I.

BY

Mary A. Henry

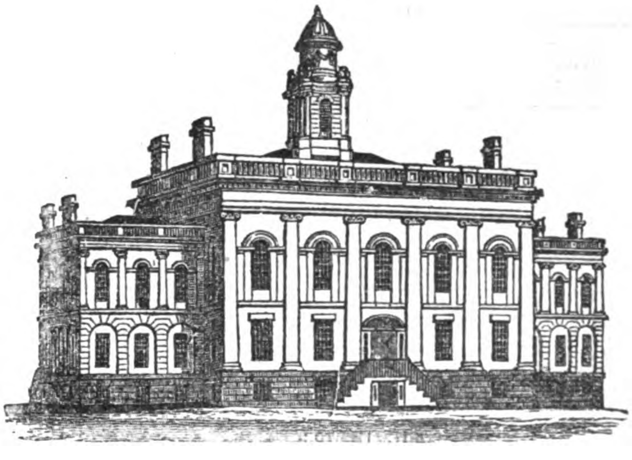
THE phenomena of self-induction and of mutual induction are closely connected, and indeed must be treated together as one whole in the modern theories of electricity and magnetism. After the discovery of self-induction by Henry, it seems to me but a step to the discovery of magneto-induction. This step was moreover made easy by the construction by Henry of electromagnets with great numbers of coils of wire. With a suitable galvanometer, also constructed with many turns of wire, there was sufficient residual magnetism in Henry's large electromagnets to give deflections of the galvanometer when the armature of the magnet was moved on or off the poles of the electromagnet, even when the latter was not excited by a battery.

MICHAEL FARADAY.

JOSEPH HENRY.

From a careful survey of the evidence presented, I believe that *Henry was the first to perceive the fluctuations of the galvanometer due to magneto-induction*, and that he had a conception of the relations of magnetism and electricity before Faraday published his first paper on the subject of magneto-induction. Henry has himself stated that he had perceived the phenomena of magneto-induction, and had been intending to study them further; but was prevented from pursuing the subject by unavoidable interruptions, and the desire to construct more powerful apparatus to continue his investigations. When we reflect that he had to insulate his wires with calico cloth, and to wind all his own electromagnets; that he was pursuing his investigations in Albany—then little more than a frontier town—while Faraday was at the Royal Institution, in the intellectual centre of the world, we feel that too much cannot be claimed for our countryman.—JOHN TROWBRIDGE.

IN the year 1774, a question of no small significance was presented as a subject for prize essays by the Academy of Bavaria. The subject was one which even at that early day had excited deep interest in the scientific world; it was no less than "the identity of the two great mysterious forces, electricity and magnetism." The essays received in the competition were so numerous as to make 13 large folio volumes of matter, but the report of the Academy nevertheless was to the effect that "although electricity and magnetism are by some experimenters proved to be the same in some respects, in other respects they are dissimilar, so much so that they must of necessity be as yet considered as distinct." In this indeterminate state the matter rested for 56 years, until 1819, when, by the deflection of a needle Oersted became immortal. While the Danish philosopher was one day lecturing to his class in the University of Copenhagen, an experiment occurred to him and he tried it then and there for the first time. It was a simple matter; nothing more than the passing of a galvanic current through a wire parallel to and above a magnetic needle. Oersted found that under these conditions, the needle, swinging upon its pivot, turned eastward, and at length came to rest at right-angles to the wire, its north pole pointing east. When the wire was held below the needle, the north pole turned westward, and settled pointing west. What had happened here? What was there in this mere swaying of a bit of steel through an inch of distance to bring fame to a philosopher like Oersted? The little needle was not a common needle, a mere unresponsive fragment of steel. Endowed with the mysterious principle of magnetism, it had as one might say, a soul, and as human soul answers to human soul, it was quick to respond to another magnetic soul. Had an ordinary magnet been brought to bear upon it, in obedience to the magnetic instinct, it would have excited no surprise, had it responded to its influence. What then, we ask again, had happened in the experiment of Oersted? The little needle was behaving exactly as if the wire traversed by the electric current possessed magnetic properties. Was this, in truth, the case? Had electricity produced magnetism in or about the wire? Or was electricity itself magnetism? Oersted published four quarto

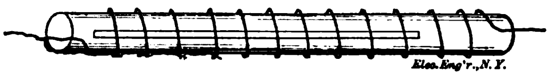


THE ALBANY ACADEMY, AS IT APPEARED IN 1826–32. FROM A CONTEMPORANEOUS WOOD-CUT.

pages on the subject;[1] the fame of his experiment spread with almost unexampled rapidity throughout the civilized world; it was repeated everywhere, and Schweigger seized upon the little needle to make of it the gavanometer,[2] so indispensable in the laboratory of the electrician from that day until this.

Very brilliant were the scientific men in the old world of that day, and about the year 1820 not a few of them were deeply interested in the question of the "identity of electricity and magnetism."

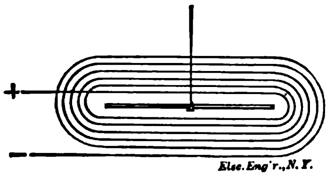
In the same year we find Arago and Sir Humphry Davy passing currents of electricity through wires and noting carefully the attractive power produced. Ampère caused two wires, each traversed by a current, to attract and repel each other, as if they indeed had been two magnets. Arago reached a result of no small importance; it was this: He placed a common steel sewing needle within a glass tube; around the exterior of the tube he wound a helical wire, through which the electric current was made to pass.



Magnetization of Steel Needle by Arago, 1820.

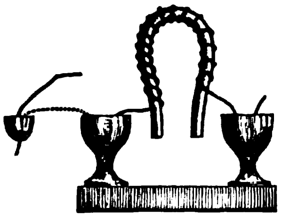
The needle under these circumstances was found to become strongly magnetic.[3] Nature here asserted, in most unmistakable terms, that electricity could produce magnetism. Five years later we find Sturgeon bending a bar of soft iron into a horseshoe and by an obvious adaptation of Arago's method rendering it so strongly magnetic by means of a current of electricity, as to be capable of sustaining a weight of nine pounds.[4]

There is not the shadow of a doubt, after the year 1825, that electricity can produce magnetism; but the reverse, Can magnetism produce electricity? With ever-deepening interest as year after year goes by, the scientific world asks this question, but with all the most eminent men of Europe at work upon it, nature vouchsafes no reply, and so we come down to the last days of August, 1831, and to two men, one in the old world, the other in the new, at work upon the problem, each unconscious of the other, an ocean between them. One of these men is Michael Faraday, professor of chemistry in the Royal Institution of Great Britain; the other is Joseph Henry, professor in the Albany Academy in the State of New York. These two were destined to find the key to the problem; the answer to the question which had baffled the world of science for half a century.



Schweigger's Galvanometer, 1820.

Copyright in *The Century Magazine*, April, 1888, by The Century Co.



Sturgeon's Electro-magnet, 1826.

We say the last days of August, 1831, because at that date, the work of the two men nearly touch in point of time; but the actual discovery of magneto-electricity, the reader will see, if with kind patience he will follow our story, had been made by the one, that is, Henry, at least a year earlier, namely, in August, 1830, while it was not fully accomplished by the other until some thirteen months later, namely, the 24th of September, 1831; for this we shall find to be the date at which Faraday first fully recognized the phenomenon, and the principle by which it is controlled.

To understand properly the work of these two men, in reference to the discovery of magneto-electricity, it is necessary to know something of the circumstances in which they were placed. When Sir Humphry Davy was asked, which he considered his greatest discovery, he answered, "Michael Faraday." Entering the Royal Institution in an humble capacity in 1813, the flower of his genius growing and expanding under the fostering care of Sir Humphry, Faraday had attained a high position, and an enviable scientific reputation, in the great London institution. Director of the laboratory, he was surrounded by every possible facility for the prosecution of his investigations; and what was perhaps even more important, had unlimited time at his command in London, the great centre of scientific light. He was now forty years of age. Henry was nine years younger. When Faraday first entered the Royal Institution as an assistant, Henry was but thirteen. Counting the years of his age with those of the century, he had entered upon a course of original investigation as early as 1827, but amid such arduous duties as an instructor in the Albany Academy, that of all the twelve sisters of the year, he could only claim the month of August, the vacation time of the institution, as really his own. During four years he had been able to secure hardly more than as many months for regular scientific research. Could we look into his laboratory at this time, we would find, instead of the well-filled cabinets of the Royal Institution, only a few rude instruments made at great expense of time and labor by his own hands. Even the material for these rude tools was often difficult to obtain. Experiments, for instance sometimes stopped merely for the want of a scrap of zinc. We say "could we look into his laboratory," but we would seek in vain for a room which could properly be so called. Each series of experiments was necessarily carried on in the large hall of the Academy, which was available for Henry's use at no other time than during the summer vacation. Invariably all investigations came to a stop with the first of September, the beginning of the autumn session of the Academy, and were rarely resumed

Faraday's Laboratory in the Royal Institution.

---

[1] A verbatim copy of Professor Oersted's original communication, in Latin, and a translation of the same may be found in *Journal of the Soc. of Tel. Engrs.*, v, 459, 464; together with a biographical sketch of Oersted by C. L. Madsden. [Editor.

[2] Schweigger's first galvanometer was a very simple affair, consisting of a small compass box, around which was coiled several turns of copper wire in a direction parallel to the meridian line of the dial. See *Schweigger's Journal für Chemie and Physik*, xxxi, 1–17. [Editor.

[3] Arago's experiments were published in *Annales de Chemie et de Physique*, xv, 93. Immediately afterwards, but before any account of Arago's experiments had reached him, Davy had also magnetized needles by the voltaic current, and by discharges of frictional electricity. He had also discovered the attractive effect of the conductor upon iron filings. His letter to Wollaston, recounting these experiments, is in *Philosophical Transactions*, 1821. It bears date Nov. 12, 1820. [Editor.

[4] *Transactions Society of Arts*, 1825, xliii, 38-52. The accompanying illustration is a fac-simile of that annexed to Sturgeon's paper.

until the month of August came again.[5] The invaluable stimulus of scientific intercourse and appreciation too, was wanting. Very different was the dull commercial town of Albany, from London, the intellectual metropolis of the world. A wide expanse of waters, not yet crossed by the swift ocean steamer, lay between Henry and all the culture of the old world, and in provincial America, little could be found to make good its place. Moreover, it must not be forgotten that Henry was the first who had undertaken a series of electrial experiments in America since the time of the immortal philosopher who first drew lightning from the clouds; "the mantle of Franklin"—said Sir David Brewster—"has fallen upon his young shoulders." Excepting Dr. Hare of Philadelphia, who was making notable improvements in galvanic apparatus, almost alone in the electric field, he stood to face the army of the old world.

Recalling the wide difference in condition surrounding the two, it is of no small interest now to see to what eminence each had at this time attained, the one during his eighteen years of culture and unimpeded work; the other in his few months of intermittent study, snatched at long intervals from the crowded days of four years of arduous professional labor. Constantly pursuing similar investigations, making many identical discoveries, Faraday and Henry seem like two competitors in a closely contested race, upon whose course we have suddenly come in these August days of 1831, and with curious eyes we scan the field to see how they are running. Bence Jones says:

> "If Faraday's life had ended at this time, when he finished his higher education, it might have well been called a noble success, but when we turn to the eight volumes of manuscripts of his *Experimental Researches* which he bequeathed to the Institution, we find that *his great work was just going to begin*."[6]

Henry had begun his course with a series of original discoveries which might well weigh in the balance with anything Faraday had as yet accomplished, while in the particular field in which lay the "*great work*" of Faraday, which he was now "*just going to begin*" he had not only entered, but was already far ahead. The mysterious phenomena of the induction of electric currents, the reciprocal production of the magnetic and electric forces, were to him already old stories, intimately familiar, singularly well comprehended by him at this early date. He is in truth but amplifying the results which Faraday has just begun to seek, in these waning days of the summer of 1831. The younger man, as it were, had struck almost immediately into this particular path, and is now almost lost to sight in it, while the elder has only just come to the spot where his entering footsteps began.

Let us dwell for a moment upon the importance of the answer to the great question we have been considering, the value to the world of the discovery made by these two men.

It is not too much to say that it constitutes a veritable epoch in electrical science; upon it depend many of the most important applications of electricity to the uses of man, and new applications are developing day by day. Tyndall, the successor of Faraday in the Royal Institution, does not attempt to restrain his enthusiasm in the contemplation of it:

> "I cannot help thinking" (he says) "when I dwell upon it that this discovery of magneto-electricity is the greatest experimental result ever obtained. It is the Mont Blanc of Faraday's own achievements. He always worked at great elevations, but higher than this he never attained."[7]

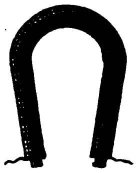
Edward N. Dickerson, the eminent advocate, said of Henry:

> "The towering heights that were scaled by the daring spirit of Faraday from the East, were at the same time surmounted from the West by our own countryman; both were climbing from opposite sides at the same time, and neither was conscious of the other's efforts till both stood face to face upon the summit."[8]

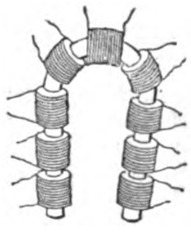
But the standard of the West had been floating many months upon these towering heights before the standard of the East was planted. It was Henry's foot, not Faraday's, which first touched the untrodden peak.

It was curious, that with such a host of the most brilliant minds of Europe at work upon the problem, the discovery which solved it was so long delayed. But there was a fact, which, it would seem almost with malicious or mischievous intent, successfully eluded all research. This fact was the necessary condition of *motion or change* for the production of the effect, and consequently the transitory nature of the phenomenon. If a magnet is thrust into the opening of a hollow helix of wire, electricity is manifested in the wire, but only for a brief instant, when the magnet is inserted and when it is withdrawn.

There is a fairy tale of a farmer's wife, whose heavy labors were lightened by a friendly gnome, who was never seen because he could never be caught at the moment he was at work. In all these years magnetism had been producing electricity under the very hands of these wise philosophers, but had never been detected in the act. *It was not caught at the moment it was at work.*



HENRY'S INTENSITY MAGNET.



HENRY'S QUANTITY MAGNET.

Let us see in what way Faraday and Henry, these two favored children of nature, ask of her the all-important question, so as to win at last a reply. Courtesy to the elder man and to the inhabitant of another country, would seem to suggest that we first go over the sea to Faraday; but this may not be, for we must look among Henry's own instruments for the stepping-stone to the great discovery, made by Henry's own hands to be a stepping-stone not only for himself but for Faraday.

Young Henry had before this time, as one of his friends has said, "made the lightning his familiar, his demon, his servitor; had lured it into his lecture-room from out of its cloud home in the thunder-storm, and tamed it so that he could bridle it, mount, ride it and spur it at will."[9]

He had taken the soft iron horseshoe of Sturgeon, with its spiral of loose uninsulated wire, an infant lifting but a few pounds at an inordinate expense of battery power, and had transformed it into a giant capable of sustaining fifty times its own weight, under the stimulus of a battery of a single pair of plates of copper and zinc, scarce a hand's breadth in area. He had made two magnets; his "intensity" magnet with a long single wire, and his "quantity" magnet with many short wires; the latter the stronger in actual physical force, but the former endowed with the subtle capacity which enabled it to respond to the electric influence at long distances; the magnet, in fact, which made the electric telegraph a commercial possibility instead of a philosopher's plaything. He had discovered and made plain the law governing the relation between the electric flow and the electric resistances in battery and magnet, and by this discovery had married, as it were, his magnets to their respective batteries; the "intensity" magnet of a long single wire to the "intensity" battery of many pairs of plates; the "quantity" magnet of many short wires to the "quantity" battery of a single large pair of plates; and had sent forth these children of his brain, through the pages of *Silliman's Journal*, to take their places as willing servitors in all the physical laboratories of the world; all this in the early days of this very year, in January, 1831.[10]

---

[5] The Albany Academy, in which Joseph Henry occupied the chair of Mathematics and Natural Philosophy from 1826 to 1832, is an institution which for three quarters of a century has been held in deservedly high esteem, not alone in the community in which it is situated, but throughout the United States. Among the oldest foundations of its kind in the country, "its venerable walls seem imbued with that subtle spirit of the past, that favors study, and that nothing but time can give." The Academy building, beautifully situated on the public square near the head of State street at the right of the Capitol, is a dignified and admirable architectural example of the classical or "colonial" type. In the words of the late Dr. Meads in his oration at the semi-centennial anniversary of the Acadamy in 1863:—"Time has not rendered it in any degree unfitted for its purposes, nor unworthy of its position among the public buildings of Albany. It seems to have had a power to charm down and repress even the proverbial destructiveness of youth, and it stands to-day, after the lapse of half a century, unmarred by any spoiling hand, in all its original freshness and beauty."

The room in which Henry prosecuted his memorable experiments in electricity and magnetism, during the vacations of the Academy, has remained almost unchanged since his day. It is a lofty, well lighted and spacious hall of admirable proportions, and chaste and classical decoration, and is in no respect unworthy of the interesting associations that cluster about its venerable walls. [9] S. S. Cox, Memorial Speech in the House of Representatives Jan. 16, 1879.

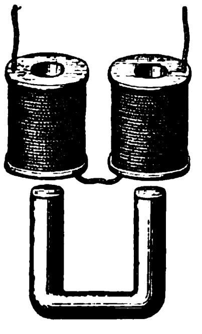
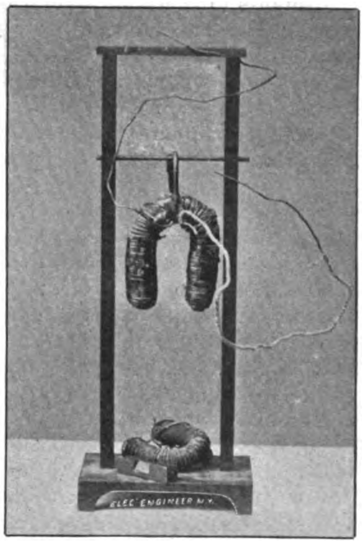
Prof. William B. Taylor says:

> "The importance of this discovery can hardly be over-estimated. The magnetic 'spool' of fine wire, of a length—tens and even hundreds of times as great as that ever before employed for this purpose was in itself a gift to science which really forms an epoch in the history of electro-magnetism. It is not too much to say that almost every advancement which has been made in the fruitful branch of physics since the time of Sturgeon's happy improvement; from the earliest researches of Faraday downward has been directly indebted to Henry's magnets. By means of the Henry 'spool' the magnet almost at a bound was developed from a feeble childhood to a vigorous manhood. And so rapidly and generally was the new form introduced abroad among experimenters, few of whom had ever seen the papers of Henry, that probably very few indeed have been aware to whom they were really indebted for this familiar and powerful instrumentality. But the historic fact remains that prior to Henry's experiments, in 1829, no one on either hemisphere had ever thought of winding the limbs of an electromagnet on the principle of the 'bobbin,' and not till after the publication of Henry's method in January, 1831, was it ever employed by any European physicist."



THE PRINCIPLES OF THE SPOOL OR BOBBIN, AS APPLIED BY HENRY TO THE ELECTRO-MAGNET.

> "But in addition to this large gift to science, Henry has the pre-eminent claim to popular gratitude of having practically worked out the differing functions of two entirely different kinds of electromagnet; the one surrounded with numerous coils of no great length, designated by him the 'quantity,' the other surrounded with a continuous coil of very great length designated by him the 'intensity' magnet. The latter and feebler system (requiring for its action a battery of numerous elements) was shown to have the singular capability, never before suspected or imagined, of subtle excitation from a distant source. *Here for the first time is experimentally established the important principle that there must be a proportion between the aggregate internal resistance of the battery and the whole external resistance of the conjunctive wire or conducting circuit.* This was a very important, though unconscious, experimental confirmation of the mathematical theory of Ohm, embodied in his formula expressing the relation between electric flow and electric resistance, which, although propounded two or three years previously, failed for a long time to attract any attention from the scientific world."
>
> "Never should it be forgotten that he who exalted the 'quantity' magnet of Sturgeon from a power of twenty pounds to a power of twenty hundred pounds, *was the absolute* CREATOR of *the 'intensity' magnet; and that the principles involved in this creation constitute the indispensable basis of every form of magnetic telegraph since invented.*"[12]



INTENSITY MAGNET MADE BY HENRY IN 1829; NOW IN THE CABINET OF THE COLLEGE OF NEW JERSEY.

It detracts nothing from Henry's independent and original discovery of the law of relation between the "electric flow" and the "electric resistance," that Ohm, in far-distant Munich, had a theoretical dream of such a law, which, with a sagacity little short of marvellous, he reduced to a concrete mathematical formula. Consider for a moment the distinction between the man who propounds a theory and the man who makes a veritable discovery; for precisely in these two attitudes stand Ohm and Henry in relation to this fundamental electric law. A theory may, it is true, be of inestimable value; but however ingenious, however founded upon intimate knowledge of the subject, it at the most can only suggest *what may be;* can only point out an intelligent mode of asking Nature a question. The theory may, or may not, prove to be true. A discovery, on the contrary, tells us *what is;* it tells us that a certain fact or a certain relation in nature actually exists. Of the theory of Ohm, now at the tongue's end of every schoolboy, but for a long time ridiculed, or at least unnoticed by the scientific world, Henry, in far-distant America, knew absolutely nothing. Five years later, in a letter written from Princeton, dated December 17, 1833, we find him asking Dr. Bache: "Can you give me any information about the theory of Ohm? Where is it to be found?" In another letter of about the same period: "Who is Ohm? What is his theory?" It was not until 1836, during his visit to London, that he sees at last Ohm's theory, and finds that, after all, it is in substance nothing more nor less than his own discovery, interpreted in the language of mathematical prophecy.

ASBESTOS PORCELAIN.

IN a recent communication to the Académie des Sciences, M. F. Garros called attention to a new form of porcelain brought out by him. He takes asbestos fibre and reduces it to a fine powder. If pure, it exhibits an exceedingly white apparence, but if traces of iron oxide are present there is a slightly yellow tint. In the latter case the oxide is removed by sulphuric or hydrochloric acid. The powder is then made into a paste, moulded into shape, dried slowly, and baked (1200° C.) from 17 to 18 hours. If placed in a very high-temperature furnace, a remarkably transparent species of porcelain is obtained. This "asbestos porcelain" has already been used for filtration and sterilization purposes, experiments showing that it is a more rapid and effective filterer than ordinary porcelain, and that the pores are less liable to become clogged up.

[10] Silliman's *Amer. Jour. Science*, Jan. 1831, xix, 404-5.

[11] "It is evident"—says Mr. Fahie—"that it was not until after the interview with Henry [on April 11, 1837] that Wheatstone recognized the applicability of Ohm's laws to telegraphic circuits, the study of which would likewise have enabled him to ascertain the best proportions between the length, thickness, etc., of the coils, as compared with the other resistances in the circuit, and to determine the number and size of the elements of the battery necessary to produce the maximum effect." [*History of Electric Telegraphy*, p. 515.] Yet Wheatstone—characteristically, it must be said—has not hesitated to claim Henry's discovery for himself. In a statement written by him in 1841, to be presented to the arbitrators in a disagreement which had arisen between himself and Mr. Fothergill Cooke, he says:—"These methods of completing the secondary circuits have lost nearly all their importance, and are scarcely worth contending about, *since my discovery, that electromagnets may be so constructed as to produce the required effects by means of the direct current even in very long circuits.* [*The Electric Telegraph; Was it Invented by Professor Wheatstone*, ii, 96.] In a subsequent portion of the same document he nevertheless says of himself:—"Wherever I have borrowed an idea from Ohm, Gauss, Steinheil, or any other person, I have, and shall always be ready to acknowledge it." Yet Henry's paper in *Silliman's Journal*, had then been published for some years, and Henry himself had explained to Wheatstone in King's College, on April 11, 1837, the construction and use of his "intensity" magnet. In later years, however, Wheatstone became somewhat more guarded in his assertions, for we find him writing to Cooke in 1856, in reference to the same matter:—"With this law and its applications, no persons *in England* who had before, occupied themselves with experiments relating to electric telegraphs, had been acquainted." The words which we have italicized are significant, and are only capable of construction as an acknowledgment—though not a particularly graceful one—of the priority of Henry. [EDITOR.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—I.

BY

Francis B. Crocker and S. S. Wheeler.

INTRODUCTION.

THE purpose of these articles is to set forth the more important facts which present themselves in the actual handling of dynamo-electric machines and electric motors, as a guide for those who use or study these machines. The authors do not claim for this treatment of the subject that it is anything more than a set of directions in which the various points are arranged under headings for convenience of reference.

The subjects considered are: Chapter I, General Principles of Dynamos and Motors; Chapter II, Directions for Selecting; Chapter III, Installing; Chapter IV, Starting; Chapter V, Running; Chapter VI, Stopping; and Chapter VII, Testing Dynamos and Motors; also Chapter VIII, Directions for Locating and Remedying Troubles in these machines.[1]

Heretofore writers on the dynamo or motor have usually treated these machines entirely distinctly, and books or papers on the dynamo usually contain nothing about the motor, or merely consider it briefly in a few special chapters, and books on the motor only refer to the dynamo incidentally. The authors have found that there is no necessity for this separation; in fact, nine out of ten statements which apply to the dynamo are equally applicable to the motor, and if the word machine is used instead of dynamo, the statement covers both and becomes doubly important and useful. Occasionally, of course, it is necessary to distinguish between the two machines, but, as a matter of fact, the difference in treatment required for dynamos and motors is often less than for different kinds of dynamos; for example, a shunt dynamo and series dynamo differ from one another much more than do a shunt dynamo and shunt motor.

CHAP. I.

GENERAL PRINCIPLES OF DYNAMOS AND MOTORS.

Definitions.—*A dynamo-electric machine is a machine for converting mechanical energy into electrical energy;* in other words, *it generates electric current when driven by mechanical power.* The term dynamo-electric machine is so long that it is usually and unavoidably shortened into "dynamo," which has exactly the same meaning. The name "electric generator" or simply "generator" is often applied to the dynamo, especially when used to produce current for electric railway or other motors, but this distinction is merely for convenience. An alternating-current dynamo is commonly called an "alternator."

An electric motor is a machine for converting electrical energy into mechanical energy; in other words, *it produces mechanical power when supplied with an electric current.* An electric motor is usually called simply a motor, and although motor might mean anything producing motion, it is very rarely used in any other sense and is perfectly definite in connection with electrical matters.

Principles of Action.—The dynamo is based upon the discovery made by Faraday in 1831, that an electric current is generated in a conductor by moving it in a magnetic field. The electric motor works on the principle that a conductor carrying a current in a magnetic field tends to move. Thus it will be seen from the above statements that the dynamo and motor are exactly the reverse of each other in their action.

Similarity of Dynamos and Motors.—The two machines are, however, very similar in their construction. In fact, the same machine can be used for either purpose equally well. In practice there are sometimes slight differences between dynamos and motors, as will be explained further on, but these are not very important. Hence, as already stated in the introduction, the two machines will be treated as one, except where some distinction is specially stated.

General Form.—We have seen that both the dynamo and motor depend for their action upon the movement of conductors in magnetic fields. Now it has been found as a result of scientific experiment and practical experience during the 60 years since Faraday's discovery, that the best way to carry out this principle is to arrange the conductors in suitable form and rotate them between the poles of a magnet, or magnets. This rotating part is called the *armature* and the magnet is called the *field magnet.* In alternating-current dynamos this plan is sometimes reversed, the field magnets being made to rotate and the armature being fixed.

Armature.—This usually consists of an *armature core* of iron on which are wound or attached the conductors which carry the current. This core should be split up or *laminated*, that is, made of discs, tape or wire, of iron separated by paper, varnish or rust, instead of one solid piece; otherwise it will have useless currents generated in it which would waste the power of the machine. This core is almost always made either in the form of a *drum* or a *ring* and hence we have these as the two principal types of armature.

Field Magnet.—This consists of one or more iron *cores* on which are wound the field *coils.* Attached to the field cores are the *pole-pieces* which form the magnetic field or space in which the armature revolves.

CHAP. II.

DIRECTIONS FOR SELECTING DYNAMOS AND MOTORS.

The choice of a dynamo or motor will, of course, depend largely upon the circumstances in each particular instance. There are, however, certain general facts which apply to almost all cases.

Construction.—This should be of the most solid character and first-class in every respect, including material and workmanship, both of which should be of the best possible quality. All the parts should be of adequate size and strength to ensure durability.

Finish.—What is called a fine finish on a machine is also very desirable, first, because it indicates good construction, and its absence indicates poor construction (there is no essential reason for this, but it seems to be a fact in most cases), and second, it usually causes a machine to receive much better treatment.

Simplicity.—The machine and all its parts should be as simple as possible, and any very peculiar or complicated part or attachment should be avoided. These are sometimes successful but should be well tried and proved before accepting.

Attention.—The amount of attention required by the machine should be small; for example, the brushes should be capable of being easily and securely adjusted, and the oiling devices should be effective and reliable, self-oiling bearings being very desirable. The screws, connections and other small parts should be arranged so that they are not liable to become loose, and the delicate parts should not be particularly exposed or liable to injury. The machine should be made so as to be easily and thoroughly cleaned.

---

[1] This chapter has already been published in the Sept., Oct. and Nov., 1891, issues of THE ELECTRICAL ENGINEER, under the title of "The Localization and Remedy of Troubles in Dynamos or Motors."

Handling.—The machine should be provided with rings or other means by which it can be easily lifted or moved without injury. It should be possible to take out the armature conveniently by removing one of the bearings.

Regulation.—Some form of regulator should be provided by which the E. M. F. or current of a dynamo or the speed of a motor can be reliably and accurately governed.

Armature.—This should turn very freely in the bearings, and should be perfectly balanced so as not to have any appreciable jar or vibration at full speed. There should be a uniform clearance of at least $\frac{1}{16}$ inch all around between the armature and pole-pieces. The armature should be capable of moving lengthwise in the bearings at least $\frac{1}{8}$ inch. It is not usually desirable to have the speed of an armature at its circumference more than 3,000 feet per minute. The ring-form of armature is especially suited to high voltage since the coils differing most in potential are at the greatest distance apart. A section of a ring armature can also be more easily rewound than in the case of a drum armature.

Capacity.—This should be ample in all cases. It is a very common mistake to underestimate the work required of a given machine, and, even if the machine has sufficient power at first, the demands upon it are apt to increase and finally overload it. No one is ever likely to regret choosing a dynamo or motor with a considerable margin of capacity, since these machines only consume power in proportion to the work they are doing. For example, a 30 h. p. machine would probably run with a 20 h. p. load more economically and satisfactorily than a 20 h. p. machine with the same load.

Form.—The machine should be symmetrical, well proportioned, compact and solid in form. If it is either very tall or very flat it is usually inconvenient and clumsy. No part of the machine should project excessively, or be awkwardly formed or arranged. The large and heavy portions of the machine should be placed as low as possible to give great stability. For the same reason the shaft should not be high above the base, nor should it be so low that there is not ample room for the pulley or other attachment. A horizontal belt, for example, will sag and strike the floor if the pulley is very low.

Weight.—The common idea that it is desirable to have a very light dynamo or motor is a mistake when it is for stationary use. There is no advantage in a light machine for stationary work, and it has the disadvantages of being less strong, less durable and less steady in running. A sufficient weight to make the machine thoroughly substantial is obviously a great benefit.

Cost.—It is also a mistake to select a cheap machine, since both the materials and workmanship required in a high quality dynamo or motor cost more than in almost any other machine of the same size and weight.

(*To be continued.*)

ONE WAY OF SAVING POWER ON ELECTRIC RAILWAYS.

BY LUCIUS ELLIOT MARPLE.

It is a well-known fact that much of the power generated at the central station of an electric railway is lost in overcoming the resistance offered by poor rail connections. Not only this; but there is consequently a much greater wear and tear on the machinery, and an undue heating of the motors because of the unsteady current resulting. As these are prominent features, it is of no small importance to the railway superintendent that there should always be the best possible connections between the car wheels and the rails.

The following instance, in which the writer was recently called in court to testify, shows that this may be the cause of annoyance in more ways than one:

A car happened to be stalled by dust on the track for a moment, when a "green" horse passing by took fright at it and stumbled, striking his head on the step of the car. It was claimed before the magistrate, and allowed, that a current of electricity from the car had, in some way, caused the animal's death. This decision was appealed from, and happily reversed in a higher court.

Several railways, have, however, overcome this trouble and effected quite a saving by applying water to the tracks in the proper manner.

The simplest and most effective way seems to consist in employing specially made carts, with wheels just fitting between the tracks. On each pair of wheels a large tank is placed six feet or more above the ground. By means of pipes, this delivers a stream of salty water with considerable force directly over either track.

By making several trips daily over each route, the tracks can be kept thoroughly clean and moist. Where this has been tried it has been proved that a very considerable amount of power may be thus saved.

To show the effect of a clean track, the instance may be cited of Nashville, Tenn., where the surface consists very largely of limestone rock. The writer has several times made careful note of the station output before and during a sudden heavy shower.

A reduction of from 900 to 600 amperes, or more than 30 per cent., was actually observed.

Probably the greatest effect will be felt in towns where the streets are unpaved and the travel is heavy enough to keep the rails continually covered with dirt.

THE EXPERIENCE OF CITIES WITH THE TROLLEY SYSTEM.

BY

S. W. Balch

The citizens of Yonkers have recently been discussing at much length the advisability of permitting the trolley system in their city, and the city council have finally decided to permit its use with certain restrictions. In connection with this discussion, one of the enterprising papers of the city, the Yonkers *Daily Herald*, addressed a number of inquiries concerning the trolley to the mayors of 108 cities in which it was understood to be in operation. Replies have thus far been received from 66 cities and towns. Sixty-two show a practical experience with the system and are, therefore, noted in the answers below.

The first question put to the mayors was as follows: "Do you consider that the trolley system has been operated successfully in your city?" All but five answer this in the affirmative. Three report that it is fairly successful, and two say that it has not succeeded.

The second inquires if the fault is believed to be in the system or in the management. From Toledo, O., where the Thomson-Houston and Westinghouse systems are used the answer considers the fault about equally divided. Zanesville, O., reports that good management is everything. Ottawa, Ill., reports that the management is a little lame. Akron, O., and South Bend, Ind., say that the electric cars are not a success on account of the management.

The mayor of Rockford, Ill., considers all overhead wire business bad and hopes that Edison will make a success of his two-track idea. He also remarks that the system is good when well carried out with double motor cars, revolving snow-brushes and heavy rails, and lays the faults to cheap equipment. Camden, N. J., reported that their system was not successful at first because the power generators were not suitable.

The third question inquired whether the system had benefited the business interests of the city. This question is answered affirmatively, and in many instances with emphasis, by all except South Bend, Ind., in which the answer to the question is omitted, and Buffalo, N. Y., where the use has not been sufficient to warrant an opinion. The mayor of Wilmington, Del., reports that the electric cars have infused new life into the people, and that a horse is too good an animal to put to a street car. The city electrician at Springfield, Ill., reports that there is a car every 15 minutes for those who live five miles from the centre of the city and that the great beauty is that the cars are on time.

The fourth question asks, Which system is used? As many cities use more than one system, or combinations of two or more systems it will, therefore, be seen why the numbers here given will sum up more than the number of replies which have been sent in. In 12 replies no answer, or an indefinite answer, is given to the question. From the others it appears that they are in use in, and endorsed as good by, the following places:—

	Used by	Approved by
Thomson-Houston	31	24
Sprague-Edison	24	17
Westinghouse	5	4
Short	3	2
Van Depoele	1	1
Detroit Electrical Works	1	1
Daft	2	0

The fifth question asked the mayors if they consider their system the best. Their replies are incorporated in the above table, but as each appears to be contented with the system which he happens to have, his opinion does not appear to be much of an indication as to which one is the best. In several instances where two systems are used both are endorsed without preference. The mayors of Milwaukee, Quincy, Mass., and Reading, Pa., make no choice between the Thomson-Houston and the Sprague. On the other hand the mayor of Marlboro, Mass., has the latter but prefers the former. The Thomson-Houston system is also especially endorsed by the mayor of Peoria, Ill., and the city electrician of Springfield, Ill. The Sprague and Edison systems are endorsed by the mayor of Canton, O., and the Sprague and Westinghouse systems by the mayor of Wilmington, Del. The mayor of Lancaster, Pa., prefers the Edison to the Daft system.

The sixth question inquired if any persons had been killed by the electric current from the trolley line, and the seventh, how many. These are answered in the negative in every reply but one. This one is from Louisville, Ky., and reports five or six killed by carelessness of passengers. It is not thought from the answer that they were killed by the current. In Canton, O., a little girl was run over. Toledo, O., mentions two injuries. The mayor of Lynn, Mass., mentions accidents to carriages being run into, and Zanesville, O., reports the killing of several dogs. A number report no accident of any kind.

The eighth question asked if accidents from the current were very likely to happen. This was answered unqualifiedly in the negative in 40 of the replies, and no affirmative answer was received. The city electrician of Springfield, Ill., says: "On three occasions I have seen the entire current (480 to 510 volts) pass through a man. Of course he was burned but was at work again in 48 hours. Such cases as these are due wholly to the carelessness of the men while repairing hooks." Streator, Ill., reports that the current has been taken without injury. Johnstown, Pa., answers, "No, the current is not over 500 volts." And Camden, N. J., replies that the voltage is 220 and that fatal accidents are not looked for. The mayor of Milwaukee thinks an accident is possible upon contact with a live wire.

The mayors of several cities referred to their experts for the information sought. Saginaw, Mich., referred to W. J. Hart; Salem, O., to W. H. Wheldey, and Springfield, Ill., answered through Edgar L. Gross, city electrician.

The mayor of Aurora, Ill., sent a very interesting reply, of which the following is an abstract: "We have an elaborate and costly system of street railway propelled by the trolley system, and it operates successfully save when a snowstorm shuts it off short. Nobody has been killed by the electric current, but we have had some narrow escapes from death. Telephone wires are liable to break, and if they fall across the trolley wire it will kindle a fire in the office or residence, a mile away perhaps. One of the trolley wires fell recently in this city and knocked a horse down. If you are about to insert the trolley system, I suggest that you require the company to light the streets which it occupies without charge, placing a lamp on every second or third pole. The city of Providence, R. I., has been considering the granting of a franchise to a street railway company, and I recommend that you send to the Hon. H. Howard of that city for a copy of the pamphlet publication No. 8, of the Advance Club of Providence. It contains the contract which the city of Toronto has with its street railway company, which has many safeguards. The rate of speed should be regulated from time to time by the city authorities, and the company should be held to a rigid accountability for the condition of the street and road-bed which it occupies. A city should prepare its own ordinance granting the franchise, for if prepared by the company they will get the best of you and gain many little advantages by cunningly devised phrases which will hardly be apparent upon casual reading."

The mayor of Allentown, Pa., says that he considers the T rail better than the flange rail in every particular if wagon gauge is not required.

THE LAW OF MOTOR EFFICIENCY.

BY

C. O. Mailloux.

In the issue of The Electrical Engineer of December 16, Mr. H. Ward Leonard attempts to set aside my objections to his so-called law of motor efficiency. I will encroach upon your valuable space once again, not so much for the purpose of further argument with Mr. Leonard, as of straightening out certain questions of fact on which he does not appear to be as well informed as he might be. Mr. Leonard's statements, in fact, tend to strengthen the impression that he has neglected not only the theory but even the history of the "art to which his invention appertains."

It was in 1882 that Marcel Deprez first accomplished what Mr. Leonard now claims as his discovery or invention. He described his method in *La Lumière Electrique* (Oct. 3, 1885, pp. 6, 7). His experimentss have been freely quoted, among others, by Kapp, (Elect. Transm. 3d Ed., p. 89); and also repeated by others, (Thompson Dyn. Elec. Mach., 3d Ed., p. 539).

M. Deprez took a motor which was loaded artificially so as to give a constant moment of resistance, and consequently requiring a constant torque to make it turn. He applied to this motor a source of E. M. F. which he caused to vary from zero up to an extreme limit. He found that for any given load the current increased until it was sufficient to produce the torque needed to start the motor. Any further increase of the E. M. F. caused the speed (and therefore the counter E. M. F. of the motor) to increase so as to prevent the current from rising above the value at which the motor began to turn. He laid down and proved the law that for any load (torque) a certain current is required, and that this current will *automatically* be maintained constant, or very nearly so, at any and all speeds, it being independent of the speed. He also showed that the speed was controlled and governed for a given load, entirely by varying the E. M. F. of the source of supply.

In the original experiment the E. M. F. was regulated partly by varying the speed of the dynamo, and partly by a variable resistance in the circuit. He described later (Oct. 17, '85) a method of varying the E. M. F. of a generator (or motor) run at constant speed, by varying its magnetic field, which is the method of E. M. F. regulation found in Mr. Leonard's method.

Even the plan of separately exciting the motor was first made known and used by Deprez. It requires no extended comparison to see that M. Deprez's method accomplished all that Mr. Leonard's does and by exactly the same means, namely, by varying the E. M. F. of the source of supply. The only difference exists in the details and in the *theory*. Although Mr. Leonard effects his regulation solely by varying the E. M. F. of the source of supply just as M. Deprez did, yet he claims to have some control on the amperes, while M. Deprez made no such claim, but on the contrary recognized and admitted the fact that the amperes do and will control and take care of themselves automatically. The fact that the efficiency is more nearly constant when the E. M. F. is varied with the speed of a motor run at constant torque, has also not escaped attention. The table of tests of a ½ h. p. Immisch motor, quoted by Thompson, (Dynam. Elec. Mach., 3d Ed., p. 562) gives a sufficiently clear indication of it. Every one who has had experience with storage battery cars wherein the speed regulation is effected by grouping or varying the cells, has doubtless observed the fact. The present writer has many records of brake tests made in 1887, and subsequently, which show this very clearly.

In a later portion of his discussion in the same journal, M. Deprez gives (Oct. 24, '85, p. 158) an equation of efficiency which is an extension of that which I gave in my previous article, and which Mr. Leonard may find of interest.

According to M. Deprez, the efficiency depends on three things *only:* 1. The speed of the motor, *i. e.*, the counter E. M. F. 2. The ratio of the total circuit resistance to the motor resistance. 3. The ratio of the watts spent in heating the motor to the torque obtained by the current—which is what he calls the "cost of the torque."

These statements can be made to embrace almost any case of electric power transmission. The conditions and the rule which I gave for obtaining maximum efficiency are in harmony with M. Deprez's views.

So much for the facts as to the novelty of the method or the accuracy of the "law." Let us now see what are the facts in relation to the question of torque in the street car motors commonly used, *i. e.*, in plain series motors.

I quote:—"Mr. Mailloux is, I think, in error in stating that in the street car motors commonly in use the amperes vary as the torque. Such a condition could only be realized in a constant field and with the series field commonly in use, as a constant field is not realized under varying torques, although the commutation of the field is, of course, an endeavor to approximate to it."

The fact is that the amperes vary as the torque in all forms of motors, though not in the same way. In a shunt motor the curve of torque is nearly a straight line; in a series motor it is convex toward the axis of amperes, for the lower values. In both cases, for higher current values the line is either straight or slightly concave to the axis of amperes. The physical or mathematical reasons do not interest us now.

It is sufficient to know that the amperes do vary as the torque in series motors. For medium and high current values the series motor has the great advantage that it requires less amperes per unit of torque than does the shunt motor, and is not so likely to spark, because its load is constant, while that of the shunt motor will change with the current.

I do not regard a constant field as a condition *sine qua non* for accomplishing what Mr. Leonard's method does. A series motor used in place of his separately excited motor would operate quite as satisfactorily in most cases, and more so, in many cases. Mr. Leonard ininsists that when he groups the six motors in different ways, he varies the volts as the speed desired. Until his explanation is made intelligible however, or a more logical one substituted therefor, I must adhere to my previous opinion.

Mr. Leonard has also permitted himself to make the absurd statement that "there is no question that the current *will* be constant for all groupings, neglecting, of course, the slight effect of the losses in heat, etc." No question admits of more easy demonstration. In the abstract, one might ask, if the current is the same for all groupings, then since the direct E. M. F. is also constant, the electrical energy abstracted from the circuit, is constant. Where then would the energy come from which causes the increase of speed? In point of fact it must and does come from increase of current. Let us take a concrete case by assuming that each car requires for keeping it in motion on a given grade that the motors should each develop 200 pound-feet of torque or 1,200 pound-feet for the three cars constituting the train. This torque will, it is evident, be the same, at all speeds usually employed. Hence, each motor must furnish the same torque, no matter at what speed it runs, so long as the load and the grade remain the same. Starting with the six motors in series, a given current, say, 15 amperes is required to produce in each motor the desired torque of 200 pound-feet.

Let us now connect the six motors in two multiple series of three. Each series will again take 15 amperes to give the same torque. The line current will therefore be 30 amperes. If we connect the motors in three multiple series of two, the line current will be 45 amperes; with all the motors in parallel the current will be 90 amperes. The electrical energy supplied to the train, and, in consequence, the speed, will of course increase at each change in grouping. The change of speed will, in most series railway motors, cause a further complication from the fact that the same current will not maintain quite the same useful torque at all speeds, partly owing to changes in the coefficient of friction, and partly to armature reactions. For a given torque the current must be increased slightly as the speed increases. Mr. Leonard's emphatic statement is therefore without foundation. He has apparently confounded this case with one in which the motors remain always connected the same way.

Lastly Mr. Leonard's explanation of my abhorrence of commutators also falls to the ground, in view of the fact that in the method proposed by me the sparking was entirely obviated. There was also no rheostat. The voltage of the dynamo side of the converter was not expected to exceed at any time 25 volts for the function it was to perform. Its output would not exceed 2,000 watts at any time.

As for the question of weight, if Mr. Leonard can really make with 500 pounds of material a motor dynamo, having two distinct fields, of the watt capacity stated in his article, and running at reasonable speeds, and fair efficiency, he has done something that will produce a far greater and more lasting impression than his so-called "law" of efficiency.

RATHITE.

RATHITE is a new insulating compound, composed of vulcanized india-rubber and silk fibre. The idea is to apply this form of insulation in all cases where solidity rather than flexibility is wanted. The compound is due to MM. Waddington, Rath et Cie.

AN ELECTRICIAN'S APPEAL TO PORCELAIN MANUFACTURERS.

The subjoined appeal to porcelain manufacturers is from Mr. Francis W. Jones, the well-known electrical engineer and inventor, and now electrician of the Postal Telegraph-Cable Co., of this city. What Mr. Jones says on the matter of insulators is not only important but true, and it does seem to us that American porcelain manufacturers should have no difficulty in meeting the demand. It should certainly be worth their while, as the insulators used by the Western Union and Postal companies alone must run up into millions, with a steady consumption every year:

To the Porcelain Manufacturers of America:

Up to the present time in this country, glass has been chiefly used for the insulation of telegraph lines. In Europe, however, porcelain is the prevailing material and presents three or four times more resistance to the leakage of current than glass. The great cost of importation under a high tariff, coupled with a lack of knowledge of the advantages gained in Europe by the use of porcelain, are undoubtedly the reasons why glass has been so long adhered to in America, notwithstanding that great loss of business occurs during rains and fogs by the electricity leaking down the poles, rendering the wires inoperative. The insulating properties of porcelain depend on its quality. It requires a good smooth surface, must be perfectly vitrified throughout so as to be homogeneous, impervious to moisture and free from flaws; the glaze must be good. If such an article can be produced in this country, it sooner or later undoubtedly will replace all the glass in use, even should quite a difference in price exist in favor of glass. It would be an advantage if the shape could be made to conform to the present double-petticoat glass, but it may be thought best to adopt the English Post Office pattern. To convince you of the soundness of my views, see F. L. Pope's 1891 edition of "Modern Practice of the Telegraph," page 115. Also Preece & Sivewright's last edition on "Telegraph," page 267. Mr. Preece is electrician of the British postal lines. You will feel convinced, I am sure, that a field is open for your careful consideration and action. I shall be pleased to hear from you further on this (to me) important subject.

F. W. Jones, Electrician.

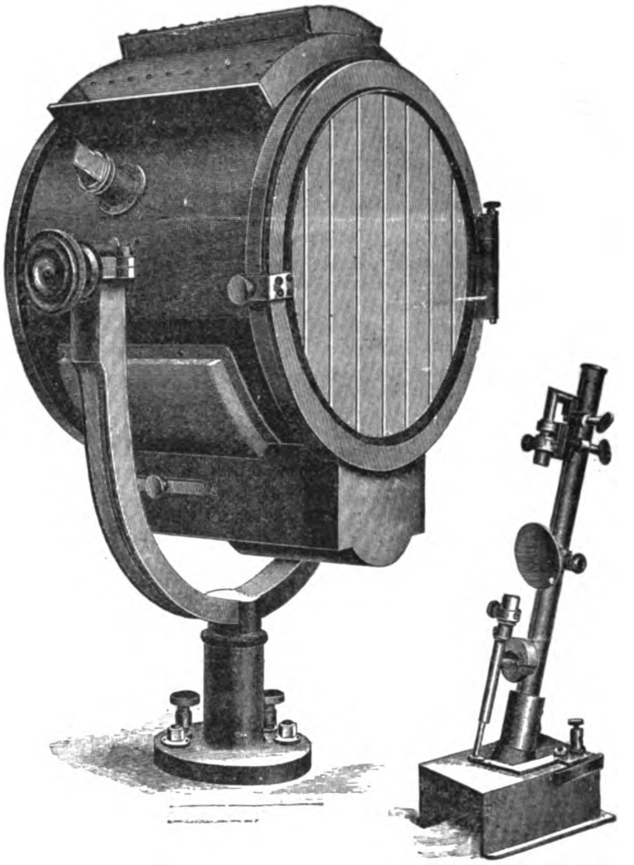
Postal Telegraph-Cable Company,
New York, Jan. 5, 1892.

THE ELECTRIC LAUNCH "ZURICH."

The following particulars from *L'Electricien* with regard to the electric launch, "Zurich," which attracted much attention at the recent Frankfort Exhibition, may be of some interest. The launch was constructed by MM. Escher, Wyss et Cie., of Zurich, and the Oerlikon Maschinenfabrik. The hull was of steel, and the boat was capable of carrying 100 passengers. The dimensions were: Length, 53 ft.; beam, 10¼; mean draught, 3½ ft. The screw, which was 28 in. in diameter, was coupled direct to a 10 h. p. two-pole Brown dynamo run as a motor at 350 revolutions. Power was supplied by a battery of 56 Schoop 31-plate gelatinous accumulators, having a capacity of of 450 ampere hours, and a maximum discharge current of 80 amperes, and weighing in all about 5 tons. The total weight of the electrical equipment was 6½ tons, that of the boat being 15 tons. The motor, when running at 365 revolutions, and absorbing 10 h. p. (102 volts x 75 amperes), propelled the launch at the rate of 8 miles an hour; when only 8 h. p. was absorbed the speed was still 7 miles an hour.

THE THOMSON-HOUSTON SEARCH-LIGHT ON BOARD THE STEAMER "FAIRFAX."

The electric lighting plant on the steamer "Fairfax," described last week in The Electrical Engineer, is, in many respects, a model marine plant. There are 243 16 candle-power lamps in use distributed in the various parts of the ship, those in the three lower decks having water-tight fixtures. The junction boxes, 75 in number, are of bronze, and water-tight, as are also the switches, 10 in number, and the wires are lead-covered waterproof. The lamps are on nine circuits controlled by cut-outs and switches in the dynamo-room, and the mains run to four distributing boxes, conveniently located in different parts of the ship, containing the branch cut-outs and switches.



Thomson-Houston Search Light, with Focusing Lamp.

The search-light or projector, shown in the accompanying illustration, is located on the mast forward of the pilot house, and is equipped with an automatic focusing lamp. The controlling device is placed in the pilot house so that the lamp can be moved vertically and horizontally. The projector takes 20 amperes of current, and is rated at 20,000 candle power.

PROF. AYRTON.

Prof. W. E. Ayrton, F. R. S., president of the Physical Society, at the annual meeting of the Institution of Electrical Engineers was elected to the presidential chair of that body.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JANUARY 13, 1892. No. 193.

The discoveries of great men never leave us; they are immortal; they contain those immortal truths which survive the shock of empires.—Henry Thomas Buckle.

BOODY BARBARISM.

IT has become a fairly well recognized fact that public improvements or the erection of large engineering works must involve, to a greater or less extent, the loss of human life, and indeed in not a few instances this consideration has been made the subject of actual calculation in advance of the undertaking of such works. We might refer to hundreds of instances in which the erection of large structures has been accompanied by loss of life, and we need go no further than to select the Brooklyn Bridge as an instance in point. We have selected this particular example in order to show the fallacy of one of the arguments, if arguments they can be called, which Mayor Boody of Brooklyn has brought forward in connection with his veto of the resolution of the Board of Aldermen granting permission for the introduction of the trolley electric railways in that city. Mayor Boody believes that while "we are called upon to yield many of our present inconveniences for the public good, no citizen in time of peace can be justly asked to hazard life and limb; no amount of material benefit can compensate for the loss of one life!" Would Mayor Boody, we would ask, see Brooklyn isolated from the world because the erection of the Brooklyn Bridge involved a loss of life or because steam boilers on ferry boats have exploded or railroad accidents have occurred? The proposition is so absurd that it needs no further discussion. But we invite Mayor Boody to bring forward a single instance in which human life has been lost due directly to the electric current from an electric railway circuit. Persons have, it is true, been run over by electric cars in the same way as they have been for many years by horse cars and steam railways; but no one dreams of stopping these valuable adjuncts of traffic and returning to the omnibus and stage-coach because people are imprudent enough to cross the tracks upon the approach of trains. Another of Mr. Boody's reasons for vetoing the resolution is that no city of the size of Brooklyn has felt justified in adopting the trolley system. Considering the fact that New York and Chicago have granted trolley privileges within their limits, this part of Mr. Boody's objection is evidently based upon a lack of knowledge; but, aside from that, the reasoning in itself is about as convincing as would be the argument that, because a town of 10,000 inhabitants had adopted a railway trolley system, the method was not adapted to one of 20,000 inhabitants.

Somewhat more than a year ago the *Daily Advertiser*, of Boston, obtained the views expressed by the mayors of a large number of cities where electric railways operated by the trolley system were in operation, and the opinion expressed almost unanimously was, that the community was largely benefited by the increased comfort due to the introduction of the electric railway, and that the advance in the taxable valuation of property was of direct benefit to the taxpayers themselves. Considering that Brooklyn has permitted the erection of many miles of elevated railways, the attitude of its present mayor is hardly consistent, and we are glad to believe that his veto will be overridden by the city council. The more recent opinions of mayors after prolonged operation of electric railways will be found on another page, on which Mr. Balch gives a résumé of the replies received to inquiries emanating from the *Herald*, of Yonkers, N. Y., in which place the subject of electric railways is now being agitated. We are convinced that if the questions involved in the introduction of the trolley system were made a proper subject of study by the mayors and councils of such cities, no difficulty would be encountered in the obtaining of suitable franchises for their introduction.

STORAGE BATTERY WORKING.

IT is about a year since Prof. Ayrton and his associates published a remarkably exhaustive paper on the behavior of the storage battery during charge and discharge, in which special attention was devoted to the examination of the changes which take place in the active material during these stages, a large number of analyses being made to determine the chemical composition at short intervals. In this issue we publish an abstract of an exceedingly interesting paper read by Dr. G. H. Robertson, in which particular attention has been paid to the investigation of the condition of the acid electrolyte and its effects upon the plates during the various stages through which the cell passes in charging and discharging. He recognizes distinctly the great influence of the "active oxygen," hydrogen di-oxide and persulphuric acid, and arrives at the conclusion that for improvements in the cell we must look more to the manner of its handling than to any change in the manufacture of the plates.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.

The large number of works which have appeared during the last ten years treating of the dynamo and motor have done much to make the principles and method of construction of dynamo-electric machinery matters of common knowledge among those interested in the science. But while these books have served an excellent purpose, it cannot be denied that almost without exception they have been wanting in so far as they lacked the details necessary for the practical operation of such machines. By practical operation we mean such a knowledge of the principles of operation as will enable one to select intelligently the machine best suited for his purpose, erect and operate it in the place best adapted for it, and in a manner such as to insure its steady operation under all conditions of use. That such a treatise was needed is evidenced by the fact that several of our large electric companies issue books of instruction intended to supply the information just referred to. But none of these go as deeply into the subject as its importance warrants, and hence we are led to believe that a thorough and systematic treatise on this subject will be welcome at this time. As such we present to our readers the first instalment of the work on "The Practical Management of Dynamos and Motors," by Prof. F. B. Crocker and Dr. S. S. Wheeler. Our publication some time ago of "The Localization and Remedy of Troubles in Dynamos or Motors," by the same talented authors, which may be said to form a part of this work, has given a foretaste of that which is to come; and we thus hope to place before our readers a work which will be of the highest practical value and which will form a fitting addition to the already excellent descriptive works available on the subject of electric machinery.

BLOCK SIGNALS FOR STEAM RAILROADS.

It has taken the public a long time to become fully awakened to the full extent of the parsimonious recklessness and callous indifference to the safety of passengers which has characterized the administration of America's self-styled "greatest railroad," but the past few days have given evidence that the campaign of education is making rapid progress. If anything further were needed to give point to the scathing, if not always intelligent, criticism of the public journals, and to add fresh fuel to the flame of popular indignation, it might have been found in an article which appeared a few days since in an afternoon journal, which, for reasons not necessary to particularize, has generally been regarded as in some sense the mouthpiece of the management of the railroad in question.

This apparently inspired article informs the world that "block signals get out of order continually and lead to delays and collisions. Much better"—the writer says—"is the service of living, faithful flagmen, and *the results have shown how pre-eminently best this system is*. The block system is not worth a cent in comparison." From which profound observation we are made aware that this pretentious ignoramus does not even know what the system is, which he is so swift to condemn. He actually does not know the difference between the block system itself and the special apparatuses which are frequently, though by no means necessarily, employed in operating it. He does not know—or wilfully suppresses the fact—that the "living, faithful flagman" is never dispensed with even under the block system. He asserts that "if the whole system of the Pennsylvania Railroad were to supplant the whole system of the Central, not a train a day would be on time, and accidents would be four times more frequent than now." The all-sufficient answer to this is a comparison of the records. The Pennsylvania, with a much heavier traffic than the Central, has been operated for many years between New York and Philadelphia, under the block system, without the occurrence of a serious collision involving a passenger train, while on the Central, the actual money loss from preventable collisions south of Poughkeepsie during the same length of time, not to speak of passengers slaughtered, has been enough to equip and maintain an efficient block system twice over.

GILBERT, THOMSON, HENRY.

It is with no little pleasure that we begin in this issue a series of articles on the work of Prof. Joseph Henry, by his daughter, Miss Mary A. Henry, who proposes, and gives evidence of her ability, to prove that her distinguished father made an independent discovery of the principle of magneto-electricity. Her charming narrative goes to show not only that Henry, in this, was abreast of the immortal Faraday, but even anticipated him by several months.

Our issue this week contains also a biographical sketch of Sir William Thomson, who has just been raised to the peerage of Great Britain; and since distinction in England takes this form, the honor thus conferred upon one so thoroughly entitled to it will be noted with warm approval by every American electrician and electrical engineer—not omitting Dr. Park Benjamin, who would prefer to see the recognition take some other shape than the award of an empty title. The description given by Mr. Shaw of his visit to the great and modest Scotch philosopher is full of interest and not less so because it is timely.

But we do feel that there is some warrant for the indignant outburst of Dr. Benjamin, in our columns this week, as to the neglect shown to the memory of William Gilbert, who was at once the Henry and Faraday of his remote times, and who enjoyed consideration while alive at least equal to that which we all have long delighted to pay to Sir William, now Lord, Thomson. Why is Gilbert allowed to fall into such oblivion, or if he be remembered, why are not the memorials of his life and work preserved with as much reverence as after ages will evince for the mementos of Henry and Faraday and Thomson? We will not find fault with our English friends in this matter, for our own pages this week show that it has become a duty to vindicate the memory of Henry; but it is at least safe to say that if they do not soon take the matter up it is one that American electricians will feel constrained to be active about.

WIPING OUT THE MEMORY OF GILBERT.

BY

Park Benjamin

It seems to me that it is about time to organize in this country a "Gilbert Society" for the purpose of preventing the wiping out of the memory of William Gilbert. That task was begun by Francis Bacon probably in Gilbert's lifetime, and repeated attempts in the same direction since then have not been wanting; as witness the stupid article concerning him in the ninth edition of the Encyclopædia Britannica. I suppose that such a magnificent tribute as was paid to Gilbert by Galileo would be sufficient to keep any man's memory green even during the 17th and 18th centuries; but towards the end of the latter period despite the praises of the great Italian, some one found it necessary to make a new and peculiarly insidious attack upon Gilbert; and this I happened to unearth the other day in a rather curious way.

Pretty much everybody who has written a biographical sketch of Gilbert within the last dozen or so years has alluded to his portrait as existing in the Bodleian Library at Oxford. It is well known that that portrait was painted at the order of Gilbert himself; that it represents him in about his 48th year, and depicts him in his doctor's robes standing with his hand on the "terrella," which was his artificial earth made out of a piece of loadstone. Upon the picture and above the figure there was inscribed, first, the word "*Terrella*," then the date "1591; *ætatis* 48," and also in the background and a little below his left shoulder were the words: "*Magneticarum virtutum, primus indagator Gilbertus.*"

A couple of years ago there came into my possession an old print purporting to represent William Gilbert, and tallying in all respects with the description of the ancient portrait except in the following very significant details: The inscriptions were totally absent, and for the terrella had been substituted an ordinary terrestrial globe with the usual signs on it. As it struck me that these omissions were certainly very remarkable, and quite in line with previous efforts to slaughter Gilbert's reputation, I took occasion last September when in England, to go to Oxford for the express purpose of seeing the picture, and if possible of having a photograph made from it. I found in the Oxford stationers' stores abundant photographs of every one of the other historical portraits in the famous library, but none of Gilbert; and so I addressed a courteous request to the librarian asking permission to make the photograph in question. That gentleman in reply asked me to call upon him, which I did, and once more proffered my request, expressing at the same time the great interest which all American electricians felt in the fame and reputation of William Gilbert. He heard me through patiently, and then with a half smile, remarked:

"Well, I should be very glad indeed to allow you to photograph the picture but for one reason, which I fear must be controlling."

"And that is"—I asked.

"There isn't any picture."

As this was rather staggering in view of the repeated statements by British writers living within a hundred miles of Oxford, including various professors, I ventured to suggest that perhaps the librarian was mistaken, or was confusing the portrait in question with some one of the many others hanging in the gallery. He smiled superior once more and proposed that I walk through the room and see if I could find that portrait, which, perhaps with more zeal than politeness, I did. Then I came back to him and asked:

"Well, where is it?

"Seeing that it was removed," he answered, "over a hundred years ago, I do not know."

"Who removed it?"

"I do not know."

"Why was it removed?"

"It got decayed. It was on board, and the board rotted."

"Might I ask the source of your information?"

"Certainly," he said.

And thereupon he went to the shelves of the library and brought me a copy of the "Histories and Antiquities of the University of Oxford" by Anthony A. Wood, dated 1796, opened it at page 96 of Vol. 2, and there appeared a brief paragraph describing the picture as I have described it above, terminating with the laconic statement "Decayed and removed."

"Is there no record," I asked, "that it was ever returned?"

"None."

"Is there any receipt in the archives from anybody who took it away?"

"None."

"Has any other picture been removed from this famous collection?"

"None that I know of or have any record of."

"It is a fact, isn't it, that there are a great many pictures here of far earlier date than that of Gilbert?"

"Certainly."

"Judging by the looks of those pictures, a number of them have been restored?"

He assented.

"Well, don't you think it is remarkable that such a thing could have happened in the most conservative institution in the most conservative town in the most conservative nation in the world?"

"Very."

Then I asked him if he knew of any picture of Gilbert, and he very obligingly went to the Department of Engravings and Prints and brought me a copy which he said was of a very rare publication, but which turned out to be the same print that I had myself.

Now, it is rather a singular coincidence that the date on this print, 1796, is the same date that is on Wood's book. The print was made by a London engraver. If he did not make it from the old portrait, what did he make it from? If he did make it from the old portrait, why did he carefully leave out of his copy every word and everything which could do credit to Gilbert as the great discoverer that he was? Who allowed Gilbert's portrait to be taken from the Bodleian Library without a word of record being left behind? How did its board come to be decayed when other panel pictures did not so become? And even if it had become decayed, what was to prevent the film of paint being taken from the surface of that board, as has been done in hundreds of instances in restoring the oil paintings of the old masters, almost invariably done on panel, and remounted centuries later on canvas after their original boards had almost fallen to dust?

Gilbert, when that portrait was painted, was at the zenith of his fame as a physician. He rose to higher eminence ten years later when his book appeared. He was a graduate of Cambridge, and therefore Oxford did not hang up his portrait merely as one of its alumni, but as that of a man whom it honored itself by honoring. It cannot be said therefore that his portrait represented some one of no importance, for even when it was stolen, Gilbert's reputation was ineffably above that of dozens of the noble nincompoops and nobodies who still smirk down from those venerable walls.

So much for the past. Some time ago there was organized in England a so-called "Gilbert Society," which, we were told, was very solicitous for the fame and reputation of the discoverer. In the announcement of its establishment there appeared a long list of eminent scientists as members headed by that of the distinguished philosopher recently degraded to the English peerage. This concern was going to translate Gilbert in the highest style of the art. It has, I believe, taken subscriptions on this side of the Atlantic for its forthcoming translation. It was going to conserve and promote the memory of Gilbert. I made some inquiries while in London recently, about that society and its work, but gleaned little information. In fact, it was not easy to demonstrate its existence, although, subsequently, I was informed that it still lived, but that the preparation of its translation of Gilbert's book was not being very actively pushed; a statement that made me regret that on learning of the superior ability to be devoted to the matter abroad I had laid down the pen with my own translation of the work half finished.

Meanwhile, still pursuing my quest, it occurred to me that if I could not get a photograph of a picture of Gilbert, perhaps I might get one of his tomb; and so I sent over to a friend in London asking him if that could be done. The tomb is in the parish church in Colchester. His reply, just received, after pointing out some difficulties (the monument is high up on the church walls, there is a deficiency of light in the interior, and it will perhaps be troublesome to arrange a camera) sets forth what I suppose is the most recent attempt to blot out the memory of Gilbert; and it is a little startling. "Gilbert's memorial," writes my correspondent, "narrowly escaped destruction some time ago, when the church was in process of restoration; but our friend, Mr. Laver, a scientific man, who was then one of the church wardens, fortunately happened to see one of the workmen *wheeling the monument off in a barrow* and rescued it from demolition."

As I said in the beginning of this communication, it seems to me high time that some action, in this country, should be taken to protect the memory of William Gilbert from British depredations. *Quis custodiet custodes?*

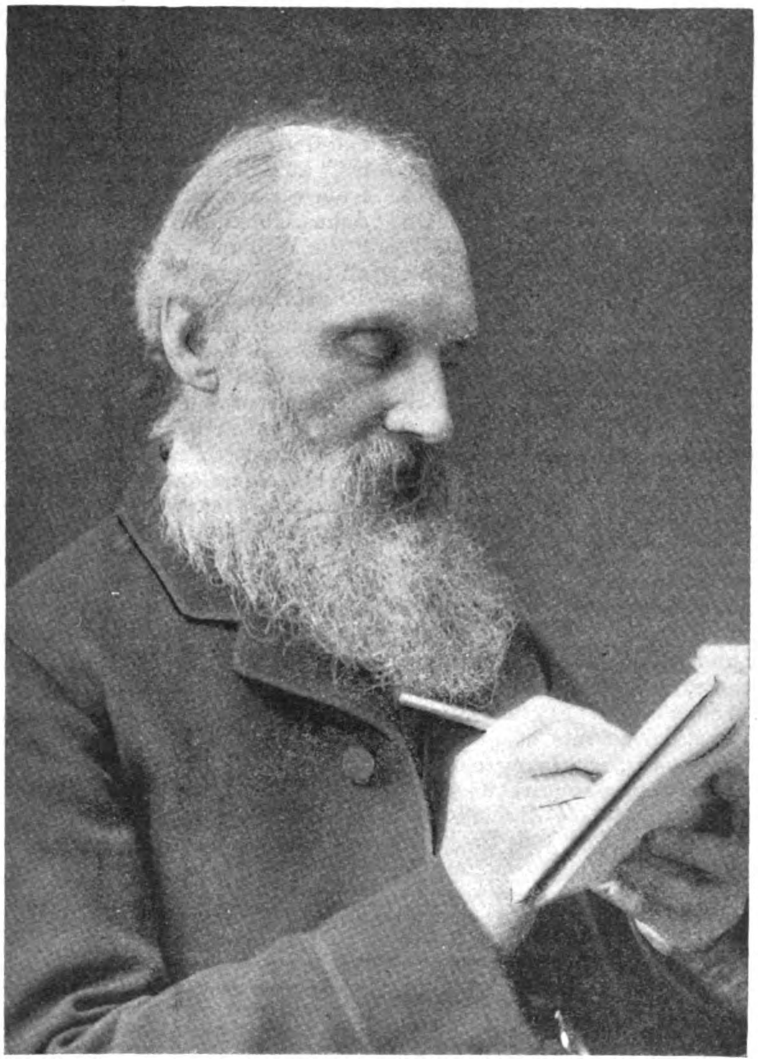
M. C. L. Weber, in an article recently published, gives the details of construction advocated for a small battery of accumulators. Two coils of lead wire, one above the other in long, thin glass tubes, is the arrangement shown. Such batteries would be used for laboratories or to charge electrometers.

WITH SIR WILLIAM THOMSON IN GLASGOW.

BY

A. C. Shaw.

The Atlantic cable has just brought to us the gratifying news that Sir William Thomson, the world-renowned electrician, has been raised to the peerage of England, and will hereafter be known to the world as Lord Thomson. Only a month or two ago Sir William was the recipient of high honor at the hands of his fellow-citizens of Glasgow, who, to commemorate the occasion of his election as president of the Royal Society, presented him with his portrait painted by the famous artist Herkomer, through the Right Honorable A. J. Balfour, then on a visit to Glasgow. At that time I had the good fortune to be sojourning in Glasgow, and had the pleasure of calling on Sir William first at his home in the University Yard, and afterwards at his laboratory, whence have come so many of those wonderful electrical instruments, which have served to win for him a world-wide reputation as the most eminent English electrician of the day, and have made his name a household word not only with scientific men, but among the people at large. Who, for instance, has not heard of the Thomson reflecting galvanometer and siphon recorder for cabling, or the sounding machine, enabling investigators to get accurate ideas of the nature of the ocean bed, or the Thomson mariner's compass, that wonderful instrument which seems to correct all errors in compass readings, and enables the mariner of to-day to make the trip from New York to Liverpool with as much accuracy as if the ship were guided on steel rails from one city to the other?



William Thomson
Glasgow Nov 28/91

It was, therefore, with feelings of profound gratification that I took the opportunity of a visit to Glasgow to call on Sir William and procure data regarding his life's history, which I now take pleasure in presenting to your readers, along with his portrait, which I may say, in passing, is an excellent likeness, and one which finds favor in Sir William's own eyes. As has been previously said, Sir William received me in his own home, in the University Yard, tendering me a hearty welcome and true Scotch hospitality. Being naturally interested in everything electrical, he then plied me with questions as to the *modus operandi* of the various systems of electric light and power in this country, being particularly interested in the wonderful and rapid development of electric street railway work. Practically there had been (with the exception of Leeds) almost no work of this kind in England, especially with the overhead trolley, and many were the pertinent questions asked as to the success and efficiency of such a system. Taking Boston for a text, and the West End Street Railway Company as an example, I assured Sir William that Americans had heartily endorsed the overhead system, and had found that electric railways were actually a necessity to the success of any enterprising city in the United States, and that though there had been severe opposition at first, the overhead wires were conceded to be much less of a necessary evil than the old antiquated horse cars. It may interest readers of THE ELECTRICAL ENGINEER to know that the city of Glasgow is at present considering seriously the question of adopting electricity as a motive power on its street railways, so that the subject was doubly interesting to Sir William at that time. On arriving at the laboratory I was presented to Dr. J. T. Bottomley, who has for so many years ably assisted Sir William, and who is himself well known to all electricians as the author of many familiar and valuable works. With Dr. Bottomley's assistance, I made a careful examination of many of the most recent inventions of Sir William, paying particular attention to his new standard electrical instruments for accurately measuring potential and current either in very small or very large quantities, and which are made by Mr. James White, of Glasgow, who has built all the Thomson instruments for the past thirty years. The most notable of these instruments are the standard direct-reading ampere balances, instruments founded on the mutual forces, discovered by Ampere, between movable and fixed portions of an electric circuit. These instruments are totally different from any other instruments in the market, and are absolutely accurate. Even more interesting than these, however, are the Thomson electrostatic voltmeters, which have the great advantage of being available as accurate measurers of potential on both direct and alternating circuits, and being electrostatic, use no current, and consequently require no temperature correction. These instruments are divided into three classes, the multicellular, the vertical and the electrostatic balance, and have a range of from 40 to 100,000 volts. It is needless to say that there were many other interesting and novel instruments to see, notably the latest invention, the Thomson wattmeter, and a variety of very large ampere-meters capable of measuring up to 100,000 amperes, without in any way heating—but I must hasten on to a short résumé of Sir William's life.

Sir William is an Irishman, by birth, though of Scotch descent, having been born in Belfast, in June, 1824. His father was educated at Glasgow University and afterwards became professor of mathematics in that college. Sir William, with his brother, James (now professor of civil engineering in Glasgow University) early took honors at the college, afterwards going up to Cambridge, where he graduated as second wrangler, in 1845, and first Smith's prizeman. At this early stage he was already noted for his success in mathematics, although other sciences had also great attraction for him, and at the same time he found leisure to devote himself to literature, music and even athletics. About this time he became interested in the study of magnetism and electricity, and gave birth to entirely new ideas on the subject of electric "potential," a subject at that time very imperfectly understood. In 1846, Thomson was elected professor of natural philosophy, in the University of Glasgow, which position he fills to-day with so much honor, having refused most tempting offers to go to English universities. In 1855 and 1856 he first gave his attention to ocean telegraphy and supplied the 1858 cable with the mirror-reflecting galvanometer, which first allowed the ocean cables to be successfully used commercially, and overcame the great difficulty of retardation. This was the first of the instruments which Sir William patented, much against his wishes, at the instigation of the Atlantic Company, as he was ready to give the public freely the fruit of his labors. Then followed the Thomson siphon recorder which was invented in 1867. This was generally brought into use three years later, and is the standard ocean cable instrument of to-day. The sounding machine and his mariner's compass were perfected about the years 1875 and 1876, and are both so well known that it is unnecessary to say anything about them. It is impossible to enumerate in this short sketch the many important points in Sir William's history, or the many useful instruments he has given to scientists, but it is interesting to note that he was in Philadelphia, in 1876, at the International Exhibition, and again in 1884 visited this country and delivered a course of lectures "On Molecular Dynamics," at Baltimore, to a class composed mainly of professors from various parts of the world, gathered together at the Johns Hopkins University.

Sir William has had honors presented to him from nearly all the universities of Europe. He is now president of the Royal Society, and ex-president of the Royal Society of Edinburgh, member of the Institut de France, the Academia dei Lincei at Rome, the Berlin Academy, the Amsterdam Koninklije Akademie and the American Academy of Sciences. He has attained almost every honor that scientific bodies can bestow on him, and, as has been already stated, has recently been recognized by the Queen by his elevation to the peerage. And yet with it all, what a modest, true-hearted, kind, genial man is there! A man whom it is an honor to meet, and yet who greets every one with a hearty frankness which at once dispels all sense of intrusion, and who inspires feelings of confidence, respect and love. Sir William, though now in his sixty-seventh year, is still as active as ever, intensely interested in all scientific work, beloved by his students, and honored by his fellow-citizens; and it is my sincere hope that he may yet be long spared to his sphere of usefulness, and the pursuit of these studies, which have yielded so much valuable fruit in the past, and which can form an ever-fruitful field of research to such penetrating genius as he so richly possesses.

SECONDARY BATTERIES.

MR. G. H. ROBERTSON'S paper, read recently before the London Society of Arts, brought out several interesting points relating to the chemistry of secondary batteries, or more particularly the chemistry of the acid, which are worth the careful study of those engaged in this specialty of electrical science. Referring to experiments with electrolytes, he says:

> Although so many different modes of manufacture and preliminary treatment have been resorted to, all the batteries, so far as I am aware, which depend for their action on the couple formed between lead and lead peroxide in dilute sulphuric acid, exhibit the characteristic peculiarities noticed by Planté in his cell, namely: The high initial E. M. F. of a freshly-charged cell; the fall of E. M. F. on breaking the charging circuit, with corresponding rise on breaking the discharging circuit; the very rapid fall towards the end of discharge which occurs earlier, the more rapid the discharge is, and is not due to the exhaustion of the active material, as, after a rest, a fresh discharge can be obtained.
>
> As the defects, namely, sulphating and buckling, which have retarded the introduction of reversible lead batteries, are also common to the two types, it appeared possible that they were due to the same causes which produced the variations in E. M. F.; therefore, as the work of Dr. Oliver Lodge[1] in 1883, and of Miesler[2] in 1888, had shown that the causes of the variation must be sought either on the lead plate or in the acid next it, and the chemistry of the plates afforded no explanation,[3] I last year, with Dr. Armstrong's advice and assistance, undertook the investigations of the reactions occurring in the acid.

---

[1] Cantor lecture.

[2] "Monatshafte für Chemie," viii, 713.

[3] For references and a summary of the principal work done on the cell, see the London *Electrician*, Vol. xxvii., No. 682, p. 165; No. 692, p. 437.

In 1878 Berthelot[4] discovered persulphuric acid ($H_2 S_2 O_8$), and brought forward evidence to prove that it is the primary product of the electrolysis of sulphuric acid solutions, and that the hydrogen dioxide—which, from Faraday's time, has been well known to be present in sulphuric acid after electrolysis—is really due to the action of this body on the acid. The products of electrolysis vary with the strength of the acid, 40 per cent. acid (density 1.300) yielding practically no hydrogen dioxide; while below and above that strength it is present in varying proportions. High current density and an electro-negative condition of the electrodes favor their formation.[5] Persulphuric acid is an unstable body, and begins to decompose as soon as the current which has given rise to it is stopped, and its decomposition is accompanied by the formation of hydrogen dioxide, unless the sulphuric acid is too dilute. Hydrogen dioxide is also unstable when concentrated, but a weak sulphuric acid solution of it is comparatively stable, and the stability increases the less hydrogen dioxide it contains; therefore this body is found in estimable quantities long after the persulphuric acid which gave rise to it has disappeared. Persulphuric acid is at once decomposed by spongy metal, such as platinum black, by heat with evolution of oxygen,[6] and resembles hydrogen dioxide in these reactions, and in releasing iodine from potassium iodide, but, unlike it, has no action on permanganate of potassium or peroxide of lead. The effect of electrolyzing a sulphuric acid solution of hydrogen dioxide is simply to increase the rate of the decomposition occurring spontaneously, if a weak E. M. F. is used[7]; but on increasing the E. M. F., though the rate of decomposition is increased, a little persulphuric acid is reformed. Subsequent workers have in the main confirmed Berthelot's conclusions. To the oxidizing oxygen in the products of the electrolysis of sulphuric acid, Berthelot gave the name of "active oxygen," and as they pass one into the other, and for most purposes connected with a battery it is not necessary to discriminate between them, I have retained it.

EXPERIMENTS AT THE GENERAL POST OFFICE.

That the nature of the electrolyte affected the behavior of the cell, was evident from information received from Mr. Barber-Starkey with respect to the effect of the addition of sodium carbonate, and it seemed possible that the different behavior of cells containing this substance was due to its catalytic action on hydrogen dioxide, which is known to be exceedingly unstable in the presence of a trace of alkali; and hence a comparative study of the reactions occurring in cells containing ordinary dilute sulphuric acid, and in those which had been treated on Mr. Barber-Starkey's plan seemed likely to elucidate the causes of the sulphating during rest, and the high initial E. M. F.—the two features most affected by this treatment.

Mr. Preece most kindly aided the investigation by allowing experiments to be carried out at the General Post Office, where one-half of the secondary cells contain 1 per cent. of sodium sulphate, and the other half ordinary dilute acid, density 1.180. He also put at my disposal the records of the behavior of the cells, and they proved that there was much less sulphating with sodium sulphate, as shown by the density of the acid never falling to the same extent as in the plain cells. The following readings, taken from short-circuited cells with badly broken plates, illustrate this. In two cells containing ordinary dilute acid, the density of the electrolyte had fallen to 1.100, while, according to the last readings before the short circuit occurred, it had been 1.170 and 1.180 respectively; while in two sodium sulphate cells the density had only fallen to 1.180 from 1.200 under similar circumstances. This was strong evidence in favor of the hydrogen dioxide formed in the working of the cell being appreciable in quantity, since if sulphating were only due to local action between the support and the paste, there does not appear any reason why the addition of sodium sulphate should affect it.

Whenever the cells were tested they were always found to contain "active oxygen," which was due to the presence of persulphuric acid and peroxide of hydrogen in varying proportions. During charge, persulphuric acid is the main constituent; during discharge the quantity of hydrogen dioxide gradually increases, while in a cell which has been at rest some time, there is very little except hydrogen dioxide to be found.

In addition to the tests made on the cells in the electric light and telegraph batteries, I studied the formation of the "active oxygen" during charge and discharge on some cells which were kindly set apart for my special use. The "active oxygen" forms at once on the passage of the current, decreases slightly, and then increases to a little above its first value. Starting either charge or discharge always causes an initial increase, except in the case of cells which have been long idle, when there is a diminution, due to the decomposition of the excess of hydrogen dioxide in the acid.

To test whether electrolyzed acid was able to reduce pure peroxide of lead, two equal lots of peroxide were taken by weighing one against the other, and put in two flasks. One to each, 100 cc. of acid, from next the positive plate of a cell at full charge, was poured, and this caused the evolution of oxygen, which continued slowly for some days. At the end of a fortnight the amount of peroxide of lead in each sample was estimated, and it was found to have decreased from 97.4 per cent. to 93.94 and 94.04 per cent. respectively. This appears to explain the well-known deleterious effect of rest on a cell, for although persulphuric acid itself does not reduce peroxide of lead, it forms hydrogen dioxide on standing, which is capable either of oxidizing the lead plate to litharge or of reducing the peroxide plate to the same substance. In each case the litharge is converted into sulphate by the sulphuric acid. In an ordinary cell in good order the amount of "active oxygen" is small, varying in quantity from about 0.01 grm. to 0.02 grm. per litre; but this means that in a 45-pint cell (the size used at the Post Office) there was always sufficient to convert from 3.25 grms. to 7.5 grms. of peroxide of lead into sulphate, or to undo the work of one to two ampere-hours' charge. The figures just given do not represent the total amount of "active oxygen," since the acid absorbed by the plates cannot be tested; but as the acid has more oxidizing power, the nearer you get to whichever is the positive plate, except at the commencement of discharge, and the total quantity of "active oxygen" increases rapidly soon after breaking circuit, it seems fair to assume that this increase is due to diffusion from the plates of acid which has more oxidizing power than that in the body of cell. This increase is followed by a decrease which is rapid at first, and then gradually gets very slow, and practically ceases while there is still a fair proportion of "active oxygen" left in the cell.

In the sodium sulphate cells the amount of the oxidizing agent was usually less than in the plain cells; and the amount of hydrogen dioxide was always so, unless the battery had been at rest for some time, when the conditions were occasionally found to be reversed. This, I suppose, is due to the proportion of "active oxygen" in the form of hydrogen dioxide, at the moment of stopping the current, being greater in the plain than in the sodium sulphate cells, while the latter contain more persulphuric acid. In both cells the hydrogen dioxide present at the time of stopping the current will be reduced on the plates, sulphating the surface, and more or less screening them from further action; but, as the sodium sulphate cell contains more persulphuric acid, the subsequent formation of hydrogen dioxide will be greater in it than in the plain cell. As far as I could discover, sodium sulphate has little or no action on the acid unless it is added during electrolysis, or to acid which has just been taken from a cell through which a current is passing.

The Effects of Hydrogen Dioxide on the E. M. F. *of a Cell.*—The presence of hydrogen dioxide having been thus proved, both directly and indirectly, its effect on the E. M. F. of the cell was tested. This was done by using strips of lead packed tight into small porous pots, with peroxide of lead to represent the peroxide plates, and using plain strips as the lead plates. A solution of pure sulphuric acid, density 1.180, was used as the electrolyte. The E. M. F. of the couple was taken by the deflection method, and then a drop or two of hydrogen dioxide was added to the acid, which produced a great diminution, or even reversal, of the E. M. F. The effect of introducing hydrogen dioxide into the body of the peroxide paste was also tried with a view of reproducing, if possible, the conditions of a cell which is started discharging directly the charge is completed, and in which the "active oxygen" would be accumulated at the positive plate, leaving the lead plate free, and I found that there was a slight increase in E. M. F.

Thus the variations in E. M. F. appear to depend on which plate hydrogen dioxide is formed at. When present at the peroxide plate it causes a rise, but when diffused through the acid and present at the lead plate it causes a lowering of the E. M. F.; and the rise in E. M. F., sometimes noticed on starting the discharge of a cell which has been at rest (mentioned in Prof. Ayrton's paper, J. I. E. E., 1890, p. 572), is probably due to the electrolysis and decomposition of hydrogen dioxide, for, in a cell which has been long idle, practically the whole of the "active oxygen" is due to this body.

CONCLUSIONS.

From the same faults appearing in batteries of such different construction, and judging also from the results of the experiments recorded in this paper, it would appear that the troubles occurring in batteries are due rather to causes arising in the working than in the manufacture. What is required is some substance which can be added to the acid to check the formation of the oxidized bodies in it, which cause sulphating, without at the same time injuring the plates in other ways. Nearly all the "forming" baths which have been introduced are baths in which hydrogen dioxide would be broken up as soon as formed, and, perhaps, in some modification of them the electrolyte of the future will be found; though, since the products of the electrolysis of sulphuric acid vary with the strength of the acid and the current density, no hard and fast rule can be laid down for the treatment of cells.

In cells containing acid below density 1.200, in which the proportion of "active oxygen" existing as hydrogen dioxide is high, the addition of one per cent. of sodium sulphate, or similar substance, is likely to prove beneficial, particularly if the work of the cells is intermittent. As the strength of the acid is increased, however, and the conditions are more favorable to the stability of persulphuric acid, less hydrogen dioxide will be produced, and there is more chance of the alkali released from the sodium sulphate during electrolysis damaging the plates.

[7] Berthelot. (*Compt. Rend.*, 86, 8–11.)

Also, Dr. Marshall has succeeded in preparing pure persulphuric acid, and has shown this year that it forms salts with the alkalies which are very stable; and what the effect on a cell of the formation of of sodium persulphate in it would be, is quite unknown. Although the formation of peroxides in the acid does not apparently account for the great gasing and sudden loss of charge sometimes observed, still we have seen that makers are reverting to Planté's process of manufacture, or modifications of it, and we may find that in this case also he was right, and that it is to the electrolyte we must look if we wish to find the means of materially improving the lead reversible battery.

LONG-DISTANCE TRANSMISSION OF POWER BY ELECTRICITY.[1]

BY FRANCIS R. HART.

GIVEN a point were power is best obtainable and another point where such power can be most advantageously used, the problem given to the engineer for solution is that of transmitting this power from the one point to the other. If the transmitting agent is electricity, the method is called one of *electrical power transmission.*

There are two general types of electrical methods that can be employed, (1) haulage, and (2) line transmission.

The first is comparable to the haulage of coal from the mine to a distant factory, there to have its stored energy utilized in mechanical work. The skeleton of such an electrical power-transmission system is shown in the following diagram:

TABLE I.

SOURCE OF POWER, { Fuel. / Water. / Wind.
|
ENGINE, { Steam-engine. / Water-engine. / Wind-engine.
|
MECHANICAL-ELECTRICAL TRANSFORMERS, (Dynamos).
|
STORAGE DEVICE, (Storage batteries).
|
HAULAGE SYSTEM, { Carts. / Tramway. / Boats.
|
ELECTRO MECHANICAL TRANSFORMERS, (Motors).
|
MACHINERY TO BE DRIVEN.

More anologous than the haulage of coal to this method would be a compressed-air system. If the steam-engine or turbine at the source of power drove air compressors which filled portable vessels with compressed air, and these vessels were transported and attached to air engines at a distant point, we have a system directly comparable with the electrical haulage plant.

The storage battery street car is an example of this method of electrical power transmission.

The other general type of electrical methods for distant delivery of power employs a line of conducting wires between dynamo and motor in place of the cumbersome system of haulage.

The second system has obvious advantages for long-distance transmission and I shall consider with you that only. There are conditions, however, where even for other than tramway work the haulage system may be the only or best system that can be employed.

I have given *fuel*, *water* and *wind* as the three power sources which may be employed to drive a power system. Some of the uses to which electrical methods of transmitting power may be put are shown in the following table:

Steam:
1. Large number small users obtain more economical power from one engine.
2. Local distribution from lighting companies.
3. Street railways.
4. To replace long shafts.
5. Special works (mines, etc.).

Water:
1. Locate mill with reference to shipping conveniences.
2. Concentration of small water-powers.
3. Carrying power into cities for factories, street railways, etc.
4. Continuous use of power (power during day and lighting at night).

Wind:
1. Pumping (mines and irrigation); wind-engine at best point and pump anywhere.
2. Lighting with storage cells.

The skeleton of the system is as follows:

SOURCE OF POWER. { Fuel. / Water. / Wind.
|
ENGINE, { Steam-engine. / Water-engine. / Wind-engine.
|
MECHANICAL-ELECTRICAL TRANSFORMERS, (Dynamos).
|
CONDUCTING WIRES.
|
ELECTRO-MECHANICAL TRANSFORMERS, (Motors).
|
MACHINERY TO BE DRIVEN.

In practice, except for street railway and mining work, fuel is not an economical source of power for long-distance transmission plants. Ordinarily it is cheaper to deliver the coal at the distant point and obtain the power directly. In connection, however, with water-power the usefulness of an electrical power system can hardly be exaggerated.

Before describing to you the various systems that can be employed for line electrical power transmission I wish to call your attention to certain points concerning the efficiency of such a method and how far we can govern this efficiency. We call the mechanical efficiency of a system the ratio of the power delivered to the dynamo-electric machines at one end of the line to the power delivered by the electric motors at the distant end.

The commercial efficiency of a dynamo or motor, as I shall show you later, varies with its load. The maximum efficiency of good machines should not be under 90 per cent. and is seldom above 92 per cent. Under the most favorable conditions, then, we must expect a loss of, say, 9 per cent. in the dynamo and 9 per cent. in the motor.

The loss in transmission, due to fall in electrical pressure or "drop" in the line, is governed by the size of the wires, the other conditions remaining the same.

For a long-distance transmission plant this will vary from 5 per cent. upwards.

With a loss of 5 per cent. in the line the total efficiency of transmission will be slightly under 79 per cent.

With a loss of 10 per cent. in the line the efficiency would be slightly under 75 per cent. We may call 80 per cent. the practical limit of the efficiency with the apparatus of to-day.

The methods for long-distance power transmission by electricity may be divided into three general classes: (1) Those using continuous current; (2) those using alternating current; and (3) regenerating or "motor-dynamo" systems.

I have tabulated the subdivisions of each of these general classes as follows:

- Continuous current.
  - 2-wire.
    - Low voltage.
      - One machine.
      - Machines in parallel.
    - High voltage.
      - One machine.
      - Machines in parallel.
      - Machines in series.
  - 3-wire
    - 2 machines in series.
    - Machines in multiple-series.
  - Multiple-wire
    - Machines in series.
- Alternating current.
  - Alternating single phase.
    - Without conversions (1).
    - With conversions (2).
  - Alternating multi-phase.
    - Without conversions.
    - With conversions.

---

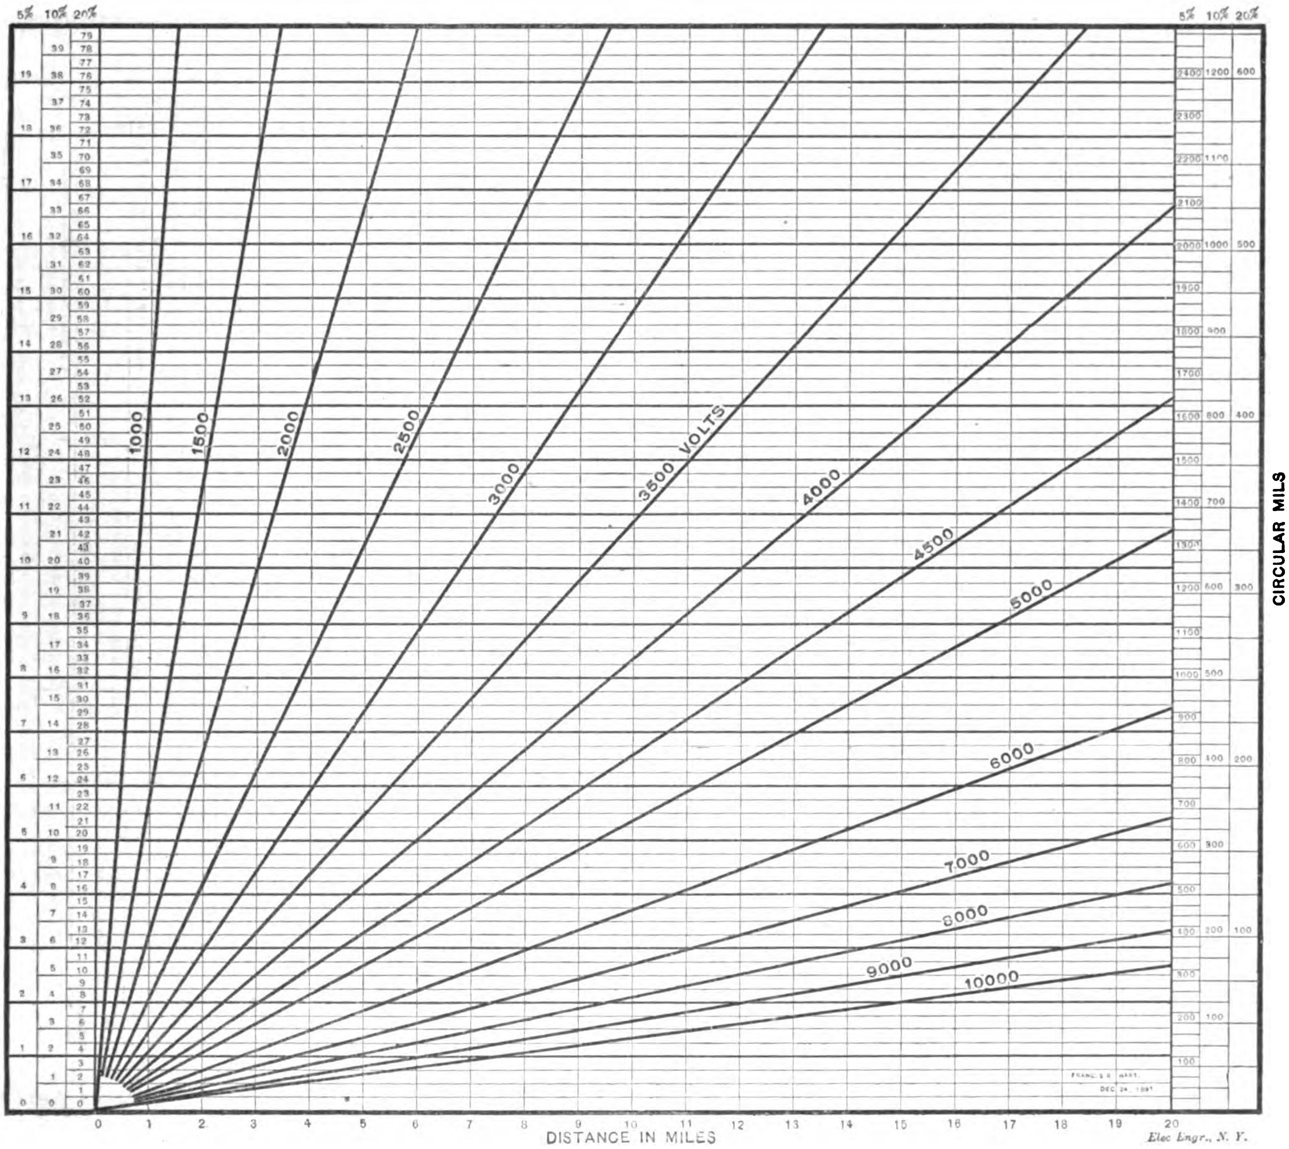
[1] A paper read before the Society of Arts, Boston, December 29, 1891.

Regenerating systems.	Alternating-continuous.
	Alternating converter; line converter; alternating-continuous.
	Continuous-continuous.
	Partial reconversion of any system.

The relative advantages of these systems vary with each particular transmission problem, but in a general way may be tabulated as follows:

The system selected must (1) fill construction and operation conditions, and (2) give minimum cost per horse-power delivered. There are many factors which govern the selection of a system. For each problem considered there will be found certain fixed and certain unfixed conditions.

In general the fixed factors are as shown in Table II.



Elec. Engr., N. Y.

FIG. 1.

1. Capacity of source of power; 2. Cost of power at source; 3. Cost of power by other means at point of delivery; 4. Danger considerations at motors; 5. Operation conditions; 6. Construction conditions, (length of line, character of country, etc.)

The partly fixed conditions are:

7. Power which must be delivered (*i. e.*, the efficiency of the system). 8. Size and number of delivery units.

The variable conditions are:

9. Initial voltage; 10. Pounds of copper on line; 11. Original cost of all apparatus and construction; 12. Expenses, operating: (Fixed charges, interest, depreciation, taxes, insurance, etc.) 13. Liability of trouble and stoppages; 14. Danger at station and on line; 15. Convenience in operating, making changes, extensions, etc.

Assuming that the cost of dynamos, motors, etc., will be approximately the same whatever the initial pressure, I shall show you the great variation in the cost of wire at different pressures. For convenience in working out such problems for rapid and approximate determinations, I have drawn a diagram on chart, Fig. 1, from which can be determined the pounds of copper required for transmitting any number of horse-power from one to twenty miles with an initial pressure of from 1,000 to 10,000 volts, at various losses in transmission. The scale of ordinates on the left gives the total pounds of copper required for one horse-power for each mile transmitted at 5 per cent., 10 per cent. and 20 per cent. loss in transmission. The scale of ordinates on the right gives the area in circular-mils of one of the two necessary wires at the same percentage losses.

To illustrate the use of the diagram, suppose we wish to know the weights of copper required for transmitting 100 h. p. 5 miles at 2,000, 3,000, and 10,000 volts and at 10 per cent. and 20 per cent. loss respectively. By inspection of the diagram we obtain the following figures.

Voltage.	Drop.	Total Pounds Copper.
2,000	10 per cent	33.6 × 100 × 5 = 16,800
	20 per cent.	16.8 × 100 × 5 = 8,400
3,000	10 per cent.	14.8 × 100 × 5 = 7,400
	20 per cent.	7.4 × 100 × 5 = 3,700
10,000	10 per cent.	1.24 × 100 × 5 = 620
	20 per cent.	.62 × 100 × 5 = 310

Very interesting mathematical deductions can be made showing conditions which give minimum cost, maximum efficiency, etc., but in practice these become of small value as almost in-

THE
Electrical Engineer.

VOL. XIII. JANUARY 6, 1892. No. 192.

THE BUILDING OF PERRET DYNAMOS AND MOTORS.

I.

FEW developments in the electrical domain of late years have been more rapid and more interesting than those which pertain to the electric motor industry. The practical utilization of electric power may be said to date from the International Electrical Exhibition of 1884, but it is only within the last two or three years that motor building has taken prominent place among the electric arts, opening up a field of activity and usefulness the limits of which no man can set. It is said by some observers that already the production of generators to furnish current for motors is larger than that of generators for lighting; and while this may not be true, it is evident that when the employment of lighting generators during daylight hours for power purposes is taken into account, the motor is even to-day well abreast of the lamp as a consumer of current. This state of affairs is in many respects matter for congratulation, and the double demand for current cannot but hasten the coming of the time when electric mains will ramify as universally and be availed of as freely as are water mains at this moment.

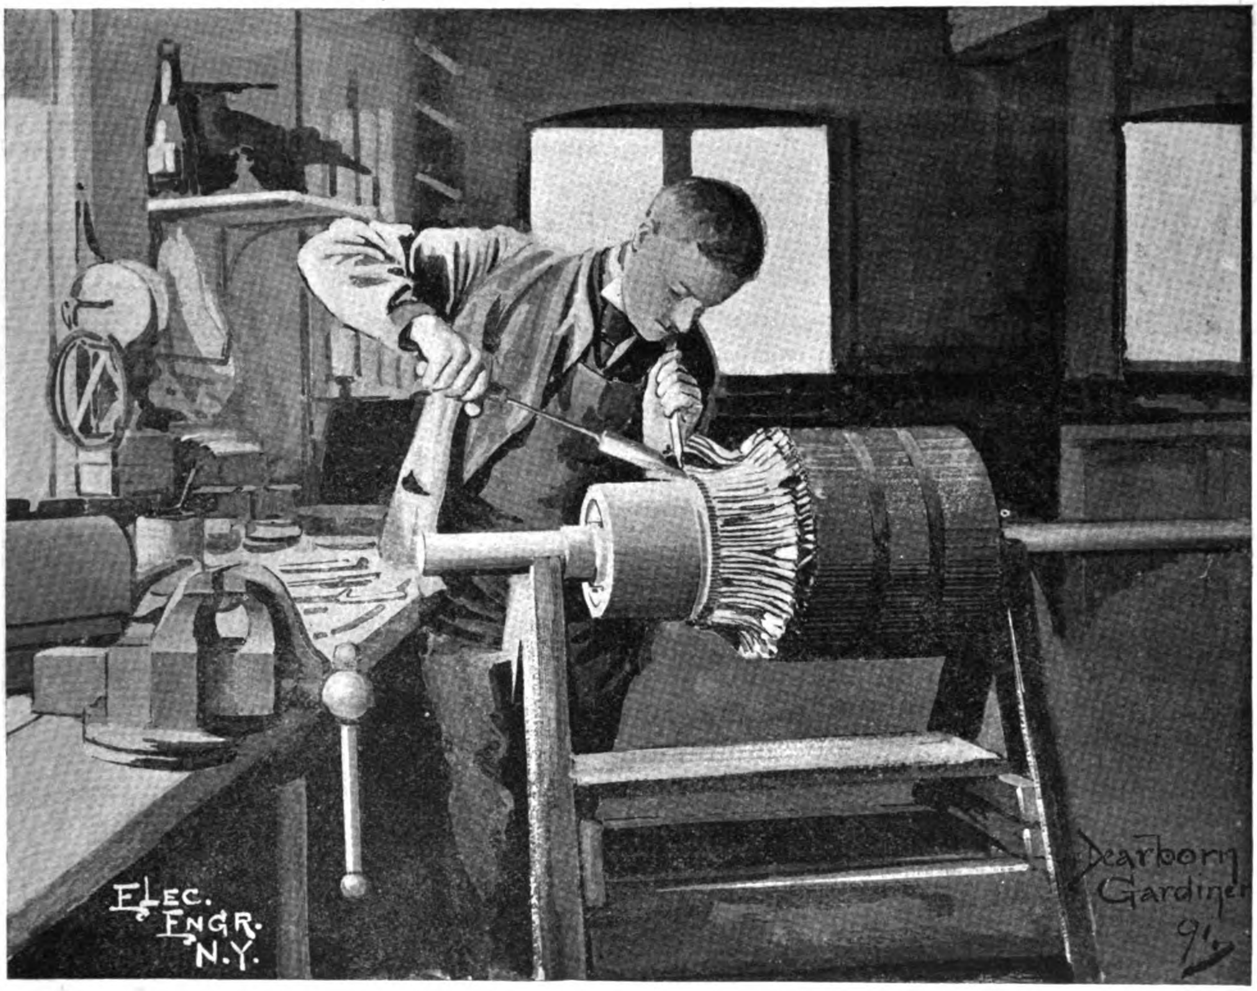

FIG 9.—CONNECTING ARMATURE COILS WITH COMMUTATOR IN A PERRET MOTOR.—(See page 6.)

The popularity of electric power has, as readers of THE ELECTRICAL ENGINEER are well aware, called various types of motors into existence, the majority of which were of the high-speed type, a feature against which no small portion of the public raised objection on the very natural ground that such high speeds rendered it difficult to effect feasible and satisfactory combinations between the driving and the driven mechanism. One of the very first inventors and designers to give attention to the production of "slow speed" motors, was Mr. Frank A. Perret, and his ideas enlisted so much support that the Elektron Manufacturing Company was formed and a large factory started in Brooklyn, N. Y. Owing to the rapid growth of the business, larger quarters became necessary, and after the inspection of a number of properties, choice was made early last year of a fine manufacturing building at Springfield, Mass., whither a removal was made during the summer. The new factory is now in full swing, and the various processes and ideas there illustrated are so important, interesting and ingenious that no apology need be offered for making here an extended description of them, setting forth standard methods of motor manufacture in America.

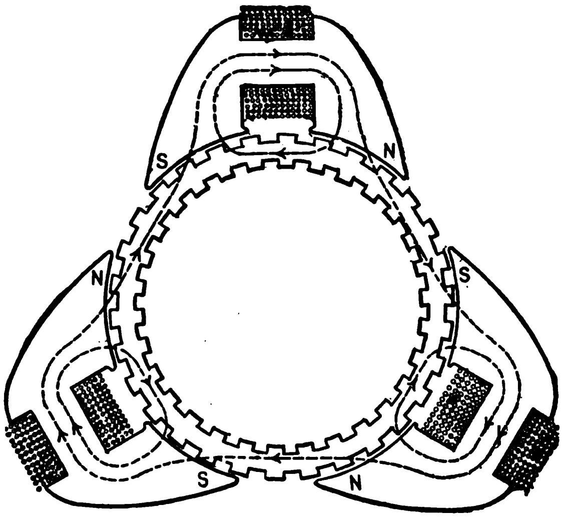

FIG. 1.—PERRET MULTIPOLAR FIELD.

II.

Before entering into a description of the method of manufacture adopted in the Perret motors, it may be well to touch briefly upon the reasoning which led Mr. Perret to design the machine as we find it. He had long recognized that the speeds at which the original types of bi-polar motors were operated were such as to lead to inconveniences and additional care in attendance at the motor, and necessitated as a rule the employment of countershafting, which always involved an additional expense whenever such a high-speed motor was installed. He had, therefore, started out at once with the problem of producing a slow-speed motor; that is to say, not to wind an armature to run slowly, but to design a machine for low speed which should have as high an efficiency as those of the high-speed bi-polar type. But how was this to be accomplished? Mr. Perret argued that in the ordinary two-pole machine the armature conductor crosses the magnetic circuit and cuts all the lines of force twice during a complete revolution, viz., where they enter the armature core at one pole and where they leave it at the other. Now, if we so dispose the magnetic circuit as to cause the lines of force to enter the armature core at one point, to leave it at another, to enter it again at a third point and to leave it at a fourth, it is obvious that the conductor will cut all the lines at four points in each revolution, and that it will, therefore, generate the same E. M. F. at one-half the original speed. If we increase the number of poles to six, we shall obtain the same effect at one-third the speed, etc., etc. This, then, is the principle of construction by which low speed is secured.

Fig. 1 is a diagram of the magnetic circuit of the Perret machine. As will be seen, there are but three magnets, each being isolated magnetically from the others excepting through the medium of the armature core, and completely isolated from the frame-work of the machine. They are formed of plates of soft sheet-iron, which are punched to the required shape and strung together on non-magnetic bolts by which they are secured to their supports. A single magnetizing coil forms two salient poles, and as each magnet is built of a large number of plates a uniform magnetic conductivity is secured. By this method of construction all danger of any inequality in the strength of the poles is avoided, and a magnetic circuit without joints and of the lowest possible resistance is secured. It is understood, of course, that in all cases the number of ampere turns on each magnet must be equal.

III.

The works, a view of which is given in Fig. 2, are situated on Wilbraham street, beside the New York & New England railroad, from which a side track is run in. The main building is of brick, 40 feet by 55 feet, and four stories high. It has a long three-story wing, 125 feet by 40 feet In this wing the workrooms are located. A brick engine and boiler-house, 45 feet square, is situated north of the main building, with a 15-foot passageway between. The 16-inch leather belt, by which power is transmitted from the engine to the main shafting, passes above this driveway in a covered bridge.

The plan upon which the machinery and the works at Springfield, Fig. 2, have been laid out is such as to effect the greatest economy in time, both as to the manipulation of the raw material and the assembling of the finished parts. In the reception of the raw material the works are peculiarly fortunately situated by having the New York and New England railroad beside them, so that the raw material can practically be unloaded directly from the cars into the shop basement floor. This first floor is a little below the level of the street and constitutes the heavy machine-room where the heavy lathes, planers and drilling machines, are situated. In this department, among other things, the rough castings are finished off and a number of special tools are employed to insure accuracy in the pro-

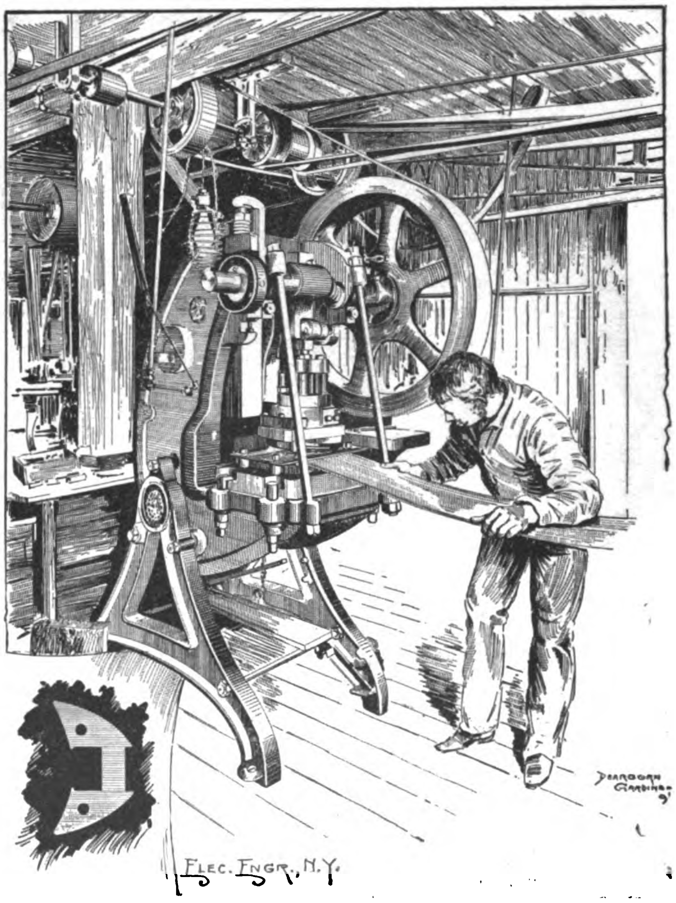

FIG. 3.—STAMPING OUT LAMINÆ FOR FIELDS.

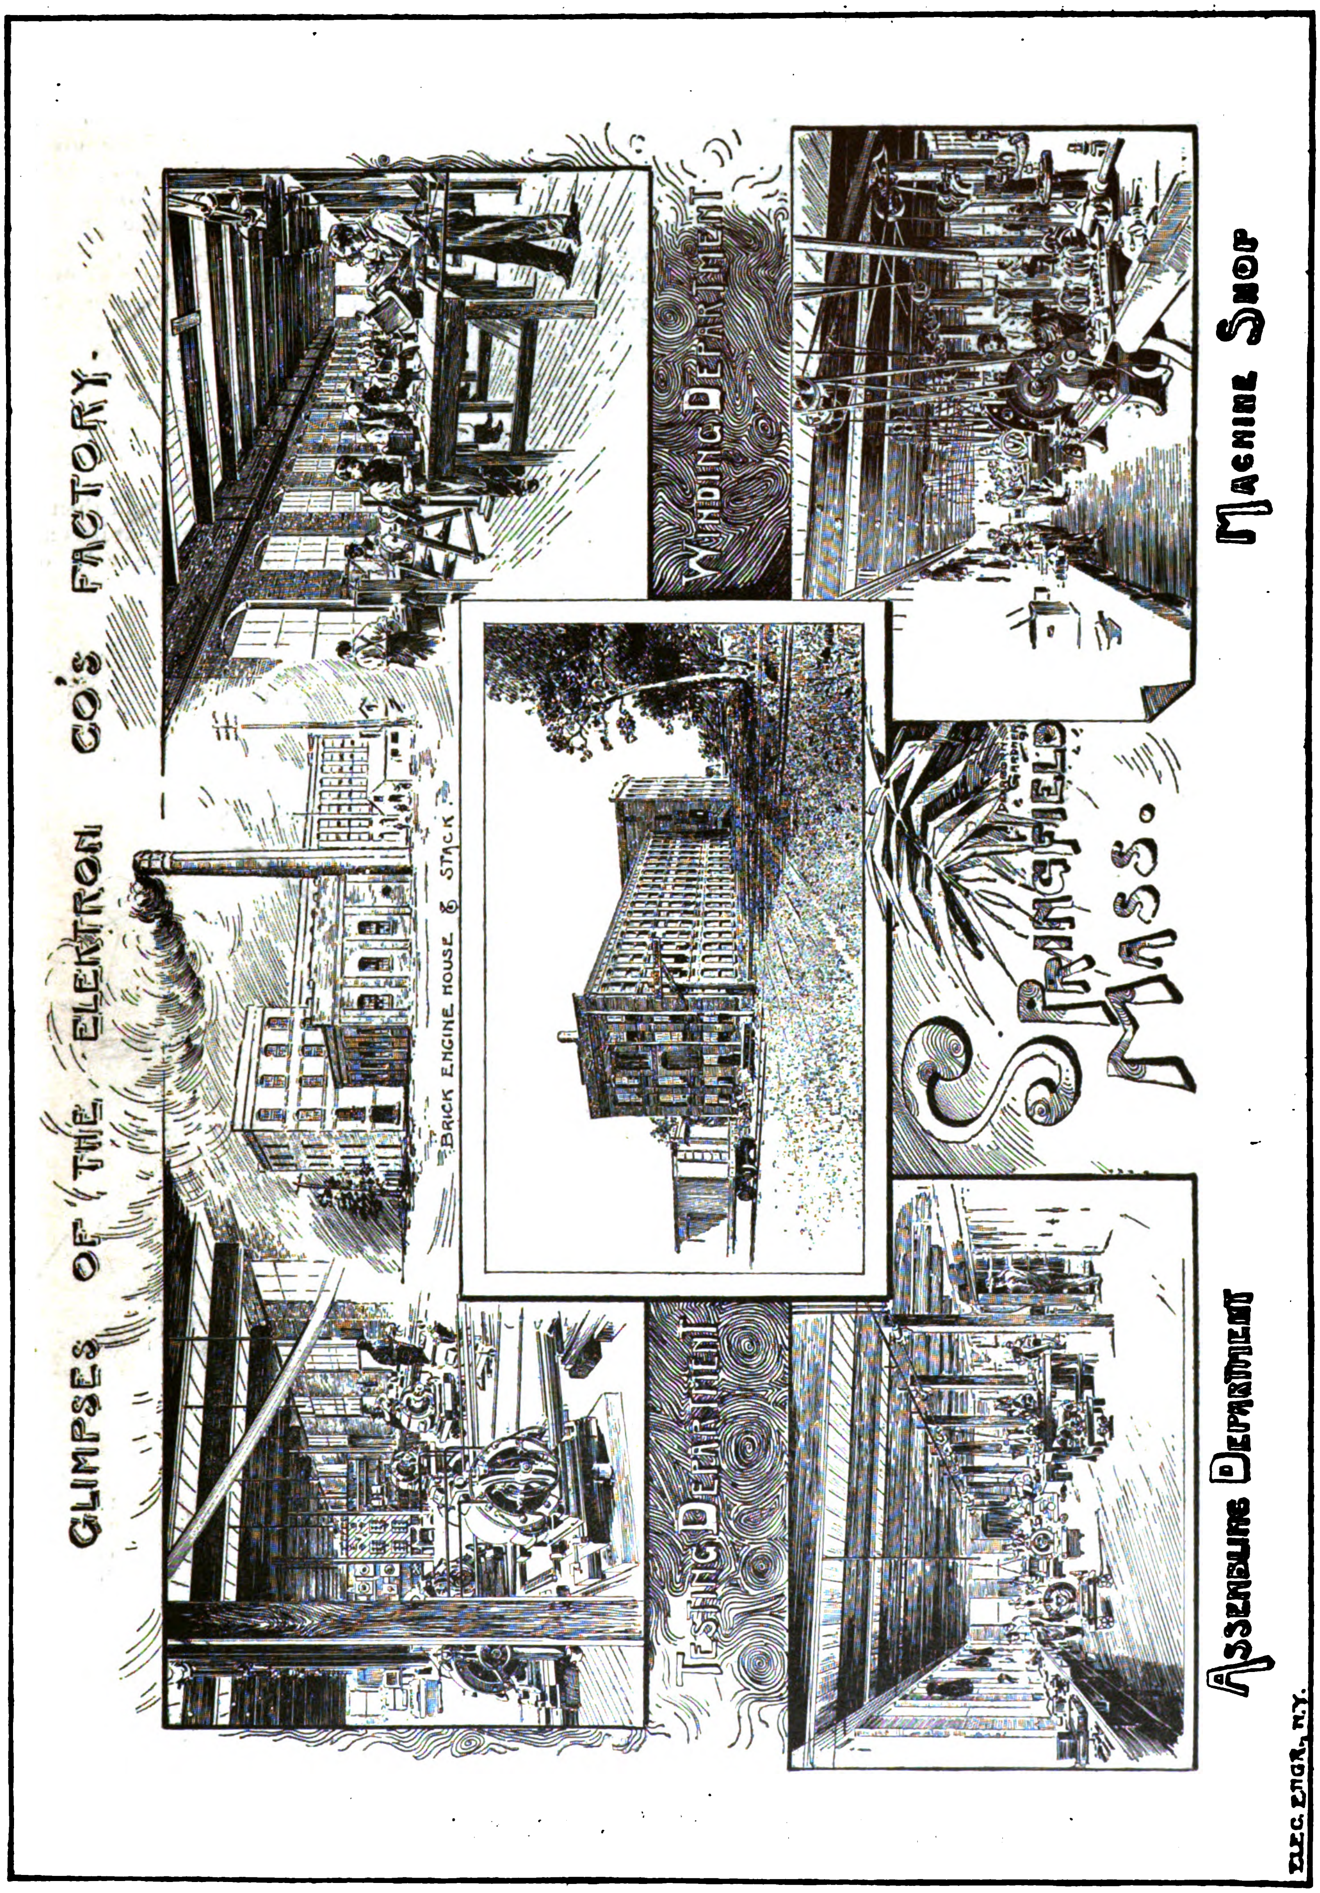

FIG. 2.—TESTING, WINDING, ASSEMBLING AND MACHINE DEPARTMENTS, ELEKTRON FACTORY, SPRINGFIELD, MASS.

ducts, as well as speed in their production. Notable among these is a special turntable "monitor" lathe, built by the Jones & Lamson Machine Works, of Springfield, which is able to take the heaviest cuts from stock and to screw thread shafts up to two inches in diameter in one operation. This machine alone performs practically automatically the work of a number of ordinary lathes attended by machinists, and on a size of work never heretofore attempted, with, of course, a large saving in time.

The engraving, Fig 2, shows the section of the machine shop devoted to the lathes and planers. On this floor also are situated the heavy presses for stamping out the sheets from which the armature and field magnets are built up. Our engraving, Fig. 3, shows one of these presses, which are able to stamp out the largest sized sheets required, and in the lower left-hand corner is shown the single stamping of the field magnet. The presses are placed close to the windows and the iron is dumped from the cars directly into a chute through the windows of the shop on to the floor. Here it is first cut up into suitable strips and then fed into the presses. Only the softest decarbonized steel is employed for this purpose, which has been rolled and pickled, and this quality of iron is used for both the armature and the field. Here we also find a well-regulated tool-room and a fireproof tool vault where the expensive dies and other standard jigs and gauges are stored, by which the work is constantly standardized in its progress and the tools kept to their correct size by comparison with the originals. The basement floor also contains the stock room where all raw material, such as castings, iron, brass, sheets, fibre and drop forgings, are kept in quantity and drawn from as the demand warrants.

Close beside this we find the room devoted to nickel plating and dipping, which the company has installed in order to avoid the delays frequently encountered in having this work done outside, and here also the polishing of the finished parts in brass is carried out. The freight elevator which passes up through the entire height of the building has its lowest landing on this floor, and is so arranged that trucks bringing in raw material back right up and deliver their goods directly upon the elevator platform, whence they are raised to the floor desired without further handling.

IV.

We will now ascend to the top floor of the building and trace the course of the work as it steadily proceeds towards the assembling-room below. This floor is devoted to the construction and winding of the field magnets and armatures.

The first operation in the construction of the field magnets is to punch the plates from the softest sheet iron that can be possibly obtained, which operation has just been described. The round holes through these plates are very carefully located and a number of the plates are then clamped together by bolts through the holes and with nuts on the same to form a field magnet, shown in Fig. 4. This constitutes one of the distinguishing features of the Perret machines, namely, that the magnets are built from plates of sheet iron instead of being made from a solid casting or forging.

The magnets thus constructed are then sent to the insulating-room where the magnet heads are applied and the magnet core and heads are thoroughly insulated by several thicknesses of canvas and tough paper prepared especially for this purpose and thoroughly shellacked.

The magnets thence pass to the winding-room where they are mounted between centres and revolved, the wire being wound on insulating and fire-proof spools, being guided by an attendant. This operation is well shown in the engraving, Fig. 4, which shows a coil almost completed.

After the magnets are wound, they are placed in a steam box and baked at a temperature of over 250 degrees until the shellac has been perfectly dried in place. Much inconvenience has been experienced in motor work, and, indeed, not a few troubles have developed, from the fact that the condition of the coils to be dried was not ascertained while the coil was in the oven. In order therefore to have an absolute means of ascertaining when the baking process is complete, the following arrangement has been adopted: Wires from the testing-room are led into the oven, one end grounded and the other touching one terminal of the wire coil. In the testing-room, one terminal is also connected to ground and the other connected to the coil in the oven. Upon closing the circuit there will evidently be a deflection if the coil has not been thoroughly baked, and the coils are thus always allowed to remain in the oven until the galvanometer shows that they are thoroughly dried. This method leaves no room for doubt and not only insures the perfection of the operation, but also saves time by allowing the coils to remain in the oven no longer than is absolutely necessary.

The coils are finally filled with shellac and then again dried. This process is so thoroughly done that it is almost impossible for any moisture to enter the coils of the magnet.

V.

While this work has been going on in the winding-room, the cast iron frames upon which the magnets are mounted have been finished in the machine department. These end frames carry the bearing in which the armature shaft revolves, and are plainly shown in Fig. 5.

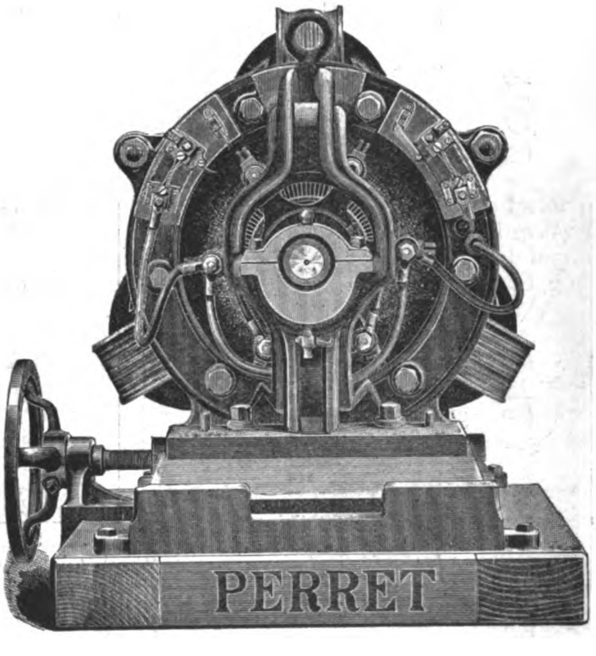

Fig. 5.—End View of Perret Low Speed Multipolar Motor.

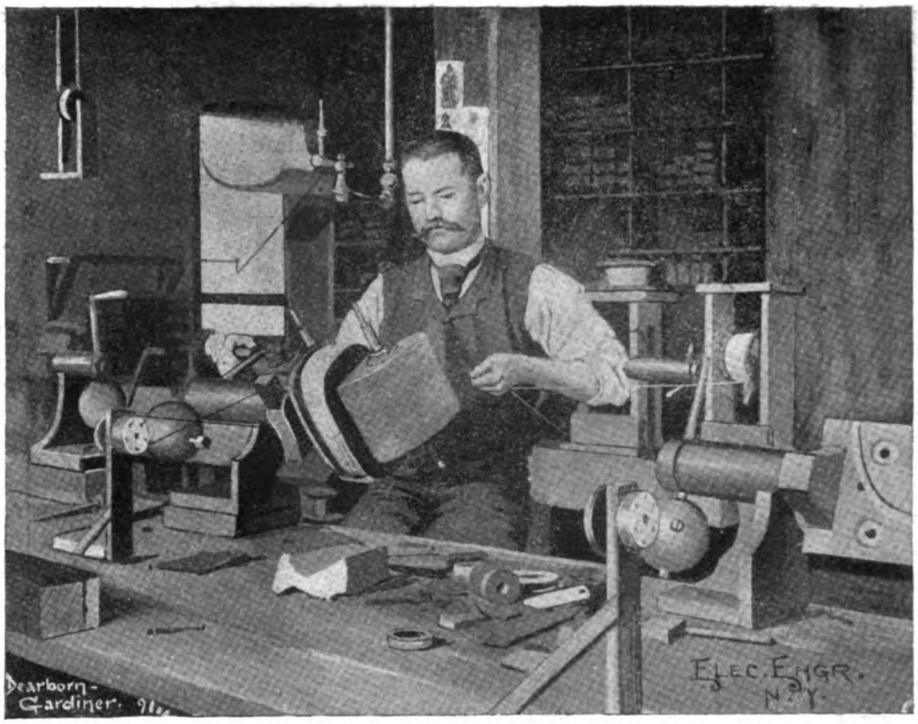
The same bolts which pass through the plates of the magnets binding them together, project through holes accurately located and drilled through the end frames and thus the field magnets are supported in perfect alignment with the armature.

There are three field magnets arranged at equal distances around the periphery of each armature. A bolt passes through the polar portions of each field, making two bolts to each magnet, six to each machine. The ends of these bolts are plainly seen projecting through the frame in the end view, Fig. 5.

The cast iron end frames are now bolted upon a cast-iron base which has been prepared to receive them. This base is so constructed that it slides in two cast iron ways or tracks which are bolted upon a wooden-base frame. The hand-wheel and screw are designed to force the machine in either direction on these tracks in order to loosen or tighten the belt which runs on the pulley of the machine.

The bearings of each machine are provided with a simple device by which they oil themselves. It consists of a brass ring of larger diameter than the shaft and which hangs upon the shaft inside the bearing and dips down into a chamber filled with oil. When the shaft revolves the ring revolves slowly and keeps the shaft constantly oiled. The only attention required is to change the oil every week or two.

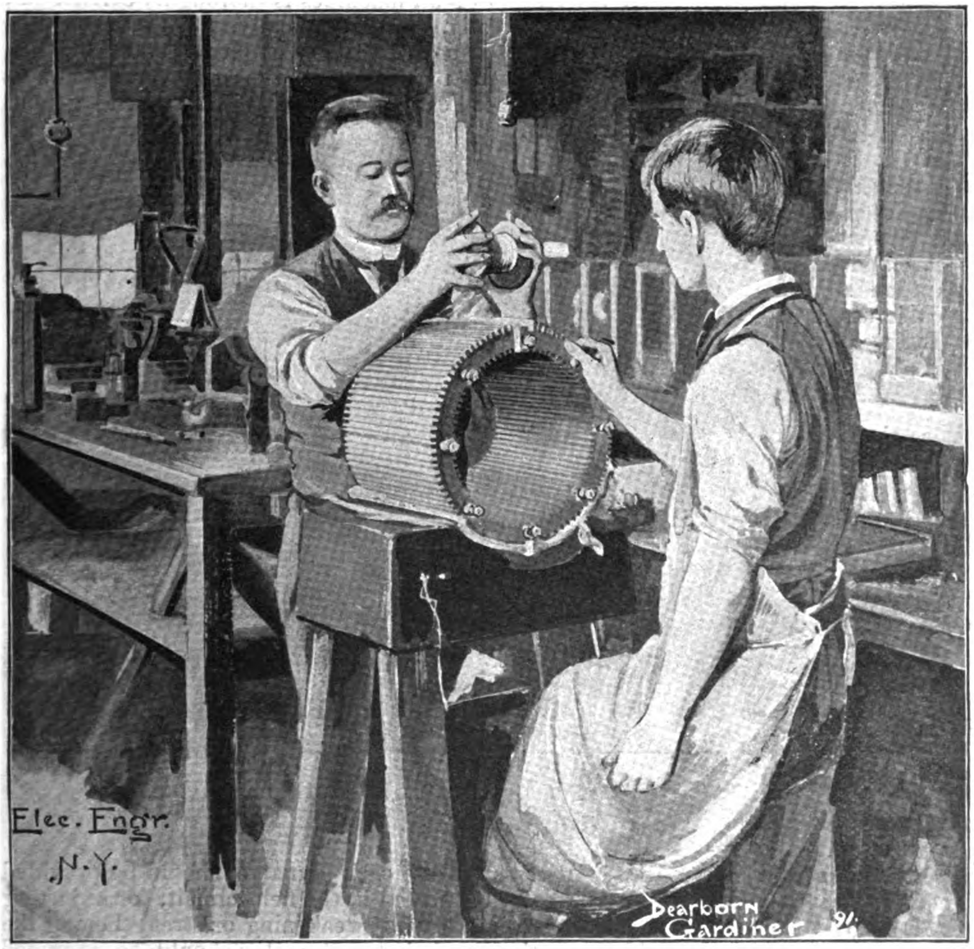


Dearborn-Gardiner. 91.
Elec. Engr. N.Y.

Fig. 4.—Winding a Perret Field Magnet.

VI.

The armature, that most important part of every dynamo-electric machine or motor, receives the most careful consideration in the Elektron Works. Its construction is commenced by cutting off a round bar of best quality steel to the proper length for the shaft and then carefully turning it in a lathe to the proper diameter; after this, keyways or slots are cut in it by which the armature proper and the commutator may be mounted upon it. The plates are then punched out with which to build the armature core, being punched from the same quality of sheet iron as the field magnet plates. In order that the machines may be very efficient it is necessary that this iron should be of very high magnetic permeability.



Elec. Engr. N.Y.
Dearborn Gardiner 91.

Fig. 6.—Winding a Perret Armature.

The armature plates are ring-shaped with teeth on both the outside and inside of the ring. The appearance of the armature core after being built up from these plates by bolts passing through them is shown in Fig 6, and the channels formed in the periphery of the core by the teeth on the plates may also be clearly seen. The plates are held together and formed into a cylinder by screwing up nuts firmly on the ends of the eight insulated bolts which pass through them; and these same bolts serve also to attach the armature to the shaft by means of a disc or "spider" of gun metal at each end. Each spider is bored out to fit the shaft and has eight holes bored to fit the eight bolts.

The armature core is now ready to be insulated and wound. The insulation is very simply effected by means of what may be called a trough of insulating material which is slipped into each channel on the outside and also on the inside of the ring, after which a spool of magnet wire is taken and the winding is commenced. For each channel on the exterior of the ring there is a corresponding channel on the inside, and the depth and width of these channels are just right to contain the proper number of turns of wire.

The method of winding is clearly shown in the illustration, Fig. 6, one man drawing the wire through on the inside and the other pulling it over on the outside until the channel is filled. After filling one channel the end of the wire is passed onward to the next.

It is of the utmost importance in electrical machines that the wire shall be of sufficient size to carry the full current without heating and that it shall be so perfectly insulated that there shall be no contact between adjacent wires or with the iron core of the armature. Also that it shall be held so rigidly that it cannot be shifted out of place by any strain that may be thrown upon it. This is all facilitated by the plan of winding the wires in channels instead of winding on a smooth round periphery as is sometimes done. After the winding of the armature is completed it is dried, shellacked, and dried again, the same as in the case of the field magnet.

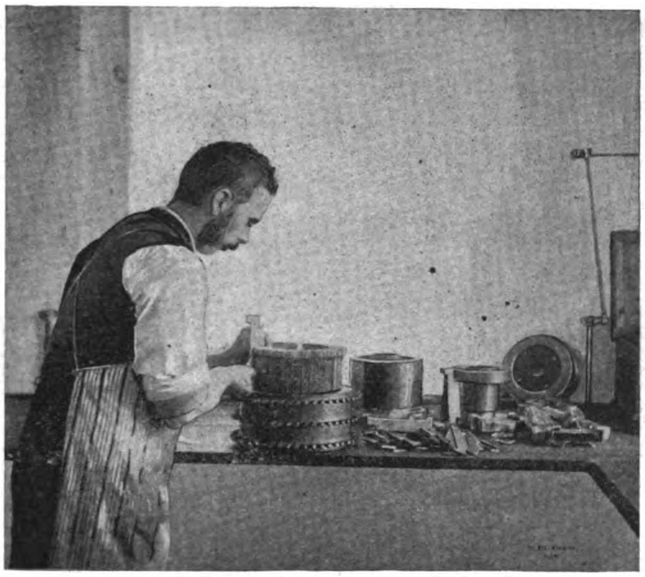


FIG. 7.—BUILDING UP A COMMUTATOR.

In order to mount the armature upon the shaft one of the spiders which we have previously described is bolted to each end of the armature ring by means of the same bolts that pass through the core and clamp the plates together, and the whole is then slipped upon and keyed to the shaft. The commutator is then slipped upon and keyed to the shaft.

VII.

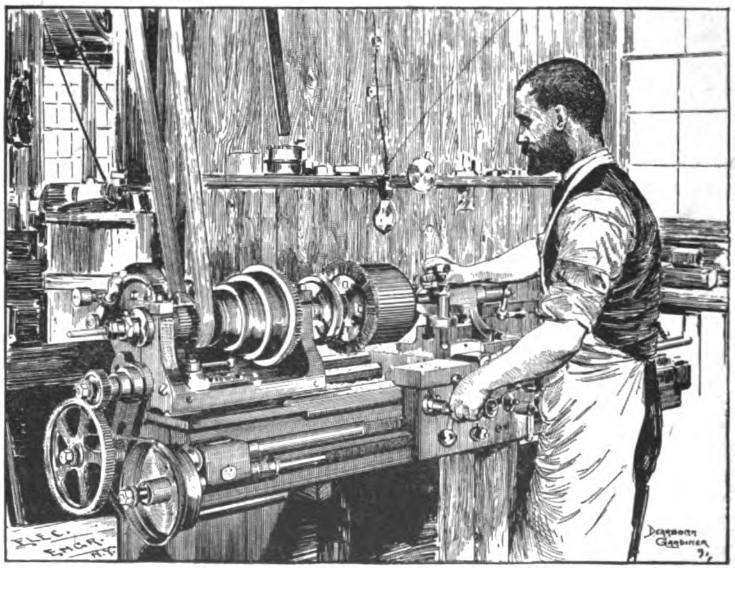
The construction of the commutator, the tender spot in every continuous-current machine, is an operation requiring the greatest care. A single error, which might not appear on the surface, might be enough to cause serious trouble in the working of the machine. The method here adopted is illustrated in Fig. 7, showing the process of building up a commutator from the copper segments, a pile of which may be seen on the bench at the workman's right. Each of these segments must be set in its exact place inside the ring-shaped fixture, and it must be thoroughly insulated by a solid layer of best quality mica from every other section and also from the two end discs between which it is clamped. When all put together the commutator has the appearance shown in Fig. 8, which shows it mounted on a mandril undergoing its final turning in the lathe. The segments are all formed of the purest copper, and are provided with lugs which are slotted to receive the armature coils. Fig. 9 (page 1) shows the armature of a 20 h. p. motor and commutator for the same mounted on the shaft, which is supported upon a "horse," while the workman is engaged in soldering the armature coils to the commutator segments, an operation requiring considerable care and skill.

One of the most interesting features of the Perret machines lies in the fact that for all sizes of the machine between 4 and 20 horse power, but one diameter of armature, namely, 14 inches, is employed, the various sizes being built up by increasing the length of the armature; and in a like manner increasing the width of the pole-pieces by adding more sheets, according to the length of the armature. The great economy effected by this method of construction is so obvious as to need no further pointing out, and it will also be conceded that the designing of the teeth to meet the requirements of the space required by the various sizes of wire with which each machine is wound shows the highest skill in the design of the machine.

VIII.

We now descend to the floor below, where we find the assembling department. Here the heavy parts of the machine are brought up from below, and the magnets and armatures brought down from the floor above, where they are assembled, the parts being fitted together and bolted into place. Upon these operations our engraving, Fig. 10, shows a workman engaged, fitting brasses to the bearings of the motor. After this fitting it only remains to place the armature in position, connect the wires and start up the machine.

The motor is now ready to be transferred to the testing department, which is also situated on this floor, and a view of which is shown in Fig. 2. This testing department still employs, as a generator, the first 15 h. p. multipolar Perret machine built, and its continuous active service is probably as good a proof as could be found of the general excellence, both in design and workmanship, of this machine. Here the testing of all machines is thoroughly carried out, not only electrically, but mechanically. For the latter purpose an Emerson power scale is employed and every machine is put through a continuous run of several hours at more than its rated capacity before it is allowed to go out of the works.

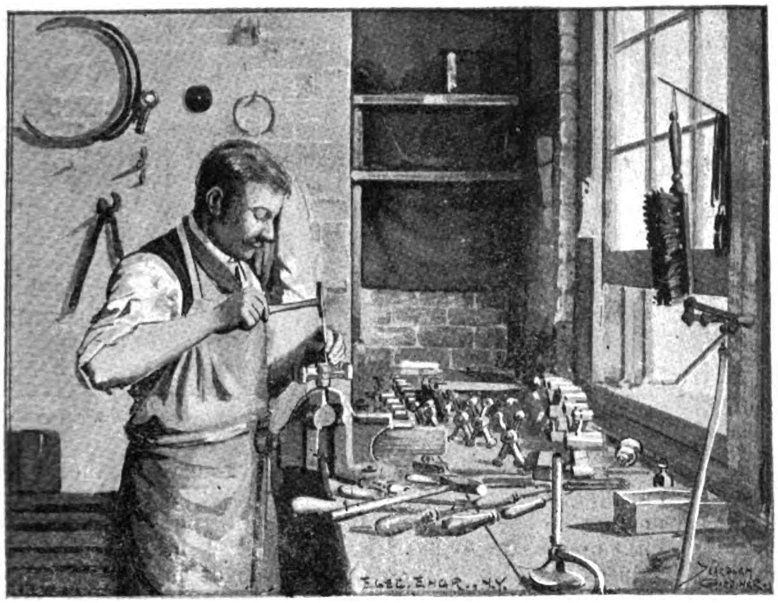


ELEC. ENGR. N.Y.

FIG. 8.—FINISHING COMMUTATOR IN LATHE.

IX.

It is necessary that each dynamo should be provided with a rheostat connected in the field circuit, for adjusting the electromotive force by weakening or strengthening the field magnetism, and that each motor should be provided with a rheostat or starting box in the armature circuit to



ELEC. ENGR., N.Y.

FIG. 10.—FITTING A MOTOR BEARING.

prevent an excessive rush of current on starting up the machine. The construction of these rheostats has been the subject of special study in order to provide an apparatus which should be absolutely incombustible. The necessity of this is evident when it is considered that machines are frequently placed in the care of ignorant persons, and rheostats intended to be placed in circuit for a few moments only, are left with the full current turned on for hours. As a result of this experience, the Elektron Co. make all their rheostats and starting boxes entirely of non-combustible material. The resistance coils are of German silver or galvanized iron wire, which are supported in the iron box by porcelain bushings, and the contact plates are of brass on a slate base. The engraving, Fig. 11, shows the method of conducting these rheostats, which have now become one of the standard products of the Elektron Co.

X.

A very important point in connection with all dynamo machinery is the brushes, and this has also engaged the special attention of Mr. Perret. Instead of using a solid carbon block a series of carbon pencils are employed, where the work to be effected is light and intermittent in its nature. For heavy and constant work, however, Mr. Perret has found the carbon block to be most efficient, when certain precautions are observed. Principal among these is the securing of a good connection between the carbon and the circuit wire. For this purpose the carbon brush is connected directly to the terminal wire by a short length of flexible cable, so that, having free movement under the influence of the springs, it forces itself against the commutator, the spring and the holder in which the carbon slides not being called upon to carry any of the current. The result is that the heating noted at the brushes where the latter take their current from the holder direct is practically overcome. Where the voltage is under 110 volts and heavy currents are to be carried, Mr. Perret still prefers the copper brush.

XI.

The engravings, Figs. 5 and 12, show the standard Perret multipolar dynamos and motors, as at present constructed. In all essential points the construction is the same as that of the first machine which was brought out about two years. The only changes which have been found necessary have been in the minor details of the frame. In this respect the machines are quite remarkable and are a constant testimony to the genius of Mr. Perret as a designer.

The production of the company consists very largely of these multipolar machines and during the past year the demand for them has been rapidly increased, not only for use as motors but also as dynamos for isolated plants, for which purposes they possess unusual advantages by reason of their high efficiency, perfect regulation and the small attention required. In these machines the reduced speed is obtained without increase of weight or of space over the ordinary, and for this reason the dynamos are in great demand for places where economy of space is important, as on shipboard.

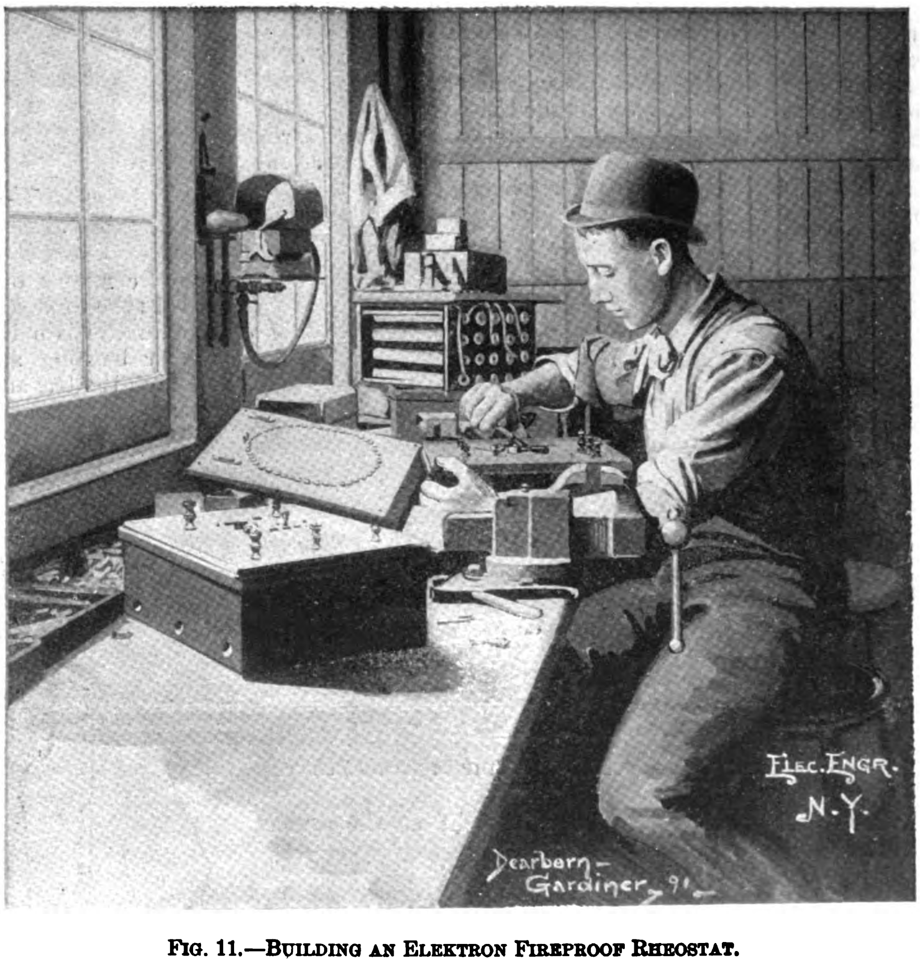


FIG. 11.—BUILDING AN ELEKTRON FIREPROOF RHEOSTAT.

One of the most important attributes of any machine, whether used as a dynamo or as a motor, is its regulating qualities. For incandescent lighting the desirability of closest regulation is obvious, and on the other hand, an electric motor whose speed is not uniform at all loads does not fill the requirements for most purposes. Perhaps the best way of demonstrating the regulating qualities of the Perret machine was that embodied in a test shown to the writer at the works of the company during a recent visit. The machine in question was coupled direct to a steam engine, the plant, illustrated in Fig. 13, being intended as a marine electric lighting plant. At the writer's suggestion the machine was loaded to its full capacity and the main switch opened and closed successively. In neither case could a variation of more than a small fraction of a volt be detected upon a Weston voltmeter. This type of marine plant will shortly be installed in a number of yachts and steamships, and it is safe to assume that it will form an important branch of the business of the Elektron Company. Certainly every one noting such a test must be impressed with the perfection to which the regulation of dynamos and motors has been brought at the present time.

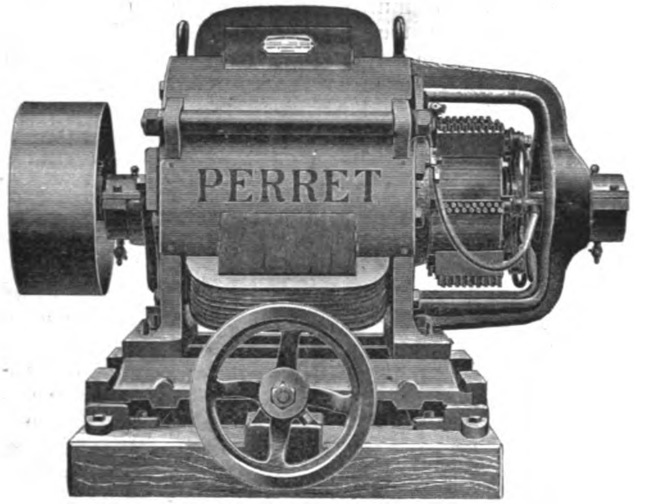

FIG. 12.—SIDE VIEW OF PERRET LOW-SPEED MULTIPOLAR MOTOR.

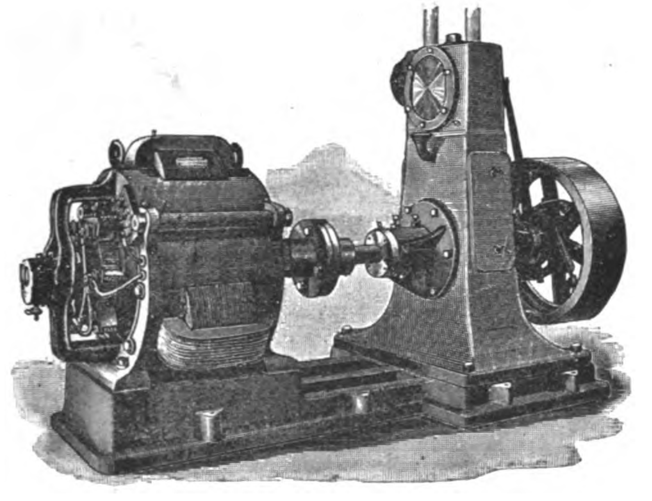

FIG. 13.—DIRECT CONNECTED PERRET SHIP LIGHTING PLANT.

XII.

There are many situations in which a machine developing from ¼ to 2 h. p. is required, and for this purpose the type illustrated in Fig. 14 has been designed and is regularly built at the Elektron Works. It is of the bi-polar type and, like the multipolar machines, has both its field and armature built up of soft laminated iron.

"Not a little attention has been bestowed by Mr. Perret upon the design of motors for small powers, such as the driving of fans, sewing-machines, jewelers' lathes, etc.

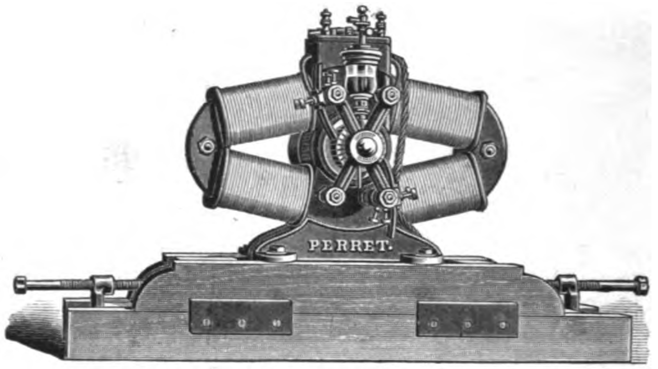

FIG. 14.—TYPE OF ¼ TO 2 H. P. PERRET MOTOR.

The same principles which have led to success in the larger machines are also embodied in these. Fig. 15 shows the manner in which the field magnets of these pygmies are built up and Fig. 16 shows a Perret ⅛ h. p. fan motor mounted on a base. Special methods of manufacture are employed in the construction of this type. For the small size of commutators employed on the fan motors, the dovetailed type of segment is not employed. In its place the commutator is built up by placing the segments on a hard rubber bushing and driving in brass pins at the ends through the bar and into the fiber. This holds the segments securely, and largely reduces the cost of manufacture. One of the features of the armatures of these machines is the peculiar spiral form given to the grooves in which the wires are wound. The pitch of this spiral is so

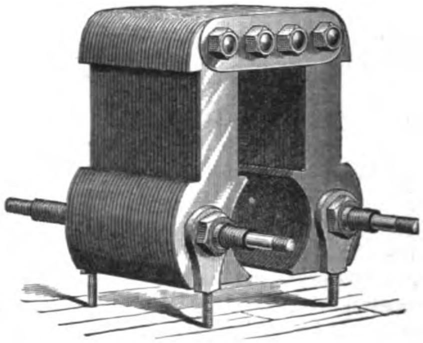

FIG. 15.—FIELD MAGNETS OF SMALL MOTOR.

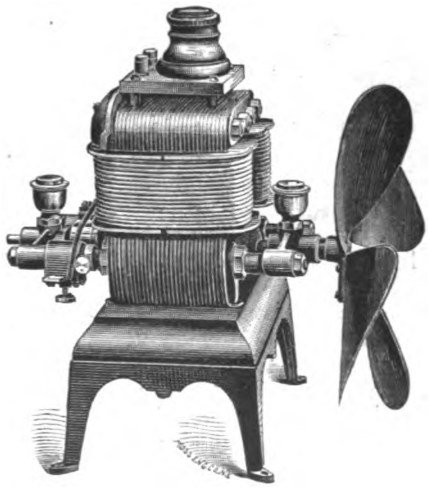

FIG. 16.—⅛ H. P. FAN OUTFIT.

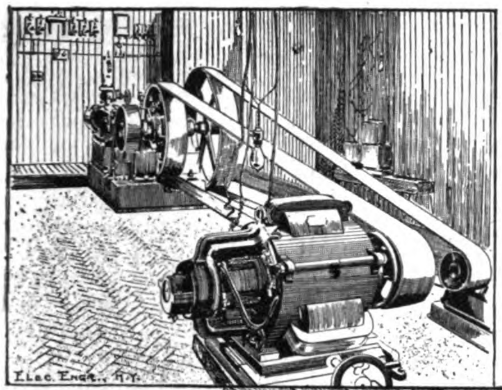
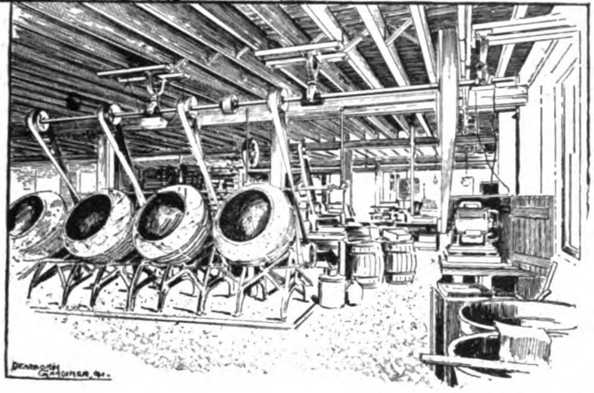


ELEC. ENGR., N.Y.

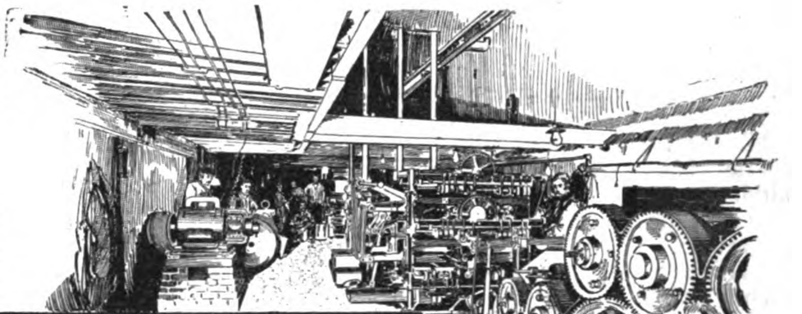


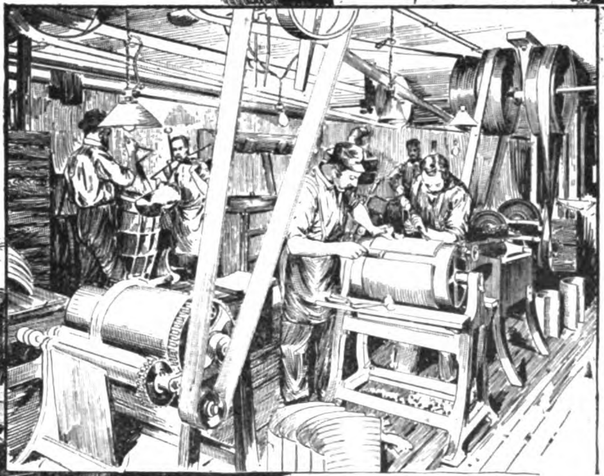
arranged that the end of one tooth leaves the edge of the pole-piece at the instant that the beginning of the next comes under it. In this way the lines of force emanating from the pole-piece are not broken abruptly, as would be the case if the teeth were parallel with the edge of the pole-piece, and as a result the action of the motor is smooth, heating of the pole-pieces is avoided, and a great deal of noise dispensed with.

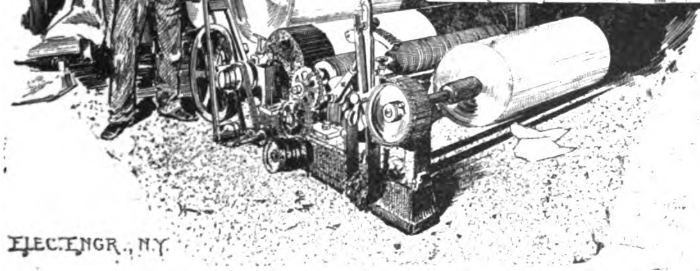
XIII.

Among other things indicating the progressive spirit of the Elektron Company is the arrangement which has been entered into by them experimentally with the Springfield Trade School. Under this arrangement the company receive into their shop twenty apprentices or students, and agree to give them the opportunity to learn the machinist's trade during a period of three years, during which the young men work in the shop one-half time and devote the other half to a special course of study in such branches as would be of most service to them in the mechanical line. The students are grouped into two divisions, one of which works one day in the shop and the other the next day and so on.

It has been a cause for regret that there has seemed to be in our present industrial system nothing to take the place of the old apprentice system which has practically passed out of existence, but this arrangement at the Elektron shops, if it proves successful, and it now appears so, will prove a solution of the problem. At all events the scheme is creditable both to the managers of the Elektron Co. and to the school. Of course the number of students at work at one time must of necessity be confined to a small percentage of the whole number of the employees, as it is not practicable to do a very large proportion of the work by students. But this new departure seems to us one of the most hopeful that has been made of late years in regard to the training of artisans, and we think it will be closely watched by economists of all schools.





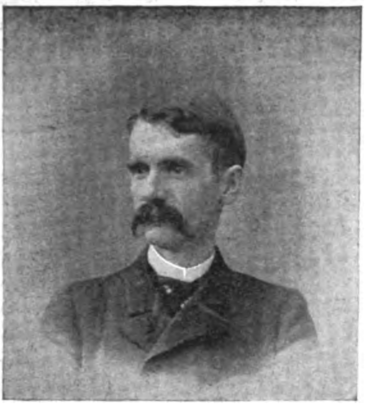


ELEC. ENGR., N.Y.

FIGS. 17 AND 18.—A NEW ENGLAND CANDY FACTORY, AND THE PRESS ROOMS OF NEW YORK COMMERCIAL ADVERTISER. OPERATED BY PERRET MOTORS.

XIV.

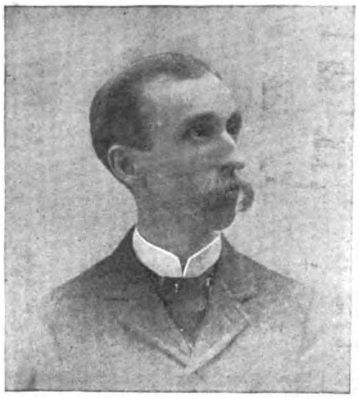
Two features are conspicuous in the construction and operation of nearly all American mills and factories at the present time. If steam is the means of distributing motive power, long and heavy lines of shafting obtrude themselves upon the eye, combined with an endless maze of belts; and the mill itself hugs closely the railroad from which it derives its supply of fuel. If water is the prime energy, not only is the mill festooned in belting but it is huddled down close to the stream, sacrificing light and air for the sake of getting power cheaply. Hitherto it has been taken for granted that these and allied conditions are permanent and must be dealt with in all power transmission within buildings. The assumption is, however, so far from the truth that new mills equipping for power transmission by other than electrical methods may safely be said to illustrate the ideas of the past rather than the practice of the future; and the work of transformation and transition has already been begun with such vigor that even now the adoption of electric motors for mills and factories promises to be as rapid as was the introduction of the electric light. But ten years ago the use of electricity as an illuminant in a mill was still a decided novelty, not a little scouted and frowned down upon. To-day it is without a rival in popularity. A similar course of events may be looked for with regard to the use of electricity for power



W. D. Sargent.

transmission, except that the stages of advance will be the more rapid because in a great many instances the existing circuits for lighting are of capacity enough to carry ample current for motors also.

The work of the Elektron Company furnishes more than one example of this peaceful revolution now going on, and that which we here illustrate in Fig. 17 is typical in many respects. The cut shows the factory or B. H. Douglass & Sons, at New Haven, Conn. The business of this company is the manufacture of confectionery. The entire factory is operated by electric power, the plant being installed by the Elektron Company, from the plans and under the superintendence of Mr. George G. Grower, electrical engineer, of Ansonia, Conn. One of the views here given shows the 25 h. p. steam engine belted to a Perret generator, which is compound wound for 110 volts and supplies current to the Perret motors located in various parts of the works. The dynamo and the motors are all of the six-pole, low-speed type. The 4 h. p. motor on the first floor operates the elevator. A 2 h. p. on the second floor drives blowers and machines used in the manufacture of fruit tablets, which are here made in great quantities. On the third floor a 4 h. p. motor drives two cocoanut grinders; another 4 h. p. motor is used for stirring candy in the steam kettles; while the 7 h. p. motor shown in our other view is used to rotate what are called the plum pans, seven in number, although only four of them are included in the engraving. This plant has now been in operation about nine months, with a marked saving in coal consumption, and with a keen appreciation of the many advantages that electric power brings with it.



E. H. Cutler

XV.

So interesting and important is this work of electric power distribution that we may be forgiven if we direct attention to another striking plant installed by the Elektron Co., who have the honor, unless we are greatly mistaken, of being the only motor builders whose machine prints a great metropolitan daily newspaper. Our illustration, Fig. 18, shows the press rooms of the *Commercial Advertiser* of this city, where a 20 h. p. slow-speed Perret motor runs a large portion of the establishment. Early this year the idea occurred to Mr. Harold Godwin, then editor of that century-old evening paper, that it would be an advantage to use electricity to run his presses, and he did the editors of THE ELECTRICAL ENGINEER the honor of consulting them on the subject. Encouraged by the advice and information he received, Mr. Godwin lost no time in making his arrangements, and on taking possession of a large new office he installed the Perret motor, together with a Corliss engine of 50 or 60 h. p. which was to operate the supplementary apparatus and to answer as a reserve. The electrical plant was put in last April, and was started almost immediately. The equipment of the pressroom comprised a large Hoe perfecting press, capable of throwing off 25,000 copies an hour, two Cottrell presses, capable of printing 15,000 an hour each, and one wetting machine, all these being on one floor in the basement, in Park Row, and driven from a main shaft directly from the motor, without the intervention of any countershafting. Besides these heavy pieces of mechanism, there were on the floor above an outfit of regular stereotyping machinery and a 48-inch ventilating fan, all run by the same motor.

This Perret motor was put in by Mr. Godwin to run the single Hoe perfecting press, but it tackled that load with such a light heart that the two Cottrell presses were added. On a sudden emergency, when no steam was available, the wetter, stereo-machines and fan were also heaped on its sturdy back, but it shouldered the whole so satisfactorily that the practice has been continued. Shortly after this plant was started, Col. Cockerill bought the *Commercial Advertiser* and started the *Morning Advertiser* which has already secured so firm a footing among the popular morning dailies of New York, and for a time the motor printed both the morning and the evening editions. But the success of the morning paper soon outran the old facilities and lately a big new Hoe press has been added to which the spare Corliss engine has been connected so as to get the full benefit of the existing equipment. The Perret motor has, however, made a most striking success in keeping with the progressive journalism that it has been called upon to aid; and it is believed that at no distant date electric power will handle not only the *Advertiser* but other large dailies in this city. It may be added that the motor is on the regular 110 volt Edison circuit and draws current from the old mains along Park Row. As the readers of THE ELECTRICAL ENGINEER are aware, the use of electric motors in printing offices, thanks to the increasing availability of electric cnrrent, is growing rapidly in the larger cities of the Union, a fact which speaks volumes for the motor, in view of the delicate and difficult nature of the work, which compares in many respects, and especially in its rapid variations of load, with street railway work.

Frank A. Perret.

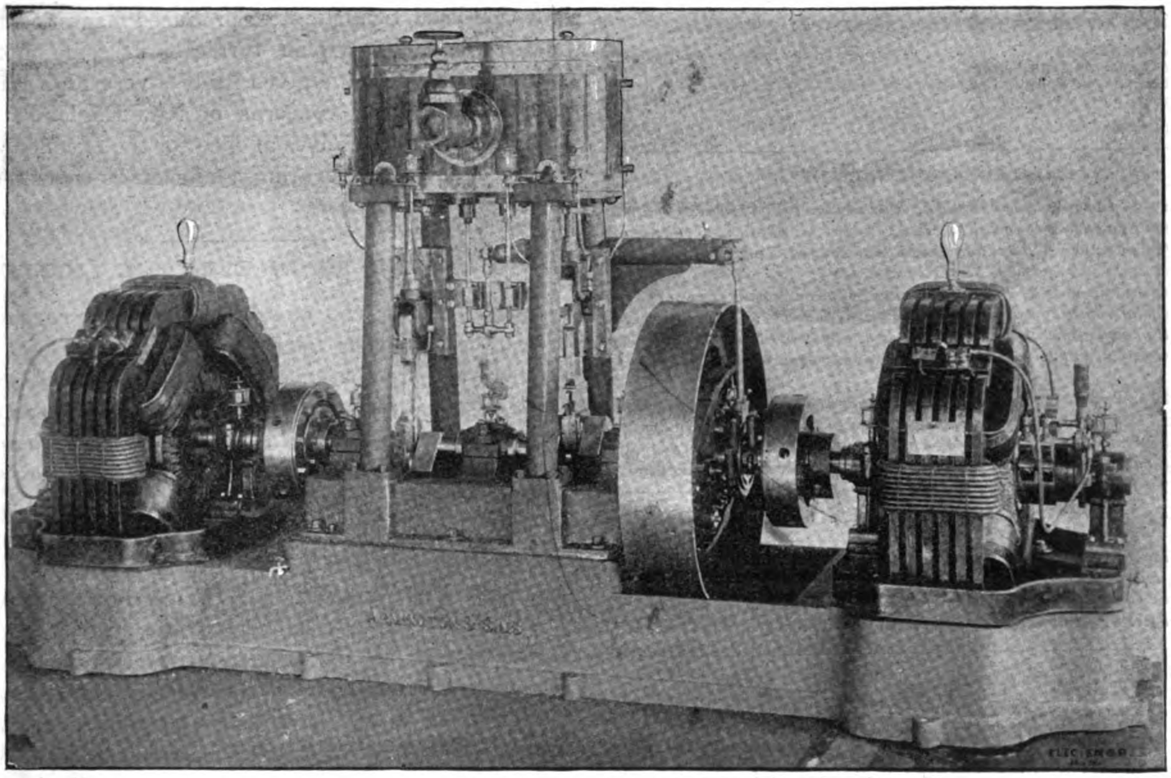
XVI.

A word by way of conclusion may not inappropriately be devoted to the personnel of the management of this progressive company, and we are glad to present here portraits of the leading officers. The president, Mr. W. D. Sargent, is not only an old telegrapher, but a pioneer telephonist, and is actively connected at the present time with the telephone companies of Long Island and New Jersey. Mr. E. H. Cutler, the treasurer and manager, has been associated with the company from the inception, and the same is true of Mr. Frank A. Perret, its electrician and electrical engi-

Leon J. Harley.

neer. Associated now with these gentlemen is Mr. Leon J. Harley, as general superintendent, a position for which a long training in the manufacture of small arms qualifies him in a special manner. The company have as selling agents, J. U. Burkett & Co., in Washington; George Baquie, in New Orleans; the Electrical Engineering Co., in Chicago; F. J. Renz, in St. Paul, and the Pennsylvania Machine Co., in Philadelphia. They have also large offices in New York under the care of Mr. Robert Watson, among whose installations may be named one of 185 lights in the building on Liberty street, where his headquarters are established, and through whom the company now have orders on hand for the equipment of a number of steamships with dynamo and engine coupled direct on one base.

The number of Perret motors now in operation in all parts of the country will figure up to several thousand and they are used for every conceivable purpose. Most of these machines are shunt wound for giving constant speed in cases where this is an important requirement, but there are many in operation that are wound to suit special work.



New Thomson-Houston Direct-Connected Marine Plant, with Armington & Sims Engine.

NEW THOMSON-HOUSTON DIRECT-CONNECTED MARINE PLANT.

We illustrate in the accompanying engraving the combination of the Thomson-Houston multipolar marine dynamo with the double upright Armington & Sims engine, connected directly to the armature shaft by an insulated flexible coupling. This combination has, it is claimed, in the opinion of the Naval Board of Electrical Experts, shown greater efficiency than any other combination of the kind they have ever tested. Over sixty of these plants have been constructed which have been illustrated and described from time to time in the Engineer. A slight change has, however, been made from the single to the double dynamo in the steamer "Fairfax" of the Merchants' and Miners' Transportation Co.

The object of the builders was to furnish a plant as compact as possible, and the preliminary test indicated that the departure had been successful. The floor space covered by the engine and dynamos is three by ten feet, a saving of nearly one-half as compared with steamship plants previously furnished. This economy of space was gained by coupling two dynamos to one engine.

The dynamos are of the Thomson-Houston multipolar marine type, 110 volts, and each has a capacity of 10,000 watts. Both dynamos will be in service when it is desired to call into use the entire capacity of the ship, and in addition to lighting the vessel, they will supply a search light of 4,000 candle-power which is automatically operated from the pilot house. By the search light, buoys can be located from three-fourths of a mile to a mile, and the lights can be seen at a distance of fifteen miles from the vessel.

The dynamos are driven by a seven by five inch double upright Armington & Sims engine, which has a speed of five hundred revolutions a minute. The entire marine plant, which weighs seven thousand pounds, is a duplicate of those furnished the Navy Department for the new cruisers, one to three of which were placed upon each vessel. There is this difference, however; the Government engines have one dynamo connected to each engine by a flexible coupling, while the electric plant of the steamer "Fairfax" has a dynamo directly connected to each end of the engine shaft. This plant has been installed and is now in successful operation.

THE ELECTRICAL UTILIZATION OF WATER-POWER AT MARBURG.

A project is on foot, suggested by the success of the Lauffen-Frankfort experiment, for conveying 600 h. p. by electricity from Marburg to St. Lorenzen, a distance of 18 miles. A head of water, over 200 ft., is available at the former place.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JANUARY 6, 1892. NO. 192.

It cannot be impressed too forcibly, both upon the student in mechanics and upon the workman, that accuracy of measurement is essential for good and efficient workmanship, and that it tends to economy in all branches of manufacture.—Sir Joseph Whitworth.

THE ART OF MOTOR BUILDING.

THE electric motor industry is still in its first decade, but it has made enormous strides and to-day constitutes one of the most active, popular and progressive fields of work in the whole domain of electricity. An evolution, strictly, of dynamo design and construction, it has yet developed many special features and principles of its own, the importance of which is daily proved in the highly ingenious and successful machines that furnish power to hundreds of different industries throughout the length and breadth of the land, either taking current from central stations or else constituting a part of some concentrated factory system of power distribution.

The art of motor construction is therefore to-day a new story, and the chapter of it presented in our description of a recent visit to the new works of the Elektron Co., at Springfield, Mass., brings out many points of great interest. The region in which these works are located is famous for the perfection of its small arms, and in various respects the electric motor belongs in the same category of fine work, intelligently designed and skilfully turned out. The motor industry, in fact, bears with its right on the sewing machine and small-arms branches of industry, and on its left is in touch with the heavy engineering of compound steam engines, and this range is one of its largest elements of promise.

A special point of interest in our article will be found in the description given of the manner in which the Elektron Co. has allied itself with the Springfield Trade School, so as to admit a limited number of students into its works for technical and mechanical training. This is an admirable departure—one, indeed, so new and novel that we do not quite see where it is likely to end. It is certainly a very ingenious and laudable attempt to give us the new system of apprenticeship of which this and every other manufacturing country so sorely stands in need ; and we are glad to know that so far it is working successfully. Nowadays we hardly expect any one to go through the old seven years of drudgery that belonged to apprenticeship ; but that hard, trying system produced magnificent artisans; and if the Elektron plan furnishes us some more of the old breed it will have given itself a very high rank among the manufacturing concerns of New England that have distinguished themselves at once for the excellence of their product and the elevating tendency of their social influences.

CONDENSERS IN ELECTRIC LIGHTING.

AMONG those who closely watch the progress of the times, the increasing importance of the condenser in nearly all electrical applications must have attracted more than usual attention during the last few years. This early adjunct to telegraphic apparatus has already vastly changed telegraphic methods and increased their scope, especially in submarine work; and it now bids fair to have a not unimportant bearing upon the future methods of electrical distribution of light and power. It is some years ago that Mr. S. D. Field and Mr. C. E. Fritts, in this country, and Doubrava, in Austria, called attention to the availability of condensers as direct-current transformers, at a time when the alternate-current transformer was fast occupying a field which it has now made peculiarly its own. But while thus early recognized in connection with direct-current distribution, recent developments indicate unmistakably that associated with alternate current distribution the condenser will find its more immediate and perhaps extended application. In view of this, the discussion of the condenser as a transformer of electric energy is eminently timely, and we therefore give the conclusions arrived at by Mr. Jas. Swinburne in an analysis of the subject. But besides their employment as pure converters, the important functions which they perform in alternating-current apparatus involving a lag of phase, such as we meet in the new types of alternating motors, give them an immediate interest of the highest order. If to this we add the possibility hinted at of obtaining the direct currents necessary for energizing the field magnets of alternating machines by means of condensers, and without a commutator, then indeed it must be admitted that the condenser is worthy of the most serious consideration. Nor must we forget the important part it is destined to play in the beautiful and almost ideal method of illumination of Mr. Tesla, whose experiments as detailed in his now famous lecture before the American Institute of Electrical Engineers show some of the difficulties met with in employing condensers at high potentials and frequencies. In this respect the condenser transformer will, without doubt, be made to conform to the most recent practice adopted in connection with the iron transformer, in that air will no longer be used as the insulating material, giving place in its stead, to oil. The cost of condenser apparatus for the various purposes alluded to, will to a certain extent be governed by the potentials employed, as this will determine their size, but the advantages which the use of the condenser will bring with it will probably offset this consideration in a large measure.

LOW-TENSION ALTERNATING CURRENTS FOR ISOLATED LIGHTING.

One of the earliest methods employed for isolated lighting purposes was the operation of low-tension alternating-current machines, a type which was adopted at the time principally for the reason that the machines were simple in construction and were claimed to give very good regulation. Our readers will remember that among those machines, the Ferranti-Thomson obtained considerable prominence about ten years ago. At present, however, this method machine is used for low tension. That there appears to be has been entirely discarded, and the continuous-current good reason for seriously reconsidering this method at the present time was, we think, well brought out in the interesting article by Mr. Horry appearing in our last issue. Mr. Horry, in fact, advocates the adoption of the low-tension alternating machine for isolated lighting, especially in view of the fact that we have now placed at our disposal a simple way of regulating the intensity of illumination in the lamps by means of a device which consumes no energy. While there may be those who doubt the value of this particular quality in a lamp installation, there can be no question as to the simplicity of the alternating machine and its excellent regulating qualities.

ELECTRICAL FAKES AND FRAUDS.

The paper by Mr. A. A. Knudson read by him before the New York Electrical Society last week, on frauds in the electrical business, touched an amusing and interesting subject that, as far as we are aware, had never before been handled at a gathering of the kind. The pity is that it is not possible to reach a larger audience or body of readers with it than is the case, where all to whom it is addressed are familiar with the questions involved and are not likely to suffer from imposition. Mr. Knudson makes an exposé for instance of the Scott electric hair brush ; but we take it for granted that no electrician or electrical engineer uses Scott's brushes or the other fellows' belts or any other swindles of that character. As to what may be termed "frauds," namely, attempts to plunder the public through the medium of new "inventions" of alleged merit and value, it is evident that in this respect also the desideratum is to get the ear of outsiders. No electrical engineer loses his money in such a fraud as the Friend electric sugar refining, but a good many of us know people who are prejudiced against electricity because they have been big enough fools to invest without investigating. There are remedies against these fakes and frauds, and it becomes the duty of every informed man to make an exposé of such deceit wherever and whenever he encounters it, either through the ever-open columns of the scientific press, or better yet, with the help of such useful functionaries as district attorneys and such bodies as the grand jury. It is, perhaps, significant that Mr. Knudson's paper was read at Columbia College. It is to the influence of our seats of learning and of the educated men they turn out that we must look for the greatest protection and advance. A large number of people like to be humbugged and need no sympathy with their peculiar manifestation of weakness of mind ; but not a few other people suffer sorely in mind, body and estate from these predatory swindlers, who take advantage of the popular belief in the ability of electricity to do anything and everything.

Cheap Street Railway Track.

It would certainly seem as if the most limited amount of common sense might by this time have taught our horse railway managers the unprofitableness of making use of the most costly kind of motive power for no better purpose than that of banging their cars to pieces against the unevennesses of a weak and flimsy track. Yet one may see to-day a new track in process of being laid in West street in this city—a location in which, to say nothing of the heavy legitimate wear, it is subjected to the incessant pounding of a never-ending procession of heavy freight trucks—in which the superstructure consists of a light side-bearing rail spiked upon longitudinal wooden stringers.

Iron in Central Station Construction.

Mr. A. E. Braddell writes us this week with regard to a point of special interest in central station construction, namely, the use of iron particularly in roofs. He states that some of the stations he has visited as an insurance inspector have suffered from the dropping of moisture from their iron roofs like a heavy dew, creating a condition of danger in the short-circuiting of the apparatus, etc. Two remedies suggest themselves. One is the construction of an inner roof of wood immediately under the iron ; the other is the erection of slight sheds or awnings just over the engines and dynamos. Further and better remedies than these should lie within reach, and we shall be glad to hear from our readers on the subject. Iron is pre-eminently a material to employ in central station construction, with brick and stone, and we are slow to believe that solid or lasting objection can be found in the troubles to which Mr. Braddell calls attention.

What Shall We Do with Our Mules?

The mule is not a thing of beauty, although his efficiency is very high, and his capacity great, and when his field of labor in the lower walks of life is suddenly closed to him his usefulness is gone. When electricity usurped the place of animal power on street railways, an opportunity was afforded the horse to turn his attention to nobler things, but when canal boats are towed, and plows driven, electrically, as described recently in our pages, the mule suffers, while his manufacturers are fain to go into the motor business.

NOTES ON ELECTRIC STREET RAILWAY CONSTRUCTION.—I.

BY

A. K. McCay.

WHEN electric railroads were first introduced, the methods of different systems were quite at variance. There has been very generally, of late, a weeding out of the older and cruder methods, and nearly all systems have adopted, more or less, the good points of their rivals. So that to-day there is a similarity, and, in fact, nearly an identity, in the best railroad practice.

Beginning with the generating station, we will endeavor to refer briefly to some salient points of construction and arrangement of a successful railroad plant. If the road is to be a small one, say under ten miles, a high speed, quick-governing engine is to be preferred; as the load is very likely to vary from zero up to full load in a few moments. The engine which is generally recommended is one that has fly-wheels especially heavy, and an automatic governor sufficiently sensitive, so that variations of load are quickly compensated for. The best practice strongly recommends the use of a simple engine where condensing is not used. If water be convenient and cheap the first cost of compounding and condensing is far outweighed by the saving in coal, very often amounting to 25 per cent. In larger plants some form of Corliss engine is very generally adopted, although the writer infinitely prefers a triple or even quadruple expansion engine directly geared to the dynamo. This latter engine, usually of a vertical type, is being rapidly introduced on ocean steamers, where economy of coal means economy of operation, just as it does in an electric light or railway plant. The latest tests of this type of engine in England give a little over 1 lb. of coal per horse-power hour, so that no doubt the large railroad installations of the future will seriously consider such an engine before introducing one less economical.

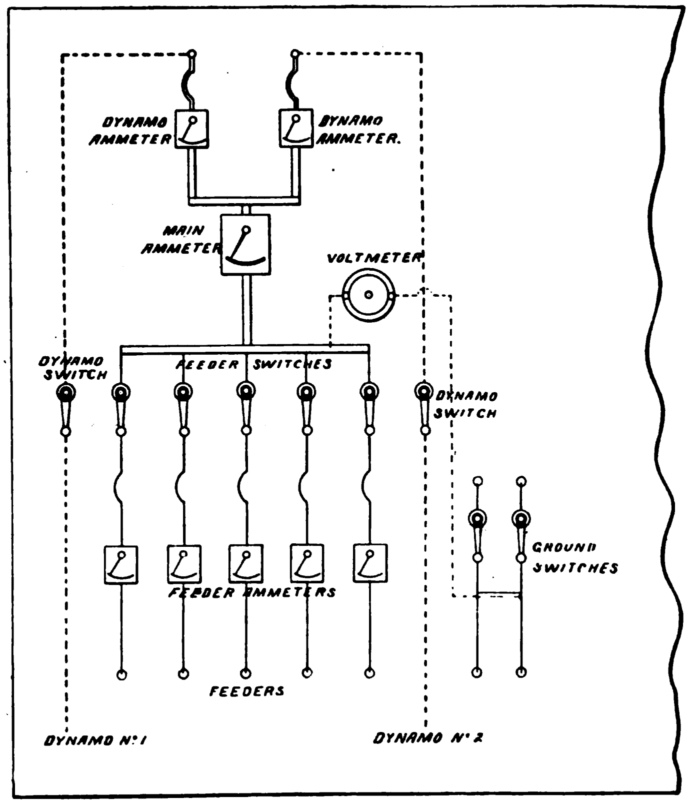

FIG. 1.—SWITCHBOARD FOR ELECTRIC RAILWAYS.

As to the dynamo, general practice has evolved a very efficient machine of the compound type, whose voltage is practically constant, and whose life is only measured by the care bestowed on it. The writer was in a large railroad plant a short while ago, and saw dynamos which have been running some eighteen months, and which are at rest just *forty-five minutes* each day, and yet the commutators were as bright, and just as large in diameter as when they began running. The application of the carbon brush practically extends the life of the dynamo indefinitely, if not heavily overloaded.

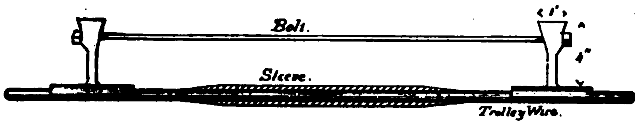

FIG. 2.—METHOD OF RELIEVING STRAIN ON TROLLEY WIRE JOINT.

Passing from the machine to the switchboard, we would recommend this to be of slate, set well away from the wall, at least four feet; and so placed as to be easy of access and perfectly safe from fire. In small stations the solid brick wall may be used; small, neat strips of wood being nailed to the wall, on which the bus bars and instruments may be secured by porcelain insulators. Fig. 1 shows the general type of a board for two dynamos. It will be noticed the main ampere meter registers the joint load when both machines are running, and checks the reading of each dynamo ampere-meter when running alone. On each feeder there is placed a fuse, a switch and an ampere-meter, so that an account can be kept of the amount of horse power required for a certain route. The wires should be brought under the floor in conduits to the switchboard and be brought from the back out to the front of the board. On installing, the board should be sufficiently large, so that additional dynamos may be connected as the business grows, as grow it will.

Passing from the switchboard to the line, we will first notice the poles. If these are of wood they should be at least 25 feet long and 7 inches in diameter at the top, and either of cedar or chestnut. In setting the poles great care should be exercised. The holes in soft dirt should never be less than six feet, while in rock formation five is permitted. Before being placed in the hole, the lower end of the pole should be coated with tar, as this will be found to materially lengthen the life of the pole. Great care should be used in setting poles. The bottom should be braced with heavy stones thrown into the hole and well rammed. The poles on a 30-foot street (between curbs) should rake some 9 inches away from the centre of the street; on a 50-foot street 14 inches will not be found too much. Special attention should be given to corner and end poles. The heaviest and stoutest poles should be chosen for these positions, and from 2 to 6 inches additional rake should be given them. Too great care cannot be given to ramming and setting

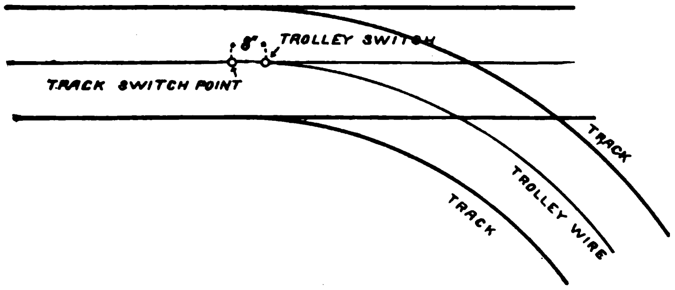

FIG. 3.—LINE CONSTRUCTION AT SWITCHES AND CURVES.

these important poles, as the life of the line and the efficiency of the service will greatly depend on this portion of the work being well done. Iron and steel poles are not given so much rake as wooden ones, because they are stiffer, and their bases are practically immovable. In setting these, care should be taken to see the concrete well rammed and that it is fresh and not set before being put around the pole.

When the poles are well set, the span wire should be strung. Modern practice is rapidly discarding the ratchet for the turnbuckle, which, to the writer's mind, is a very sensible move. Larger wire is also being used; some advocate ⅜ inch diameter, which, while to my mind it is excessive, is certainly safe. The trolley wire will probably give no trouble except at the joints. The constant passing over of the joint by the trolley wheel seems to crystallize the solder and render it brittle. If the line is stretched taut, the cool nights of the fall and early winter contract the wire, and bring a great strain on the joints, causing the wire to break at these points, entailing delay and sometimes accident. The writer has used with good effect a device shown in Fig. 2 to prevent this; and, in fact, partially to relieve the joint. It consists of two pieces of brass, whose lower part is cast to receive the trolley wire, like a bell hanger; but whose upper part is heavy enough to have a ½-inch bolt pass through it. This bolt is usually some 16 inches long and extends from one brass piece to the other; both being soldered to the trolley on each side of the sleeve. This bolt takes the strain somewhat off the sleeve, and has been found to practically overcome the trouble of the trolley pulling loose at the sleeve.

Line switches can give a great deal of trouble if not properly placed in reference to the track switch. Fig. 3 shows the relative position and the distance between the point directly below the line switch, and the point of the track switch is given as 8 inches, a distance which has been found to give excellent results. At this distance the car is well around the curve before the trolley wheel reaches the line switch. This causes the trolley wheel to bear well over in the direction the car is taking, and the trolley wheel takes the switch without fail. With these points well adhered to, little trouble and minimum expense will be found in the operation of these branches of an electric street railway plant.

A SIMPLE HELIX TELEPHONE RECEIVER.

BY

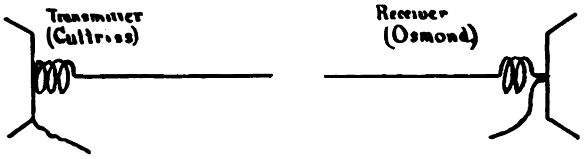
J. Thornton Osmond

MR. CUTTRISS described, in THE ELECTRICAL ENGINEER of Dec. 16, 1891, a telephone transmitter of decidedly novel and very simple construction, and possessing superior qualities as a transmitter. I would like to call attention to a point concerning its action which he appears to have overlooked, and also to describe a very simple and mechanically similar receiver which I made in 1886, and found to have superior articulation.

In his description, Mr. Cuttriss speaks as though he regarded the action as due wholly to the change of resistance of carbon with change of pressure. I think that there is another principle which, if secondary to that named, is important in the action. I refer to the electro-dynamic action of currents in neighboring conductors. When the slight increase in pressure due to a vibration of the plate causes an instantaneous increase of current, this increasing current in the coils draws them together and thus adds to the pressure and so to the current strength. This electro-dynamic action will contribute largely to the strength of the whole action.

Perhaps I should not attach so much importance to this point but for the following experiments: In 1885, in trying to form a system for classifying telephones, it occurred to me that among the various principles of electrical action which might be used to convert the energy of the current into mechanical vibrations of similar "form," the electro-dynamic action of currents, as in a helix, had not been used. It seemed to me doubtful whether the electro-dynamic action could control the natural periodicity of the helix, and its inertia.

To test this, I made, in the early part of 1886, a rude apparatus of a bored block of hard wood, clamping a tin-type diaphragm with one end of a helix soldered to the centre. The wire was bent sharply back and then off at a right angle, as shown in the illustration. The transmitter used was sometimes the Bell (Berliner-Blake), and sometimes the Reis "bored block." It required a good deal of trial, different springs, tension, etc., to get articulate speech. Sound and pitch gave no trouble at all. But occasionally, when everything was just right, words were received with great clearness and strength.



THE HELIX AS RECEIVER AND TRANSMITTER.

Of course, both Mr. Cuttriss' helix and mine, when a current passes, form magnetic fields varying with the current and acting on the diaphragm. But I found that it was possible to connect the end of the helix to the diaphragm by six or eight centimetres of silk thread without material change in the action. The proof seemed to me complete that electro-dynamic action of currents could be applied, as in a helix, for the telephonic receiver.

THE BERLINER PATENT AND THE HUNNING TRANSMITTER.

BY

Albert Stetson

THE granting of Berliner's patent of November 17, 1891, seems to have called out a great deal of discussion and the expression of a variety of opinions. Some have maintained that its granting after so long an interval was an injustice, and one that would be remedied by the courts. To the writer there seems no injustice, in fact it seems entirely in accordance with the rules of the Patent Office, and its being kept in the office appears the only possible way of keeping within the spirit of our patent law. If the patent is so basic as is claimed, a great injustice would have been done by its issuance previous to the final decision by the Supreme Court on the telephone cases. Drawbaugh claimed to be the original inventor of the telephone, and while his claim was unadjudicated, it would not have been right to issue so broad a patent. How just the action of the office was, is shown by the fact that three out of seven of the Supreme Court judges were disposed to recognize Drawbaugh's claims. Whether the patent to Berliner should have been kept in the office from that time until its issue, is a question better decided inside the Patent Office than out. At all events the Commissioner seems to deserve great credit for getting it out of the office so soon after entering upon his new duties.

If it is wrong, as is urged, for patents to remain tied up so long in interference proceedings, then the remedy is not growling over specific cases, but an earnest attempt to reform some portions of our generally admirable patent laws. This would have to be done through an act of Congress, and the real friends of our patent laws would shrink from attempting any reform from fear that in reforming one pillar of the building we may pull the edifice down upon us.

Some claim that there are certain foreign patents issued to Berliner which will limit the life of his American claims to a very short period, if they have not already expired. This may be so, and in the absence of an extended search, it is impossible to say how much weight should be given to this objection. That will be a question for the courts to decide. In the absence, however, of any such test, it is well for those who expect on the expiration of the Bell patents, to reap fortunes in the telephone business to let their feet be guided somewhat by the lamp of experience.

In view of the magnificent business management that has characterized the commercial and legal conduct of the Bell Company's affairs, the idea would naturally suggest itself that the attorneys of the Bell Company were as well aware of the existence of the alleged foreign patents as any outsider could be. Looking back over the past records it will be difficult to find any great number of instances in which Mr. Storrow has been caught asleep. Many a time opposing counsel have found him very much awake, really too much so, and their clients' pocketbooks (if opposition telephone companies ever paid their bills) have suffered severely from their error of judgment as to the ease with which the Bell monopoly could be overthrown. Before venturing too far, and expending too much money, would-be telephone investors will do well to carefully examine the alleged defences.

To the writer the easiest, and apparently only safe, attack upon the telephone field, after March 7, 1893, seems to be through the Hunning patent, No. 246,512, of Aug. 30, 1881. This patent having been taken out in England on Sept. 16, 1878, will become public property on Sept. 16, 1892, and it would seem that any one will then be free to use "carbon in a state of fine loose powder, not in any way compressed or consolidated." I cannot think the Berliner patent will be possibly interpreted broadly enough to cover this use of carbon. As to the efficiency of the Hunning transmitter, Preece & Maier, in their book, "The Telephone" (page 88) say, of transmitters of this class: "It was certainly the most powerful instrument tried in England." The so-called long-distance instrument of the Bell Company is based upon the use of carbon in a free and loose state, and all know the excellence of that apparatus. With respect to the patented improvements embraced in that instrument, there are likely to be some interesting developments in the near future.

With such reliable instruments in the hands of the public as the Hunning transmitter and the Bell receiver, it would seem to be a matter of indifference whether the last Berliner patent were sustained or not.

MAGNETIC PROPERTIES OF LIQUID OXYGEN.

PROF. DEWAR recently made a highly interesting communication to the Royal Society. He sought to determine what effect a temperature of 180°C. would have upon the behavior of liquid oxygen in the magnetic field. Having previously ascertained that liquid oxygen does not moisten or adhere to rock crystal, and consequently maintains in contact with that substance a perfect spheroidal condition, he poured the liquefied gas into a shallow saucer of rock crystal, and placed it between the poles of the Faraday electromagnet. On the magnet being excited, the whole mass of liquid adhered to the poles until dissipated.

FRAUDS IN THE ELECTRICAL BUSINESS.[1]

BY A. A. KNUDSON.

THIS subject unfortunately is one of such wide scope that to cover it fully would mean the publication of a good-sized volume. For a paper of the ordinary length therefore I shall only touch upon the various branches of electricity in which impostors have left their tracks, and relate a few instances as they have come under my notice during the past few years, which will show some of their methods. We wish it understood that in speaking of impostors or "fakirs" in this paper we mean only those who, knowing an invention to be worthless, or of but little value, will attempt by false statements to induce people to put money into the same. Neither do we wish to include under this head those inventors who, honestly believing they have discovered something new and original, seek to interest capital, although their scheme may finally prove to be impracticable or previously patented.

We will now consider one or two fakir methods in the galvanic or storage battery line which as we all know has proved in the past an inviting field for that class of men. The first will be the primary battery with the electric motor. Some years ago before the advent of the dynamo, when electric motors had to depend upon the primary battery for current, a French gentleman appeared in New York with alleged new and useful improvements in both battery and motor. He had induced a relative of mine (since deceased) who was an officer in one of the savings banks to invest in the same, and had been given the use of an unoccupied room above the bank for the purpose of exhibiting the apparatus. I was asked to call and examine this "wonderful invention," for, according to the inventor, it *was* one of the greatest scientific productions of the day. The motor did not differ in principle from those already invented and published, such as that of M. Froment or of Davenport on this side of the water. In fact it was not only the same in principle as that of Froment's but nearly the same in construction.

The battery, the inventor said, was a secret, and he would not explain it. The method of demonstrating the efficiency of both motor and battery was by lifting a weight of a few pounds to the ceiling by means of a pulley and rope, the rope being wound around a drum secured to the shaft of the motor. The battery although a secret, disclosed itself soon after the motor was started, in the strong nitric acid fumes it gave out, and the active manner in which it boiled. When spoken to about the strong odor from the battery which was enough to choke one, the explanation would generally be (with an attempt to smell): "You smell anything?" Our report as you will surmise, was not favorable and we strongly warned the banker to go no further, but he had actually become so wedded to the scheme that he would believe nothing against it and all I got for my pains was a self-satisfied smile and the remark, "Well, I can believe my own eyes when I see that weight going up to the ceiling."

You will anticipate the outcome. I left them to themselves and to their own eyes; and after several thousand dollars had been sunk in the attempt to make the scheme practical, it was finally abandoned. The banker frankly acknowledged afterwards that he believed the whole thing was gotten up with the deliberate intention to deceive. So much for that wonderful motor, and the battery that was a secret.

Another case, and this will illustrate how people will sometimes put their money into a scheme, and afterwards seek advice in regard to it, was one which came under my notice a few years ago where the primary battery played a conspicuous part (although concealed in the cellar), and was, like the one in the previous case, a secret. It had for its object the production of an electric light. The gentleman who employed me to investigate this case, had, I was informed, already invested something like $20,000 in the scheme. Knowing this I certainly expected to find something at least worthy of an invention. It is a singular fact, however, and one that I have often come across, that instead of getting full and reliable advice before embarking in a venture, people will often invest their money and then afterwards, when a sense of doubt and insecurity dawns upon them, will fly to an expert.

The object of this invention, as already stated, was the production of an electric light. It was exhibited in a room ordinarily used as a dining-room in a private house. There were three or four lights placed on the chandelier and when the current was turned on, they did make a brilliant and steady light while it was being shown. It consisted of two small carbon rods placed inside a glass tube, the point of contact between the carbons being about midway between the ends of the tube which was about six inches long with a bulb at the centre. The wire from the battery connected with the carbons, and that was practically all there was to the invention. The inventor succeeded even before any patents were obtained, with his exceeding plausibility (and he was a remarkably good talker) in inducing these gentlemen to put in this large sum of money. Why, to hear this man talk was enough to deceive the very elect if they were not posted, and to show how easy some men are induced to invest in worthless enterprises of an electrical nature when in the hands of a good talker, I will give an example of the way he talked—"Edison was nowhere. For years Edison had been trying to accomplish what he had already just perfected. In Edison's system enormous capital was required in the construction of central stations, besides the cost of running expenses for fuel, labor, etc.; but in his system all of this was done away with, and for a few cents per night a whole house or store could be illuminated, and the battery would run indefinitely," and so on, ad infinitum. All of this time he was careful to conceal the fact that he was using in the battery in the cellar electropoion fluid by the barrel and zinc by the square yard in order to produce the three or four lights for comparatively short intervals of time. He told the gentlemen present and myself that there were but four cells of battery in circuit; this to me was surprising for the amount of illumination given. By a series of cross-questions we finally found out just what he had. The four cells of battery consisted of four enormous earthenware crocks, holding about 25 gallons each. Across the top of each jar or crock was placed a bar of wood to which was secured various plates of carbon and zinc running down to the bottom of the jar, so that instead of four cells or galvanic pairs in circuit, there were actually nearer 40 of very large size and the beautiful and brilliant electric light on the chandelier was duly accounted for. I do not suppose that the gentlemen who had invested their money in this scheme thought it worth while to even inquire about the battery. They saw the light, and like the banker in the former case, when he saw the weight go up and heard the inventor talk, they thought they could believe their own eyes. After the exposure was made, there was no more money invested in that scheme.

---

[1] A paper read before the New York Electrical Society, Dec. 30, 1891, at Columbia College.

I could give many other instances where the impostor has manipulated the galvanic battery to his own profit; but as they would be almost repetitions of those just stated, we will pass on and look into some of the fakir's work in the electric and acoustic telephone business. I presume there is no electrical business of late years which has been so thoroughly worked by unprincipled men as the telephone business, and in order to have a better understanding of the methods of telephone sharpers, we will give a short résumé of the telephone situation as we understood it a few years ago. Where important lawsuits have been going on, the amount of fraud occasionally practiced in the attempt of one company to secure an advantage over another, would, if made known, be surprising. Bribery and false swearing has often been resorted to in some of the telephone patent suits in past years. Witnesses, experts, lawyers, and even the judge on the bench have not been entirely free from the baneful influence. I will give an instance: You may have heard of the man who was an examiner in the electrical department of the Patent Office at the time the Bell patent was issued, and who in later years for a certain sum of money made an affidavit in favor of the Bell Company setting forth certain alleged facts which occurred at that time, and who not long afterward accepted a fee from another company and made another affidavit setting forth alleged facts entirely contrary to the first sworn to. It often happens in patent suits where large amounts of money are involved, the temptation is strong to mislead and deceive, wherever such deception will be of advantage. Especially was this the case in the legal telephone fight during the attemps made to overthrow the Bell patent by attempting to show that the Reis telephone would articulate. It was well known that if the telephone invented by Reis in Germany (which ante-dated the Bell by several years) could be proved to have talked, and to have actually produced articulate as well as musical sounds, it would mean death to the Bell patent. Or if a telephone made exactly on the principle of the Reis could be shown to articulate in court, if only for five minutes, it would in all probability upset the Bell patent, the advantages of which would thus revert to public use. Hence there was abundant reason for the opponents of the Bell Company to prove if possible one thing or the other, and the utmost exertions were put forth. Germany was ransacked for relatives and those who had been acquainted with Reis during his lifetime, and affidavits and witnesses were obtained by the score, attempting to prove when, where, and how the Reis telephone talked; without doubt many of these affidavits were drawn from mistaken imaginations, while others were but partial truth. On this side of the water numbers of inventors were at work struggling for the prize in their efforts to make the thing articulate. I well remember the experience Mr. Mailloux and myself had in that direction. Night after night we worked at our homes in Brooklyn with varying success. Sometimes we would succeed in making it articulate, but our experience was, it seemed impossible to make it stay in that condition. We finally came to the conclusion that it was possible to make a Reis telephone talk, but it could not be depended upon to stay in a talking condition from one minute to another, and so far as my knowledge extends of this subject no telephone made exactly after a Reis pattern has ever been able to articulate for any length of time. When they did articulate it was probably on account of either an extremely delicate adjustment which was only temporary, or the oxidation of the contact points, thus for the time creating the variable resistance which is the life of articulation. But we could not trust it to remain in that condition over night; often did we lay it carefully one side after working for hours at night, feeling, that at last we had it, and in the morning find it as dumb as an oyster, and finally we abandoned the attempt entirely.

There was one party, however (and this is more in line with my subject in speaking of frauds) who claimed to have produced a constant talking Reis telephone, and to the consternation of the Bell Company actually showed it in a good talking condition; there could be no fault found with the articulation; it did talk and talk well, and things for a time looked blue on the Bell side of the house, until one of their experts, more observing than others, discovered a carbon button concealed in the box and in the circuit, so that it was not a genuine Reis telephone that produced the articulation, but one with the necessary modern improvement.

I once had a telephone case to investigate which will show to what extent a fake scheme will sometimes go before it finally reaches its end. There were but two papers furnished me to examine, one a copy of the patent (there was but one patent), and the other a copy of the prospectus. The claims of the patent were exceedingly limited, but the prospectus was broad enough to make up for any deficit in that respect. One clause in the patent set forth that this invention was based on the undulatory current principle, while a clause in the prospectus stated that the invention was not based upon the undulatory current theory but upon the make-and-break principle—a square contradiction on its face.

In point of fact it did not differ only in construction to the Bell telephone. The parties to whom I reported did not invest in the scheme, but other parties did, and a company was started. Their method of doing business was to manufacture the telephones here in New York, sell State rights on the patent, and establish local companies in cities and towns wherever they could, and supply them with telephones. In this way they earned in course of time sufficient money to pay a dividend on the stock and the stock advanced (a good deal of it being sold) and everything went on swimmingly; about this time I was asked by the party for whom I reported if I had not made a mistake, and they pointed to the fact that a dividend had been paid by this company. I said I thought not and advised them to wait a little longer. The Bell Company through the slow process of the courts finally reached them, and they were blotted out of existence.

A similar experience as we all know happened to a large number of other companies who attempted to compete with the Bell Company. In the acoustic telephone business it seemed at one time as though it was infested with fakirs. There seemed to be stronger inducements in the acoustic field for this class of people even, than in the electric, especially after the Bell patents had been sustained by the courts. I presume one reason was, there was no difficulty in convincing people that there was no infringement on the Bell patent, it being easy to show no electricity was used to carry the voice, and another reason was that an acoustic telephone when first put up for exhibition purposes generally worked surprisingly well. The voice could usually be heard from 10 to 20 feet away from the instrument, and the promoter would not be slow to exaggerate these advantages and almost always to characterize it as fully as important and valuable as the Bell telephone. They would say nothing about the difficulty of constructing the wire and of keeping it in repair, and in most cases those investing would hardly inquire if there were any wire at all, when in point of fact the wire is the most important part of the whole business of an acoustic telephone line. The difficulty of maintaining it is well known. In this respect this case would be similar to those above mentioned where people saw a weight go up, and saw a beautiful electric light. They thought they could believe their own eyes and when some people listened to the remarkable performances of the acoustic telephone they thought they could believe their own ears. The acoustic telephone has its place in the commercial world and in its place is most useful and convenient; but in the past it has been badly misrepresented by being exaggerated by men whose only ambition was to sell stock in fake companies

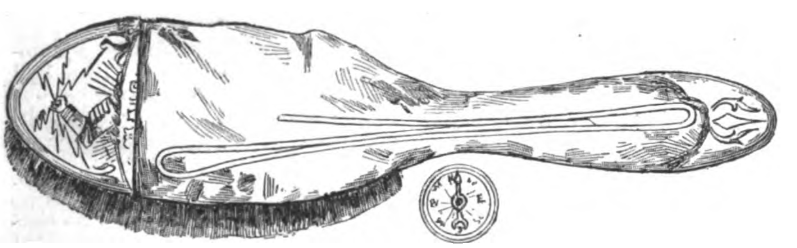
We will now leave the telephone business and pass on to the consideration of telegraph frauds. Some years ago a French Canadian appeared in Hartford, Conn., making a great stir about a new multiple telegraph system which he claimed to have invented. According to his story he could send and receive upwards of 40 messages over one wire. The duplex and quadruplex were but child's play in comparison, and so plausible were his other assertions concerning it that he succeeded in interesting some parties and finally obtaining from them a considerable sum of money for an interest in the scheme.

For a complete swindle in every detail this beat all I have ever heard of in the electrical business. It was an ingenious swindle and in order to describe it more fully I will refer to the diagram on the blackboard. A few instruments only are shown but they will be sufficient to illustrate the scheme. Several Morse sets of instruments were placed at each end of a room and a wire loop was run to New Haven, in which wire the main battery was placed. From the ends of this loop, wires were branched to one of the two binding-posts of the instruments; from the other binding-post ran a wire to all appearances to the ground, but it did not go there at all for it was purposely broken inside of the insulating covering and the ends pulled apart. Another very fine wire, however, was connected to the bottom of this same binding-post at each instrument, carefully concealed, and led to the side of the room where it was hidden entirely from view behind the paper on the wall. These fine wires all connected with the opposite instruments in their respective pair at the other end of the room. The wire in the long loop to New Haven, as you will observe, simply acted as a return ground, or one side of a metallic circuit. Under such conditions the multiple scheme, as you would expect, worked perfectly, and with any number of instruments. After the inventor had absconded with his money, which he did shortly after he got it, the instruments were removed from the room, and in doing so the fraud was discovered, for there were the wires all carefully concealed behind the wall paper.

Electrical frauds have visited the United States and plied their vocation from most every country on the face of the earth, but this man was from Canada, a country one would hardly expect to produce such a clever electrical swindler, and he showed a surprising nerve by going right into the heart of Yankeedom, in the State of Connecticut, where the people's reputation for shrewdness is so well known that it has been said, in order to dispose of some of their products such as wooden nutmegs, etc., they are compelled to go outside of the State to do it. During my sojourn in Canada for the past four years I have met but one or two who could be termed electrical fakes and they came from the States. Another phase of electrical frauds may be illustrated in a recent exhibition of a scheme in Boston.

The inventor showed a battery of peculiar construction; to the zinc pole of which was attached a wire leading out of doors to a lightning rod a short distance away. The wire from the other pole of the battery went somewhere, but supposedly to go to the ground.

The object of the scheme, according to the inventor, was to produce a constant and unlimited supply of electricity from the air. To show the practicability of the scheme a motor was placed in circuit and it ran as though it would burst; an ordinary Morse sounder was tried and that worked as though it would be torn to pieces. Mr. Frank Pope examined the scheme but was not allowed to look into it thoroughly and he said he couldn't tell just where the fake was, but it was there somewhere, and he advised the capitalist who was with him and who was in the electrical business to get some of his electricians to try and duplicate it if they could. I am sorry this scheme was not unearthed, for I believe it would prove an important addition to this paper.



SCOTT'S "ELECTRIC" HAIR BRUSH, WITH STEEL WIRE EXPOSED.

As a conclusion to this list of electrical fakes we will now consider the medical part of the business. Here we find among the so-called electrical appliances, such as belts, hair brushes, corsets, etc., gross imposition is practiced under the name of electricity upon the public and has been for years. There is hardly a complaint in the human calendar of diseases that these things, according to flaring advertisement and circulars, will not cure. To show to what an extent this imposition is practiced at the present day I will read an extract or two from a full-page advertisement taken from one of the most highly respectable magazines in this country:

> Disease is the result largely of depleted nerve force and demagnetized blood. These electro-magnetic corsets (the maker's name is here mentioned), belts, insoles and appliances have been demonstrated to be the best agency yet discovered for preventing this depletion and demagnetization as well as restoring such forces when lost. These garments are unlike any other device for electrifying the system or charging it with magnetism. As a force it is self-supplying, retaining its virtue for years and invariably benefits. These appliances so electrified can always be relied upon.
>
> These appliances promptly annihilate those weak and languid feelings, exterminate rheumatism from the system, and promptly cure the above-named disorders. They are light and comfortable to wear, and are guaranteed to imperceptibly generate a mild continuous current of electro-magnetism, all-healing in its effect. They differ from the so-called electric and galvanic belts which are usually worthless and which create sores on the body, leading to blood-poisoning. Beware of them and see that you get this one (our special make) with silver compass free. Ours are truly electro-magnetic, as any tyro in electric therapeutatics will inform you, and are absolutely reliable.

You will note the attempt is made here to work in magnetism as a curative property. Except where steel magnets are concealed of which I shall speak later), there is not one particle of magnetism produced by the action of a so-called electrical appliance of this class.

This is a point to which I wish to call special attention. Electricity properly controlled and applied is capable of wonderful effects in the relief and cure of a large number of diseases, and its legitimate use is increasing daily in the practice of the most enlightened and scientific practitioners of the age. In fact, hardly a practicing physician of any repute can be found who has not his medical batteries, some of them costing hundreds of dollars, with all kinds of electrodes, some of which are as ingenious in construction as they are humane in purpose.

It is just this point that the swindlers of to-day lay hold of and turn to their own purposes. They designedly confound electricity and magnetism, and by a skillful interchange of terms they encourage in the public mind the same confusion. In many cases where they claim that magnetism is generated by their appliances there is no magnetism at all; and in others where they claim that there is electricity there is magnetism. But this magnetism is not the result of any inherent virtue, it is the result of a smart piece of chicanery, in which the concealed magnet and the compass needle play the principal part. I claim, therefore, that in any event it is wrong and misleading to attempt to confound magnetism with the curative properties of electricity.

I have yet to learn the first case where magnetism, either strong or weak, has ever produced any effect either beneficial or detrimental upon the human system. Night after night for months I have been in the presence of the most powerful dynamos (as have thousands of men in the many electric light stations all over the world) where magnetism of the strongest kind permeates every bone and fibre and tissue of the body, and yet, so far as any effect either good or bad on the system goes, one would never know he had been in the magnetic field, and he would not notice it unless he found his watch stopped. To the best of my knowledge and belief there is absolutely nothing in the human anatomy that can be acted upon by a magnet. Of course, if a child swallows a mouthful of tacks or a paper of needles, there is something inside of the child upon which magnetism will act, but not otherwise.

What physician of any reputation has ever been known to attempt to apply magnetism, or to recommend the use of electric belts or the like? On the contrary every reputable physician with whom I have talked on the subject has denounced them as worthless. Let us go a little further into this subject, and see how some of these things will bear the light of an investigation. We will first consider the so-called electric hair brush. I have thought best to purchase one of these brushes so that we can just see how they are made and to prove the assertion that so far as any curative property is concerned they are no better than any ordinary hair brush. I will first read an extract or two from the directions pasted in the box in which it comes:

> Cures headache in five minutes; cures neuralgia in five minutes; restores the hair, prevents baldness. The "Odic force" can always be tested by moving the brush near a compass. This power is so strong that if the compass is placed upon a thick book or table and the brush is moved in a circle beneath the same the power will pass through the intervening table or book and cause the needle of the compass to rotate rapidly. A silver compass of considerable value accompanies each brush.

Now this brush I have does deflect the compass needle just as stated, but the real cause is very different from the ostensible one, and instead of any Odic force (whatever that may be) or any electricity having anything to do with its deflection, the statement is false, as I shall prove. I have taken pains to dissect the back of this brush and we find just what we expected to find. Embedded in the material of which it is composed is a steel magnet. That, and that alone, is the cause of the compass needle moving towards the brush when brought near it. When I purchased this brush I was told that the movement of the needle proved that the brush was charged with electricity, and I have no doubt everybody else is told the same thing that buys one. You will notice this magnet is made of a piece of steel wire in the form of a double loop and extends nearly to the end of the handle. The only electrical effect possible that can be produced by the use of this brush is static, and even under favorable conditions of the atmosphere, the greater part of such very small amount of static electricity as might be generated while the brush was being used would imperceptibly pass off the earth through the hand and arm and body of the user, leaving them no more benefited by its use than if they had used any other hair brush.

Electric corsets are another deception. How is it possible, I ask you, for such a thing to be of the slightest use electrically to the wearer when they are not even worn next the skin. The magnetizing of the steel ribs as is often done is of no use whatever as to any beneficial effect upon the wearer. Another of these precious frauds is the electric garter. I have seen advertisements, as no doubt many of you have, where the use of electric garters are guaranteed to give a more shapely form to the limbs of ladies. The absurdity of such an appliance is too apparent for comment but it is really too bad to disappoint and deceive the ladies in a case like that. What swindle under the name of electricity will not be attempted next? Why don't they get up an electrical hat band guaranteed to supply a lack of brains or furnish new ideas to those that wear them, yet would not such a thing be just as reasonable as some I have stated?

As an answer to some of the reckless statements which appear in advertisements and circulars, some of which I have mentioned, in regard to electric belts and other appliances I will quote an authority and read some extracts from De la Rive's "Treatise on Electricity." De la Rive was at the time of writing his work a member of the Academy of Sciences, and also of Medicine, of nearly every large city in Europe, so that he is an eminently qualified authority to pass judgment on these appliances. After explaining the construction of the electro-galvanic chains and belts of Golberger, and of Pulvermacher, he says:

> We do not very well understand the effect of this arrangement by virtue of which the current is scarcely to circulate in the chain without traversing, at least in a very sensible manner, some part of the body. For not even a derived current can be obtained on account of the imperfect conductibility of the skin. Moreover, no very positive fact has proved the efficacy of this later mode of application, upon which experience has not yet decided. And again, We do not deny that there may be a production of currents in these apparatus; even the galvanometer indicates their presence; but they are very feeble currents; and we do not see what advantages can be presented by these arrangements which at the very basis rest on false ideas of the electricity of contact.

My wonder is that the electrical journals have not been more outspoken in showing up these frauds upon the public. The public would naturally look to such a source for information of this kind, and these journals are not handicapped as others are by being paid for fat advertisements, for it is the uninformed public on electrical matters that they desire to reach; so they use the daily press and weekly and monthly publications to make known their wares. In summing up this whole matter of electrical appliances, it seems singular that they have been allowed to exist so long, especially the hair brush; one reason may be that the "public love to be humbugged"—but there is a limit to all things, and I predict, as electrical knowledge is being more and more disseminated by such institutions as Columbia College, it will not be long before people will understand the truth in regard to them.

Although I have touched upon but a few frauds and deceptions as practiced in the electrical business, I am aware of there being many more which would prove interesting were it not for the risk of tiring your patience. I have no doubt there are those in this audience who remember the electrical sugar refining frauds of a few years ago. Also the motors of Paine, which for many years continued to deceive people. Also much might be said of the tapping of telegraph wires leading to race courses, and the ingenious electrical devices and methods for supplying stock quotations to bucket shops in Wall street. Also some of the so-called telegraph schools, where young people are induced to pay their money with the promise of a situation as soon as competent. This class of fraud cannot be too strongly condemned.

In concluding this paper I cannot refrain from expressing a few words as to the position of the capitalist or investor in regard to new electrical inventions. In the few instances cited I have endeavored to illustrate how easy an investor may be deceived. It may be fairly asked by some, "Has the investor then no protection from the designs of a dishonest promoter, or from the mistaken though honest inventor?" I answer, he has. There are plenty of good, honest and capable engineers, in this and other cities, who, for a reasonable fee, will investigate and report upon any new scheme if they are only applied to. Some of these engineers are peculiarly fitted to give advice and opinions in certain branches of this business by reason of their long experience in such branches, while others have had experience, more or less, in all of them. Besides these individuals, there are now lately established in this city electrical firms composed of men of unquestionable reputation and standing, who make it their business to investigate and report upon any electrical invention; and I claim that there is now no excuse of an investor being deceived where such facilities exist for obtaining correct information upon electrical subjects. Would a man afflicted with disease undertake to cure himself if he knew nothing of the study of medicine, or would a man having an important lawsuit on his hands undertake the management of his own case if he knew nothing of the practice of law? On the same principle, then, an investor takes a large risk if he depends on his own judgment while placing his money in alleged new electrical enterprises. On the other hand, the judicious investment of capital in electrical enterprises has brought large returns to a great many people, and in very many cases handsome fortunes have been realized. As an evidence of this fact, we have but to point to the marvelous success of the Bell telephone, also the electric light (both arc and incandescent), also the electric railway. Besides these great industries, there is no end of less important schemes varying in value according to their commercial usefulness, and almost every day something new in the electrical line is being discovered.

In this paper I have endeavored to interest you by pointing out the methods of unprincipled people in the electrical business, and I have also attempted to make clear the importance of investors seeking good advice before placing their money in electrical schemes. If I have succeeded in these two points then the prime object of my paper is effected.

The paper was followed by a very interesting and amusing discussion, in which Prof. Crocker, Dr. Laudy, and Messrs. R. W. Pope, T. C. Martin and G. H. Guy participated. Several frauds and fakes were named, and Mr. Guy, as secretary, read a letter from one innocent who was being imposed upon by some persons advertising under the name of the society, and who recited a long list of swindles of which he had been the willing victim.

THE PROBABLE FUTURE OF CONDENSERS IN ELECTRIC LIGHTING.[1]

BY JAMES SWINBURNE.

It is always difficult to foretell the future in electrical engineering work, but it is sometimes interesting to try to see in what direction developments are like to take place.

The first idea of the use of condensers was to employ them like storage batteries, and mention is frequently made by the early electric light patentees of their proposed use in this way. It is needless to remark that these inventors had not the most remote idea of the vast electrostatic capacities needed for storing by the hundred ampere hours.

The project of using condensers instead of transformers is by no means dead. It has been recently taken up on scientific principles by Mr. Doubrava. As soon as a condenser is charged and discharged rapidly enough its size becomes manageable, and Mr. Doubrava is therefore working out a system in which condensers take the place of converters. This development is in good hands, and need not be discussed further. One great difficulty is in charging condensers with direct currents. A condenser of the capacity of a farad charged with one volt contains, if the expression be allowed, only half a joule. If a condenser is charged by being connected to leads at one volt half a joule is wasted over resistance and the other half is stored. The only way of charging the condenser without loss is to connect it with an electromotive force which is gradually rising. Similarly, in discharging, the electromotive force must fall gradually. This condition is not at all difficult to attain.

The greatest development of the use of condensers will probably be in connection with alternating currents. It is doubtful whether ingenuity will ever design an arrangement of condensers that will take the place of transformers in practice. In one sense there is better material to work upon. A transformer is always inefficient on account of hysteresis. The loss by "soaking in" may be taken as analogous to the loss by hysteresis, but it is infinitely less in comparison. For instance, a condenser that takes 2,000 volts and 10 amperes has a loss which is too low to measure—that is to say, it is less than 5 or 10 watts. This loss is proportional to the size of the condenser, so that small sizes are just as efficient as large. In transformers this is not the case. A 100,000 watt transformer has a loss of from somewhat less than 1,000 up to about 5,000 watts, according to the design, and if the 100,000 watts is made up of a number of small transformers the loss is much greater.

The uses for condensers are already developing. In the first place, they can be used to supply magnetizing or exciting currents to all sorts of machinery, and also to apparatus that takes lagging currents. It must be remembered that the magnetizing current in any receiving apparatus means a demagnetizing current in the generator. As an example that will soon be common, and is also striking, we may take that of running arc lamps off 100-volt circuits with choking coils in series with them. As far as the lamp is concerned, there is no better arrangement than running it off a 100-volt circuit with a choking coil in series with it to reduce the terminal pressure to about 30 volts. If such a lamp takes 10 amperes, the apparent power taken is 1,000 watts, but the real power is probably less than 300 watts. The dynamos at the station have thus to supply large "idle" currents. These not only lead to armature heating, but also demand extra excitation. If many arc lamps are used, more dynamos become necessary, as no machines will stand three times their normal armature currents, even though they are out of step with the electromotive forces. Such currents, therefore, lessen the plant output, or, as it is often loosely called, the "plant efficiency." To overcome this trouble all that is necessary is to place condensers in shunt to the choking coils and lamps, or in shunt to the high-pressure leads. The last arrangement is best, as it admits of arranging the condensers at the central station. In addition to this, condensers for 2,000 or 1,000 volts are easier to make than those for 100 volts. Condensers for such low pressures cost too much in tinfoil, and are somewhat bulky, because the dielectric has to be made thick in proportion, to make certain of the absence of flaws. At present comparatively few arc lamps are run in this manner, but that is because nearly all the alternating current systems now in use have small transformers in houses and high-pressure mains about the streets. It is probable arc lights will be run off 100-volt circuits with choking coils, and condensers will be required at the stations. Of course there is no reason why arc lights should not be run off high-pressure circuits by means of constant-current transformers. This system has never come into use in this country, probably because the low cost of this method is not generally appreciated.

---

[1] Abstract from *Industries*.

It may be well to give some idea of the size of a condenser. One cubic foot of condenser will take about 2,000 volts and 5 amperes, or 10,000 apparent watts. With higher pressures the volume necessary is slightly less, and with low pressures the size increases. Below about 500 volts the bulk increases rapidly, as the volume of tinfoil is greater. The cost, therefore, increases too. It is possible to make condensers very much smaller than this; but while they are new it is best to allow a large factor of safety. Choking coils and constant-current transformers for arc lamps are not the only things requiring exciting currents. Transformers, especially if made with open iron circuits, take "idle" currents, and this can be supplied in the same way. Nearly the whole of an open circuit exciting current can be supplied by condensers. There is always some left over, because the electromotive force never varies exactly harmonically. Even if it did, there is some loss in the iron, so the no-load current cannot be reduced to nothing. In a closed circuit transformer the no-load current is less to begin with, but the active component is much greater, so that it cannot be reduced so much by condensers. It can generally be about halved.

The next use, which is analogous to those already described, is in connection with motors. Of course it is a little difficult to say what the alternate current motor of the future will be like. If it is a synchronizing machine, with the magnets excited by a direct current, it may take a leading or a lagging current, or one in step with the pressure. If it has field magnets excited by an alternate current it will take a lagging current, and condensers will be necessary. Nearly all the multiple-current motors take large exciting currents, so condensers will be necessary in their case. Take the case, for instance, of the Dobrowolsky 2 h. p. motor, as it is the only case whose figures have been published: at no load it takes 70 volts and 30 amperes at 35 periods per second. This current is presumably in each of the circuits, so that the apparent power is 4,200 watts; at full load it takes 70 volts and 100 amperes in each circuit, or 14,000 apparent watts. It, therefore, requires two condensers to reduce the apparent watts to about a tenth of these values. The enormous exciting current taken by this form of motor is one of its greatest disadvantages. A condenser to supply 14,000 apparent watts at a frequency of 35 would have a volume of four cubic feet. If the frequency is raised to 100 the exciting current increases at approximately the same rate, and so the condenser remains the same size. As there is some difficulty in making large low-pressure condensers, it is best from that point of view to put the condenser on the high-pressure side of the transformer. This, unfortunately, demands that the transformer should be 10 times the size. Thus, a 2 h. p. motor of this type would demand a 20 h. p. transformer at a frequency of 35, or a 60 h. p. at 100 periods per second. The transformers are nearly the same size in these two cases. The enormous size of the transformer is a great drawback to machines excited by alternate currents, and, unless multiple-current motors can be greatly improved, this fault alone will be enough to render them useless for most work.

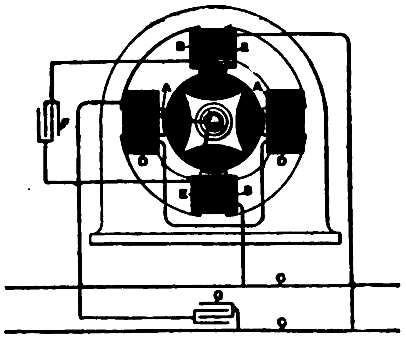


FIG. 1.

So far the condenser has been described as arranged in shunt to the circuit containing self-induction. It has then no effect on the circuit with self-induction, but affects the dynamo. In fact, it supplies exciting current instead of letting the dynamo supply it. The self-induction can, however, be counteracted by arranging capacity in series with it. For instance, suppose the alternate machine is made like one for direct currents, except that the field magnets are laminated. Suppose the machine in question is a 10 h. p. motor for 100 volts. If the field magnets are wound to suit 100 volts on a direct-current circuit, they will be only very slightly excited by the alternating pressure. If the number of turns is much reduced and the diameter increased, full excitation will eventually be reached, but the current will be enormous. For instance, if the magnets take two amperes on a 100-volt direct-current circuit, the loss in copper is 200 watts, but to drive two amperes through the inductive circuit with an alternate current would probably need something like 5,000 volts. If a few turns of large wire are used instead, the full excitation will probably be reached with about 100 amperes. Not only is the exciting current enormous, but the armature current is not in step with the field induction, so the output is lessened from this cause too. M. Leblanc was the first to point out the way to overcome these troubles by the use of condensers. A condenser may be put in series, of such a capacity that at the frequency employed the electromotive force of the condenser is always exactly equal and opposite to that of the self-induction of the magnets. This condition can only be attained approximately, as the pressure does not vary perfectly harmonically. If it did, all the electromotive force of the supply circuit would be spent on resistance, so that the same current would be produced as if the magnets were excited by a direct pressure. The field induction is then in step with the electromotive force, so that the armature current is so also, and the power taken by the motor is found by multiplying the pressure by the current.

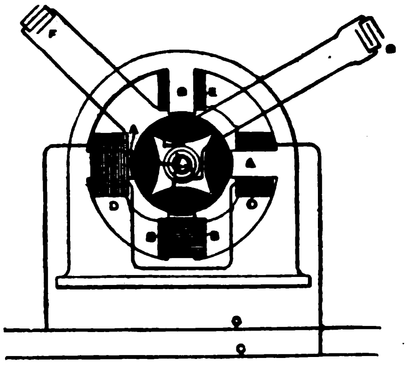

FIG. 2.

Messrs. Stanley & Kelly have designed and worked out a motor on this principle. It is constructed like an ordinary direct-current shunt motor, but has laminated field magnets. A condenser is arranged in series with the magnets. This motor has some drawbacks. In the first place, if the field magnets and armature are on a 100-volt circuit, the pressure on the condenser and on the field coils will be something like 5,000 volts, and this might make the motor too dangerous for admission to private premises. Of course this depends on the size and design of the motor. It may be possible to design a machine with much lower condenser pressure. The loss by hysteresis in the field magnets is also necessarily large; but that is not such a serious matter in a motor as in a transformer, which is on all day and all night. The next trouble is sparking at the brushes. The armature coils are short-circuited just at the time of the most rapid change of field, so that there is a large current in the short-circuited section. I would suggest that this trouble can be overcome by winding the armature with two separate circuits in parallel. The brushes then collect from both, but never short-circuit any of the sections.

The Tesla motor, as is well known, demands two or more currents differing in phase. Two currents differing a quarter of a period will do. At first special dynamos with double armature circuits were used as generators, but several arrangements involving condensers have been proposed. The first experiments of this kind were probably made by Prof. Ayrton and Dr. Sumpner. They had a small Tesla motor some years ago, but made up some arrangement with self-induction and capacity so as to split the single into a double current. The experiments have not been published, so I do not know what the exact arrangement was. Mr. Tesla has designed numerous arrangements himself; but the most complete investigations have been made by Messrs. Leblanc and Hutin, and those interested in this subject will do well to read the able articles in the *Lumière Electrique* which have been appearing recently at short intervals. These authors have gone most carefully and exhaustively into the whole subject of alternate-current motors of all sorts, and their papers are very suggestive. Fig. 1 shows a very simple arrangement due to them. One field magnet circuit E E has a condenser in series with it. Its current and induction are therefore in step with the pressure, and the wire used is the same as for direct currents under the same pressure. The other magnets A A, however, are wound with few turns of low-resistance wire B B, and take a large current, which lags practically a quarter of a period behind the pressure. In all practical cases the lag can be adjusted to a quarter of a period by using a condenser of the right capacity in the first circuit.

It is to be feared that there will be great difficulty in work-out this system to be right at various loads. As the load increases, an active current should flow in both circuits. The circuit with the condenser in series with it cannot take its load current, so that the full load output of this form of motor may be little more than half that of a double-current motor of the same size. It is probable, however, that the ingenuity of Messrs. Hutin and Leblanc in France, or Mr. Tesla in America, may overcome this drawback. A multiple-current motor is, however, thus obtained, which will work on ordinary supply circuits Only one of the sets of magnets takes a large "idle" current; but to avoid troubles from this a second condenser G in shunt to the mains C C or to the transformer that supplies the motors is advisable. This condenser is of the same cubical contents as the first, but unless arranged on the high-pressure side of the transformer it is designed for a much lower pressure and for a correspondingly larger current. By this means a self-starting motor can be obtained which has no brushes, which works on an ordinary supply circuit, and which gives full torque on starting. It has, however, the same drawbacks as the type first described. The dangerous pressure on the field coils of the first circuit may be reduced by arranging the magnet coils in small portions alternately. If the fields take 5,000 volts to drive the exciting current through, say, twelve coils, the coils and portions of the condenser may be arranged alternately, so that the maximum pressure is just over 400 volts due to the condensers. The fall over the resistance of the circuit is out of step with this, and may therefore be neglected. Mr. Tesla has also patented an arrangement on the same principle as Messrs. Hutin and Leblanc. He uses one field circuit partly as a transformer to transform up, and then places the condenser F in the secondary circuit D E D E. This seems rather to increase the difficulty arising from the very high pressures resulting from arranging condensers and induction coils in series. His arrangement is shown in Fig. 2. He has also put a condenser in the armature circuit, but it is difficult to see the inventor's object in this. Whether this form of motor is the motor of the future or not is difficult to say; but if it is, the number of condensers required will be considerable, so we are justified in discussing it at some length in this article.

There is still another possible use for condensers, and that is for exciting dynamos. An alternate machine may be regarded as made up of two elements. One has constant induction, and is called the field magnet; the other is variable, and called the armature. The field magnet may be excited by a direct current round it, or by an alternate current in the armature which is direct relatively to the field, because the armature changes position while the current changes its direction. As far as copper in the machine goes, it is cheaper to excite the fields by arranging the machine so as to have considerable armature reaction, and exciting by means of a condenser. Suppose when the field has its own coils the current density and weight of copper is the same in the field magnet and armature; if the field coils are removed and the condenser applied, the armature copper need not be doubled; it will carry the current at the same density as before, if the copper is increased in the proportion $\sqrt{2} : 1$. The total power wasted is then less than before; in fact, if the armature copper is not increased at all; the loss of power in the armature alone when the condenser is used is the same as that in the armature and field magnets together, with separate excitation. By the use of a condenser, cheapness, or higher efficiency, or a compromise of these can be obtained. The condenser itself is generally much cheaper than an exciter, and is of course very much more efficient. An alternate machine with a condenser follows practically the same laws as a shunt-wound dynamo, but it has only one copper circuit, and no commutator.

Perhaps enough has been said to show that condensers may have a large future. New possibilities are appearing every day, and there is no saying what combinations of capacity, self-induction, and resistance may be invented during the next few years.

CALENDARS FOR NEW YEAR.

WE have received a number of fine calendars for the New Year, and are making an æsthetic and effective disposition of them in our offices. Among them we may mention one from Mr. H. T. Paiste of Philadelphia, who, it will be remembered, has issued some very choice examples of time literature. We have also two calendars from the Commercial Cable Co. and the Direct United States Cable Co. The former is large, with a sheet pad; the latter has a leaflet pad, one leaf for each day. Pettingell-Andrews Co., of Boston, issue a large sheet calendar with big figures. The Bubier Publishing Co., of Lynn, is more modest in the proportions of its calendar, which is ornamented with a chromolithographic snow scene. The Ashton Valve Co., of Boston, have published a very tasteful calendar prepared for them by John A. Lowell & Co., who have put on it one of the finest "smooth" etchings. The Standard Paint Co., of this city, have sent us some charming little calendars for the pocket. They are printed in gold on tortoise shell, and are as useful as they are dainty. They are certainly "P. and B."—being both pretty and beneficial.

Letters to the Editor.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted, will oblige by mentioning the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

THE HUM OF MOTORS.

FOR the benefit of Mr. Binney, I will somewhat further elucidate my theory of the cause of humming in motors.

Sound, as any one at all acquainted with physics knows, is a mode of motion produced by a peculiar vibratory movement of matter, and is transmitted by any conducting medium to the drum of the ear, and thence by auditory nerves to the brain where it is recognized as sound; and not, as Mr. Binney says, "set up by some force or forces other than those derived from motion."

I made the statement in my article that the movement in the armature was a progressive, undulatory movement of the iron; I should have said a progressive, undulatory movement *around* the circumference of the ring, not a progressive movement of the *iron*; that is, the iron does not progress, but simply has a *progressive movement*, as on waves of water the water does not progress, simply the movement. Mr. Binney seems to be unaware that all wave motion is progressive.

The intensity of attraction on any particular spot of the circumference of the ring, as it is revolving, is constantly varying, producing a vibratory movement of the iron and a progressive wave-like motion around the ring. The vibratory movement of the iron produces also a vibratory movement of the air surrounding it, which air transmits the vibration to our ears and we recognize it as sound. The wave-motion *around* the ring is undulatory and transverse to its line, or direction of propagation and is *not* sound (and I never claimed it was); whereas the vibratory movement of the iron transmitted by the air is longitudinal to its direction of propagation and *is sound.*

If Mr. Binney doubts the slightness of vibration being able to produce the sensation of sound, it would be well for him to notice the phonograph in which the little glass diaphragm appears motionless, and yet we know it vibrates and produces sound. Perhaps it would be easier for Mr. Binney to understand the action if he would imagine the poles to revolve about the armature, which would produce the same result.

I should be pleased to know what the "more admissible theories, already somewhat numerous," are.

CHAS. J. HAYES.

DETROIT, MICH., Dec. 24, 1891.

MR. STUART AND REACTIVE COILS.

THE letters by F. L. P. and Prof. Elihu Thomson, in your issue of the 16th inst., both take me to task for saying, in my article on "Reactive Coils," that Prof. Thomson first stated that if a magnetic field cut or is moved across a conductor, a current of electricity will be generated in the conductor.

Regarding the references to Faraday's "Experimental Researches" made by F. L. P., all I have to say is, that the "principle" is not stated therein. But I am aware that the principle was *known* many years ago. I do not remember that I have ever heard it *stated* except by Prof. Thomson. However, I am willing to be corrected by such eminent authority as Prof. Thomson, and the matter cannot, probably, be better stated than in his own words: "Any one who is familiar with the work of Faraday and others will understand that the principle was known many years before I was born, and is a fact so self-evident that no statement of it would be required," etc.

Concerning Prof. Thomson's next point I desire to say, first, that I am aware of the nature of his patent, No. 428,647; secondly, that I knew of the apparatus he mentions he had in his house in Lynn, and have myself operated the same; and thirdly, that I was aware of the "problematical" efficiency, so called, of reactive coils when used for such purposes.

Prof. Thomson's patent does not describe such a device as the Ries regulating socket. The device used by Prof. Thomson in his house in Lynn was not such a device as the Ries regulating socket. Nor was I considering *who* was the original inventor of the device.

In my opinion the Ries regulating socket is one of the most interesting applications of the reactive coil. I first saw this socket at the Montreal Exhibition last September. Since then I have seen it tested, and I was surprised to find its efficiency so high. My remarks on it were made because I desired to name an application of the reactive coil of the most general interest and usefulness.

The patentability of the Ries regulating socket is a matter of opinion which I will not attempt to discuss. It seems to me as worthy of a patent as many other patented devices—as worthy, for instance, as some of the regulating coils of the Thomson Electric Welding Co.

Otis K. Stuart.

Philadelphia, Pa., Dec. 28, 1891.

IRON ROOFS FOR LIGHT AND POWER STATIONS.

When building an electric light or power plant, one of the objects in view is to have its construction as fireproof as possible. In order to secure this I know of four stations where iron roofs have been placed. These answer very well in the warm weather, but as soon as it becomes cold, very rapid condensation is the result and if not remedied very serious troubles may be caused by the water falling on machines, switchboards, etc. I know of one lighting station in particular which I visited during cold weather and found that wooden sheds had to be built over the machines in order to run them. I would ask through your numerous readers the best means of obviating this trouble, as it appears to me to be one of no little importance.

It may be a little difficult with the so-called "iron bridge" roof, but by placing a light woodwork under the rafters I should say it would answer the purpose with the least expense. Trusting you will give this a space in your valuable columns,

Alfred E. Braddell,
Electric Inspector, Underwriters' Ass'n., Middle Dept.

Philadelphia, Dec. 29, 1891.

REACTIVE COIL IN A KEYLESS SOCKET.

I have read with interest the various articles in regard to the reactive coil as used with a socket for the regulation of an individual lamp. It may be interesting to note that in the early part of 1889, when manager of the Gardner (Mass.) Electric Co. the writer made a small reactive coil and attached same to a keyless socket. This device was attached to the wires in the house of the vice-president of the Co., and turned down and up a lamp screwed into the socket. Owing to other work pressing this was laid aside to await a more favorable opportunity for placing it on the market. The opportunity never arrived however.

Eugene T. Carpenter.

Forge Village, Mass., Dec. 26, 1891.

Society and Club Notes.

PROF. J. P. BARRETT BEFORE THE CHICAGO ELECTRIC CLUB.

A paper was read by Prof. Barrett before the Chicago Club on January 4, on "Electrical Exhibits at the Columbian Exposition." With regard to electric light and power, he stated that about 25,000 h. p. will be utilized in the shape of current in the building and grounds. He said that an important part of the electrical exhibit would be the original models and apparatus of some of the greatest inventions. As to prizes and awards, he remarked:

"It is not contemplated by the National authorities of the Columbian Exposition to offer awards which would have so great an intrinsic value as to attract exhibitors, but it is contemplated to make the standard of excellence so high that the bare acceptance of an exhibit by a department will be a lasting and distinguished honor. In the Electrical Department, the space available for exposition purposes will be so small as compared with the demand, that the greatest judgment will have to be brought into play to decide what exhibits are worthy of a place and what will have to give way. It will be impossible to accept all. Therefore the presence of an exhibit in the Electrical Building will be a testimonial of its unusual merit. The awarding committees have determined to have full and exhaustive tests made of all machinery in competitive exhibition, by the juries of the different departments, and to publish these tests and the jury findings, at the close of the exposition, under the authority of the National Commission."

NATIONAL ELECTRIC LIGHT ASSOCIATION.

Work is being actively pushed for the convention at Buffalo next month, and there is promise already of good papers and a large attendance. One of the gentlemen who will contribute to the proceedings is Mr. Erastus Wiman, whose subjoined circular letter explains itself:

"Having had the honor of being especially designated by Mr. C. R. Huntley, president of the National Electric Light Association, to address the next convention at Buffalo, on the special subject of the financial side of electric lighting, I am desirous of all the help I can get to make a careful and strong presentation of the merits of this class of property. There is believed to be in the public mind, and especially in financial circles, a growing prejudice adverse to securities based on electrical properties. It would seem important at this juncture that as clear a view as possible should be had of the real facts of the case. Hence, it would be very desirable if I could be placed in possession of instances of successful companies, with particulars of the amounts of their stock, the length of time before dividends were paid, and the amounts regularly realized, cost of maintenance, and such other facts as can be readily got together. Some special instances of very successful concerns are particularly wished for, and the history of companies which have not at first been successful, but which have since been rescued from insolvency by good management; also any facts relating to combinations between gas and electric light companies, and how best it can be promoted.

"If you happen to have anything of that kind and can send it for me to Mr. George F. Porter, 136 Liberty street, New York, I shall be much indebted."

NEW YEAR'S EVE AT THE NEW YORK ELECTRIC CLUB.

The entertainment at the New York Electric Club on New Year's Eve was voted a great success by all who participated in it, and the club house between 7 p. m. and 1 a. m. was visited by about 150 members. A most interesting and eloquent address on various features of journalism was delivered by Mr. Joseph Howard, Jr., a member of the club, and one of the most celebrated correspondents in the country. The address abounded in reminiscences of the elder and younger Bennetts, Horace Greeley, Henry J. Raymond, Henry Ward Beecher and others, and bristled with anecdotes and epigrams as well as with many well-directed criticisms on the less admirable aspects of modern newspaper work. Mr. Howard was listened to for over an hour with the deepest attention and received a warm tribute of applause.

The musical part of the entertainment was begun by Mr. Alfred Grünfeld, Imperial Court pianist of Vienna, Austria, who rendered a fantasia on the themes of Lohengrin and Tannhauser. The delicate touch of Mr. Grünfeld in the piano and pianissimo passages and the feeling and expression infused throughout his rendering were remarkable, and called forth well-merited applause. He was followed by his brother, Mr. Heinrich Grünfeld, Imperial Court violoncellist, of Berlin, who played a "Romanza," composed by Mr. Alfred Grünfeld. In response to a hearty encore, Mr. Grünfeld played the "Golden Wedding," by Gabriel Marie. In response to the continued and unremitting applause, Mr. Grünfeld rendered the "Guitarre" of Moskowsky. As a violoncellist Mr. Grünfeld undoubtedly ranks among the best who have thus far been heard in this country. One of the most characteristic performances of the evening was the rendering of the "Hungarian Rhapsody," composed by Mr. Alfred Grünfeld, in which he portrayed with masterly skill the peculiar intonations and effects of the Hungarian national instrument, the cymbal.

The vocal part of the programme was inaugurated by Mrs. Anna Lankow, the well-known alto concert singer and vocal teacher, who sang the celebrated aria from Gounod's "Mignon" with most consummate finish. As an encore Mrs. Lankow sang the alto aria from "Samson and Delilah." The programme was brought to a close by Sig. Victor Clodio, tenor in Gilmore's orchestral company and now of the Italian Opera Company, who sang Tosti's "Rosa" with excellent effect, his high B, *sostenuto*, calling forth enthusiastic applause. Mr. Friedberg, the well-known pianist, played the accompaniments to Mrs. Lankow and Sig. Clodio in the most finished manner.

After the regular programme had been gone through, Steward Reynolds filled the club punchbowl and served a collation. A few minutes before midnight Mr. George H. Guy played "Auld Lang Syne" on both the pianos in the club parlor, and his music was ably seconded by a large gathering of those who had lingered to see the New Year in. Steward Reynolds is entitled to much credit for the success of the arrangements in the club and for the excellence of the table d'hote dinner and later collation.

CHICAGO ELECTRICAL ASSOCIATION.

At the regular meeting of the Chicago Electrical Association, Dec. 22, Mr. A. H. Adams read a paper upon "Chimneys and Chimney Draughts"; Mr. L. G. Bassett read a paper upon "The Speed of Electricity." The following officers were elected for six months, to begin Jan 12: President, E. G. Hovey; vice-president, J. I. Connor; secretary, F. R. McBerty, No. 227 So. Clinton Street; treasurer, Albert Scheible. This association meets the second and fourth Tuesday evenings of each month at No. 169 E. Washington street, Chicago.

GRAND RAPIDS, MICH., ELECTRICAL EXHIBITION.

Grand Rapids is about to have an electrical exhibition under the auspices of the Electromathean Society. Space will be granted to manufacturers and dealers in electrical goods, for simply the payment of the expenses pertaining to their own exhibit. Some new and attractive features are promised. Mr. Eugene B. Palmer is chairman of the Committee on Advertising and Solicitation, and will be glad to furnish information to any one interested.

NEW ENGLAND ELECTRIC CLUB.

Gentlemen interested in the New England Electric Club have elected the following-named officers: President, Mr. Ferdinand A. Wyman; vice-president, Mr. E. A. Record; secretary, Mr. Lynn M. Hays; treasurer, Mr. A. O. Smith; board of directors, Mr. Charles C. Pierce, Mr. Maybin W. Brown, Mr. Elmer P. Morris. The officers, with Mr. E. R. Tilton and Mr. James E. Cotter, were appointed a committee on constitution and by-laws and also to take all necessary steps toward obtaining a charter, and to investigate, consider and report in regard to obtaining quarters for the club. The club starts off with a membership of 110.

Obituary.

GEORGE W. COSTER.

In the death by pneumonia, at Schenectady, N. Y., of Mr. George W. Coster, district manager Rocky Mountain District, the Edison General Electric Company has lost one of its most faithful, efficient and zealous officers. Mr. Coster was educated at the United States Naval Academy, graduating from that school in 1867. He remained in the Navy until 1880, when he resigned and went into business. While in the Navy he acquired a thorough knowledge of discipline and of the handling of men under him, which he afterwards utilized to good purpose in civil life.

Mr. Coster was connected with the Edison interests for the past six or eight years, and his ability as an executive officer had been thoroughly demonstrated. He possessed to a marked degree the ability to surround himself with able assistants, men peculiarly fitted for their positions, and to secure from them the most devoted loyalty. His entire office was permeated with a loyalty to, and enthusiasm for, the interests of the company, which he himself served so ably and so well. Mr. Coster is not only a great loss to the Edison General Electric Company, but to his many intimate friends connected with the electrical business, who remember his warm friendship and genial manners, his death comes as a severe personal loss.

Personal.

MR. R. G. BROWN.

The many professional and business friends of the above-named gentleman will be greatly interested in the news of his marriage to Dr. Lucy M. Hall, of Brooklyn. Mr. Brown, who is at present connected with the Interior Conduit and Insulation Co., has had an active career in telephonic and telegraphic fields in this country and abroad. Dr. Hall-Brown is a well-known and popular practitioner, vice-president of the medical alumni of Michigan University, secretary of the Department of Health, of the American Social Science Association, and has been in many positions of importance and influence.

Legal Notes.

INCANDESCENT LAMP LITIGATION—THE UNITED STATES ELECTRIC LIGHTING CO. vs. THE EDISON LAMP CO.—IV.

ARGUMENT OF GEORGE H. CHRISTY FOR THE UNITED STATES COMPANY.

But defendant had said further that so much of the invention as was of any practical utility, was Maxim's and not Weston's, and that all manufacturers in this country were using what was spoken of as the "attenuated-gas" treatment. Mr. Christy read Shallenberger's explanation of the attenuated-gas treatment, showing that a deposit within the pores and a deposit upon the surface went together as the inevitable result of the passage of a current through the carbon filament in the presence of hydrocarbon gas. What were the substantial marks of identity of the process? Weston's claim called for the carbon pencil, filament, illuminant; for the passage of a current to raise it to a proper temperature, and a surrounding envelope of hydrocarbon liquid or gas. With reference to what? Why, the "building up" of the carbon, by putting into it, or on to it, or both, a deposit of carbon from the surrounding carbonaceous envelope. This attenuated-gas treatment they were talking about, had every element of the Weston claim, working in the same way, with reference to the same end, and producing identically the same result. Clarke the defendant's expert, had admitted that the use of hydrocarbon vapor was a part of Weston's original invention. The point was that the use of hydrocarbon vapor constituted part of Weston's invention, whether attenuated or not. Yet defendant had tried to argue that attenuated gas—lighter gas and less of it—did not come within Weston's invention. But to go a step further, it was a fact that the oil never touched the highly heated body anyhow; it was always surrounded with vapor. If you stuck a red-hot poker into water the poker would not come in contact with the water; the heat would generate an envelope of steam around it; so it was with the red-hot carbons in oil. Although oil was one of the materials mentioned in the patent, as a matter of fact the work was actually done by hydrocarbon vapor or gas.

There was another singular fact in this case; his brother Betts had conceded that Maxim had done nothing of consequence, except perhaps making one lamp, down to 1880; that he made one lamp and took some patents. Defendant had nevertheless gone to the expense of bringing Maxim from England to examine him. In his testimony in 1891 Maxim magnifies this process; claims the credit of it himself and says that he worked it practically and publicly in 1878. But his testimony in the old interference case in the record, squarely contradicts his 1891 testimony and showed that everything he did down to 1880 had been purely experimental, and had been so admitted in his previous testimony. But Maxim, their own witness, had said that between a little less than one atmosphere and a highly attenuated atmosphere, the difference was simply a difference of degree and not of principle, exactly as he (Mr. Christy), had contended, for reasons set forth in Shallenberger's testimony. Moreover defendant did not use attenuated gas, and it did not lie in their mouth to say that something else than oil was better. They had used oil, and so far as the proof went it was the only thing they ever did use.

Referring again to defendant's brief, Mr. Christy said he had already shown that it contained erroneous statements of fact. He thought it also contained some bad statements of law. Under the heading, "Rules of Law Here Relied Upon," was this passage: "It is a fundamental principle of patent law that to entitle an alleged inventor to protection by a valid patent, it must appear that he was the first in this country to reduce the invention to a fixed, positive and practical form. That was not the law, said Mr. Christy, and it never was. The rule had been well settled by repeated adjudications, especially in this circuit, that the party who first conceived an invention, provided he used reasonable diligence in adapting and perfecting it, was the party entitled to the patent, and it made no difference who came in between. Mr. Betts' next proposition was: "Mere speculations of a party, or experiments incomplete and inconclusive in their nature, or the production of drawings or models, are insufficient to sustain the issue of prior invention when the burden is upon him to prove it. That was about as bad law as the other. Judge McKennan had said, that the first inventor might by drawings, sketches and models, carry back the date of his inception, and if he had meantime used reasonable diligence, he could thereby establish priority. The third proposition was equally objectionable and for the same reasons. There had been no citations of authorities in support of those propositions.

(To be continued.)

A QUESTION IN FIRE INSURANCE.

A **case** of much interest to insurance and electrical companies has been brought at Salem, Mass., before the Superior Court.

On the 26th of October, 1890, the night employees in the power station of the Lynn Gas and Electric Light Company discovered fire in the tower or monitor cupola over the engine-room. Attempts were made to extinguish the flames, but before it could be done the tower was charred and the main light wires burned off.

The result was a quick short circuiting of the station. So big a load was taken off the engine that it began to race, and in a very short space of time the big fly wheel was hurled in fragments through the solid brick walls of the building, carrying havoc everywhere. The station was pretty well wrecked.

It was insured for $9,000 against fire in 23 companies.

The companies refused to pay their policies because the damage and loss was from the racing of the engine, as they claimed, and not from fire.

The Lynn Electric Light Company brought suit on the ground that the damage was from fire, and that fire was the first cause, as but for the fire, the burning of the wires and the release of the engine the latter would not have run away and there would have been no explosion.

Mr. R. W. Pope, secretary of the American Institute of Electrical Engineers, delivered an interesting lecture on Dec. 18, at Fitchburg, Mass., in the city hall, under the auspices of the Fitchburg Board of Trade. His subject was: "Electricity: Its Past, Present and Future."

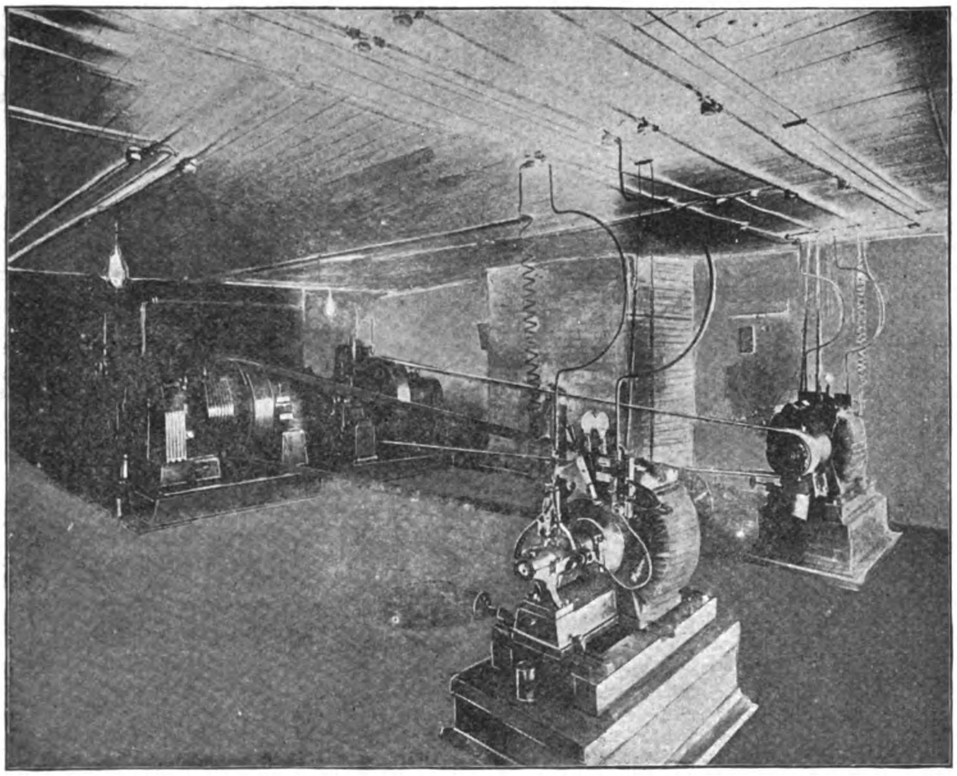
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

The man who doesn't advertise is soon out of circuit or grounded.

A "C. & C." LIGHTING PLANT IN THE ST. NICHOLAS HOTEL, CINCINNATI, O.

THE illustration on this page shows the dynamo-room of the St. Nicholas Hotel, Cincinnati. The two generators have a capacity of 300 lights each and are of the standard "C. & C." type. The fields of the dynamos are compound wound and the entire machine is constructed with a view to attaining the highest possible efficiency. The armature shaft revolves in self-oiling bearings, and the whole machine rests upon a sliding base, which can be adjusted to tighten the belt. This installation was made by the "C. & C." Electric Motor Company, New York, about a year ago, and the dynamos have been in constant service since then. The fact that a 40 K. W. dynamo of the same type has recently been added to this plant to furnish current for an increased number of lights, gives evidence of the satisfaction which these machines have given.



"C. & C." LIGHTING PLANT IN THE ST. NICHOLAS HOTEL, CINCINNATI, O.

THE EQUITABLE ENGINEERING AND CONSTRUCTION CO.

THE Equitable Engineering & Construction Co., Drexel Building, Philadelphia, announce that on the 1st of January their company will go into liquidation. Their business for the past year has been a profitable one, but the active members of the concern wish to get out of the construction business.

Mr. S. Ashton Hand has accepted a position as superintendent of the Detroit Electrical Works, Detroit, Mich.. and Mr. W. A. Stadelman wishes to devote his time for the present to his interests in Bristol, Tenn., which consist of the Bristol Belt Line Railway and the Bristol and East Tennessee railroad, in both of which he owns a controlling interest.

The company retires from business with every debt paid and a good balance to be distributed as a dividend to the stockholders.

WESTERN ELECTRIC COMPANY—MORE FACILITIES?

WHEN, some eight years ago, the Western Electric Company purchased its extensive property in South Clinton street, Chicago, and erected a large building upon a part of it, it may well have been thought, even by the company itself, that abundant provision for its Western manufacturing and for its general offices had been made for a generation. Several extensive additions to the building have since proved requisite until the entire ground has been occupied, and yet more space is required for the company's constantly augmenting business. It is now reported that a purchase has been made of a block of ground adjoining the factory on the south, and known as the Collins and Burgie property, the ground measuring 300 by 200 feet.

Inquiry at the New York office of the Western Electric Co. fails to secure a confirmation of the report, and we have been unable to learn whether it is the intention of the company to erect extensive factory buildings upon the property at once, or not. It is the well-understood policy of the Western Electric Co. to maintain its manufactories within cosmopolitan cities, rather than in suburban locations near such cities, or in smaller towns. In accordance with this plan its manufacturing business is, at present, compactly located and organized in Chicago, New York, Antwerp, Berlin and in Paris.

It is also worth noting that the company has always refrained from premature announcements of its policies and intentions, preferring to await the completion of its facilities and extensions before notifying the world of them.

The report can hardly be without some foundation in fact, though we are not apprised of the purchase price of the real estate. The property includes several buildings erected by Collins & Burgie, who have conducted a foundry business on the premises for 30 years. The property can be worth scarcely less than half a million dollars, situated as it is, near the central business part of Chicago.

As the Western Electric Company has never been known to speculate in real estate, nor to undertake any piece of business just for the fun of the thing, it seems reasonable to infer that it is about to construct an extensive addition to its present Chicago factory.

F. P. LITTLE & CO.

THE above enterprising firm of electrical engineers of 141 East Seneca street, Buffalo, N. Y., have just closed a contract with William H. Walker & Co. for the installation of a 250 light Thomson-Houston incandescent dynamo and a Rice engine, for their new eight-story building on Pearl street, that city.

"P. & B" INSULATING COMPOUNDS.

A LETTER was recently sent by Mr. George P. Low, electrical inspector for the Pacific Insurance Union, 307 Sansome street, San Francisco, Cal, to the Paraffine Paint Co., San Francisco, who manufacture the "P. & B." insulating compounds on the Pacific coast, and for the territory west of the Rocky Mountains. The letter contained among other things, the following :—

"Permit me to express appreciation of the inestimable benefit you have conferred upon the electrical industry in perfecting and bringing out your "P & B." electrical compound. I know of nothing in the way of an insulating paint for all-around work that is compared to it."

The Pacific Insurance Union controls the entire insurance work of the Pacific coast, and early this year, Mr. Low made tests of all the insulating materials offered for sale on that coast to determine the safest insulation for the wiring of buildings. Severe tests of the compounds were made, the "P. & B." standing the tests better than anything else, and it is now compulsory that "P. & B." be used in all electrical work which comes under the control of the Pacific Insurance Union. The Pacific Postal Telegraph Cable Co. are painting their bare wires, on the Pacific coast, with "P. & B.," it having been demonstrated that wires so painted have worked perfectly during the heaviest rains, and the densest fog, while through the unpainted wires, not a tick could be heard at such times.

The Paraffine Paint Co. is the Western branch of the Standard Paint Co. of No. 2 Liberty street, this city.

THE THOMSON-HOUSTON CO. IN THE WEST.

THE Chicago office of the Thomson-Houston Electric Company has just closed a contract with the Benton-Bellfontaine Railway Company, St. Louis, for the equipment of thirty cars with two motors each of their latest improved type, known as the W. P., or waterproof. The contract includes the furnishing of three 333 h. p. compound-wound generators of the Thomson-Houston manufacture, and it is understood that the railway company will do everything that is required to make this installation a model, complete and perfect in every respect.

The Thomson-Houston Company have their electric railway equipment in exclusive use in St. Louis on the following roads: St. Louis & Suburban, Union Depot, Mound City, Missouri Railroad, Suspension Bridge and East St. Louis, and it is now believed that St. Louis has more T.-H. electric railway apparatus in use than any other city in the United States, with the single exception of Boston.

ENGINEERING EQUIPMENT CO.

FACTS "talk." These are facts, reported under date December 18th by the Engineering Equipment Company, of 143 Liberty street, New York. Recent shipments of Anderson's electric railway specialties—2987 "Ætna" insulators; 150 "Boston" trolleys, complete; of Anderson pull-offs, 536; terminals, 405; tree insulators, 925; hangers, 1,595; also miscellaneous shipments in considerable quantities of other Anderson specialties. All of the above were additional to direct factory orders Besides these shipments the Engineering Equipment Company report the following: 310 clips, 1,500 eye-bolts, 7,500 rail bonds, 400 turn buckles, 500 bond clamps, 625 trolley ears, 150 curve insulators, 430 trolley bells, etc. These and other materials not mentioned have been supplied to important electric railways in Massachusetts, New York, New Jersey, Pennsylvania, Georgia, Tennessee, Ohio, and in Canada.

The Engineering Equipment Company are the authorized sales agents for Messrs. A. & J. M. Anderson's reliable line apparatus and "Boston" trolleys.

OTIS K. STUART.

THE above-named engineer has now established himself at the City Trust Building, Room 21, Philadelphia, where he will not only act as agent for the Germania Electric Co. in the Southeastern district, but will handle such electrical supplies as dynamos, transformers, lamps, sockets, shade-holders, etc. All who know Mr. Stuart, and are familiar with his activity and versatility will expect for him a prosperous career in his new sphere of labor.

THE BURTON ELECTRIC COMPANY.

AT a meeting of the board of directors of the Burton Electric Company, held on Dec. 15 at the Citizens' Bank, Richmond, Va., the following resolution offered by Maj. Chas. R. Skinker, was unanimously adopted:

Be it resolved, That after hearing the favorable report of the superintendent, Dr. W. Leigh Burton, as regards the status of its business, we, the directors of said company, hereby desire to express our entire appreciation and satisfaction to Mr. W. R. Mason, president of the company, for the zeal manifested by him in the management of its affairs, and for his untiring efforts for the advancement of its interests; and to say, further, that we are well satisfied with the success of the enterprise up to this date.

THE SECURITY INSULATOR.

A VERY pretty and pithy little circular has just been issued by the Security Insulator Co., of 136 Liberty street, on the merits of their insulator, which was recently illustrated and described in our columns. The circular makes a neatly humorous statement of the good features of this insulator, the principle of which is that of the inclined plane. The wire fits snugly into the groove and is then held tightly by screwing the top cap down on it.

BALL ENGINES AT KEY WEST.

THE electric light plant being erected at Key West, Florida, is a source of great curiosity to a great many of the natives, who have never seen anything of the kind before. The three large compound engines furnished by the Ball Engine Co., Erie, Pa., are the centre of attraction, the largest engine on the island, hitherto, being an antiquated 6 h. p.

THE CARD ELECTRIC MOTOR AND DYNAMO CO.

THE above company, of Cincinnati, O., is now ready for business under its new incorporation. The officers are: J. W. Welshire, president and treasurer; George Bullock, vice-president; C. B. Simrall, secretary; G. B. Wilson, assistant secretary; and O. W. Jantz, electrician and superintendent. The company will push for business more actively than ever, and reports a bright outlook for the coming year.

HEAVY ELECTRIC TRACTION.

IT is stated that the Illinois Central Railroad is likely to adopt electric power for the purpose of drawing its heavy trains in and around Chicago, where the smoke of locomotives has become an intolerable nuisance. It is understood that the New York Central has had a similar idea under consideration for its New York terminal tunnel. The Illinois Central has appointed two of its directors, J. W. Doane and Norman Ream, a committee to investigate and report upon the feasibility of having all trains entirely propelled by electric motors.

FACING UP GENERATOR CASTINGS.

A NEW portable milling machine has been designed by one of tha foremen of the Thomson-Houston Company, at Lynn, for facing up the castings of big generators. The tool is said to do in five hours the work of four days when a planer is used.—*Engineering Record.*

NEW YORK NOTES.

THE EASTON ELECTRIC COMPANY, of Brooklyn, N. Y., lately sold to the Messrs. J. S. & G. F. Simpson, of 28 Rodney street, Brooklyn, N. Y., a six hundred light incandescent plant, consisting of a No. 9 Easton incandescent dynamo and the lamps. The plant includes a number of the Easton arc lamps which are operated on the incandescent circuit. The entire installation was made by the Easton Company and was pronounced a success. The plant is in daily operation on the premises owned by the Messrs. Simpson, and gives entire satisfaction. This is the sixth large plant which the Easton Company have lately installed in Brooklyn. This fact is good evidence that the work of the company is appreciated at home.

MR. H. WARD LEONARD has been called into consultation by the consolidated electric light companies of St. John, New Brunswick. When all the changes that he is to supervise and suggest are made, the company will have 180 arc lights, 5,000 incandescents, and a large power plant for running the street railway.

THE LAW BATTERY Co., of 85 John street, issued as a Christmas memento a huge stocking, which typified in a degree their own capacity for receiving orders. The stockings were greatly in demand and none have been returned as misfits.

MR. F. V. DOTY.—The marriage of Mr. Doty, the manager of the Aluminium Carbon Co., of Lancaster, N. Y., to Miss. Frances E. Olmsted is announced for January 14, at the Presbyterian Church, Geneseo, N. Y.

WALTER ROACH, the bookbinder, Pearl st. and Park Row, has lately put in a 5 h. p. Edison motor to run his large establishment and is more than pleased with electric power.

"A. B. C." GREETING.

WE have received from the enterprising house of Alexander, Barney & Chapin, of 20 Cortlandt st., an extremely tasteful and pretty souvenir of the season, accompanied by greetings for the New Year. It is adorned with portraits of the company's friends and "enemies." The portraits are very faithful, and the expressions will be recognized by everybody as wonderfully characteristic. The brochure is printed in colors and comes from the Bartlett press—a fact which speaks volumes for its typographic and artistic excellence.

STAR ELECTRIX.

THE Star Electrix Co. promise some new things in the way of electric lighting novelties to begin the new year. They will be put upon the market in a few days.

RECIPROCITY IN THE WEST INDIES AND SOUTH AMERICA.

THE new reciprocity treaties with the British West Indies and Salvador admit American electrical supplies and apparatus free of duties into those regions.

WESTERN NOTES.

THE ENGLEWOOD ELECTRIC LIGHT COMPANY are doing a very prosperous business in furnishing incandescent lighting in that section of Chicago, their business having increased 60 per cent. during the past year. Among other work that they have done of late, and which is well worthy of mention, is installing and furnishing current for 300 lamps in St. Cecilia Church, of Forty-fifth and Atlantic streets, for the Rev. E. A. Kelley. This church has been modeled after Notre Dame at Paris, and the lights are arranged one-half around the dome and also around the octagonal portion. On account of the distance of the lights from the station—some three miles—they have employed "boosters," manufactured by the Westinghouse Company, to give the required voltage at the lamps, making it a very interesting plant.

ELECTRIC APPLIANCE CO.—Any one happening into the busy store of the Electric Appliance Company during the last week of December would have wondered at the unusually busy appearance of the place which at no time since the new firm started has been anything but busy. The president of the company, Mr. Willard W. Low, had just returned from a business trip and any one familiar with the personnel of the Electric Appliance Company knows what that means. Mr. Low filled the Electric Appliance Christmas stocking with orders that made holiday week a very restless one for the employés of the company and a merry one for the firm.

ELECTRICAL SUPPLY CO.—Any device that is simple and which contributes to the ease of operating the dynamo is generally welcomed by practical engineers. The Wirt dynamo brush seems to have been a particularly happy design in this respect. The Electrical Supply Co., Chicago, who are the manufacturers, say that they have met with unusual success in introducing it. Engineers who have tried it say that it entirely prevents sparking and the consequent wear of the commutator. Each set is made to order. In this way they are certain to meet the exact conditions of service where used and give the greatest satisfaction.

THE ELECTRICAL SUPPLY CO., Chicago, the Western agents for the well-known "Boston" trolley, report a very marked increase of orders since the announcement of a reduction in price. They keep a full line of complete trolleys and parts in stock. They are also manufacturing a superior grade of raw-hide pinions which are meeting a ready sale. The general inclination of the trade is toward a better quality of supplies, and it is among this class of purchasers the Electrical Supply Co. find their largest buyers.

SOME QUICK WORK has recently been done in connection with the rearrangement of the Chicago Arc Light & Power Company's station recently destroyed by fire. On December 8, this company placed an order with the Chicago offices of the Pond Engineering Co. for a 200 h. p. Armington & Sims engine. The engine was shipped, complete, from St. Louis on the 9th inst. The railroad company delivered it in Chicago on the 14th inst., and on the 17th inst. the engine was ready for operation, and is now regularly driving six 50-light arc dynamos.

MR. F. E. DRAKE is now the selling representative of the Standard Electric Co., manufacturers of arc and incandescent systems of lighting, power generators and motors, at 313 to 317 So. Canal street, Chicago. Mr. Drake is an old telegraph operator, but for a number of years past has been interested in mining engineering in the West, and later in electrical work.

THE ELECTRIC APPLIANCE COMPANY are meeting with splendid success in introducing the New England switch to the Western trade and already report large sales. The Electric Appliance Company have inaugurated what we think a new departure in the electrical supply business; that is, the publishing of a catalogue especially devoted to toys and novelties for the holiday trade. About December first they printed quite an elaborate little catalogue of this character which they have distributed all over the country through the medium of the young people's periodicals, and which is bringing in quite a valuable trade in a small way. The Electric Appliance Company certainly deserve credit for this original idea and in placing before the people in general an opportunity of securing reliable electrical toys and novelties in the electrical line, as heretofore this business has been left to irresponsible dealers and the purchasers have been imposed upon to a large extent.

MR. ERNEST L. CLARK, widely known in electrical circles, has resigned as secretary of the Illinois Electric Material Co. He has organized the Ernest L. Clark Co., which will commence business the first of the year handling poles, ties, cross-arms and all kind of wooden material for electrical construction work. Mr. Clark's many friends will wish him the full measure of success in his new venture, returning as he does to his old line of business in which in the past he achieved an extended reputation and success.

THE RACINE HARDWARE MFG. CO., of Racine, Wis., have just received a second order from the Colorado Smelting and Mining Company, of Butte, Montana, for a 15 h. p. automatic engine for driving an electric lighting plant. This company have had a 10 h. p. of the same make at work for some time and the repeat order is the result of the excellent satisfaction given by this first engine.

MR. GEO. A. MCKINLOCK has returned, with his wife and infant daughter, to Chicago, from his wedding trip around the world, on which he has been gone for more than a year. He will resume his interests in the Central Electric Company and will be back shortly at his desk.

MR. CHAS. E. GREGORY, dealer in standard makes of dynamos, lamps and motors, has leased a floor at 205 So. Canal street. He furnishes machines of all makes and sizes, either new or second-hand, and also pays attention to installing of electrical plants of all kinds.

MR. L. K. COMSTOCK, the Rookery, is doing a general consulting electrical engineering business. He prepares plans and specifications for all kinds of electrical work and supervises the same. Mr. Comstock is meeting with good success here.

THE CENTRAL ELECTRIC COMPANY recently made the heaviest shipments yet in Swan incandescents. They are filling large orders right along, and the large and varied stock they carry enables them to make exceedingly prompt shipments.

CUTTER'S PLUG HAT INSULATOR. One of the odd orders lately received by George Cutter called for "those plug hat insulators that keep the ceiling white." Many who know his E. L. insulator may have other epithets for it.

GEN. C. H. BARNEY, of New York, was a visitor to Chicago, last week, He called at the Western office of THE ELECTRICAL ENGINEER. He was much interested in the progress being made on the World's Fair work.

PROF. D. C. JACKSON, instructor of electrical engineering of the University of Wisconsin, at Madison, Wis., was in Chicago, last week, visiting his many friends among the electrical fraternity.

MR. J. G. BECKERLEY, 229 So. Franklin street, is placing on the market a noiseless back-pressure valve for exhaust steam-heating purposes. It is a very simple and effective device.

THE CENTRAL ELECTRIC COMPANY are sending their friends their handsome calendar for 1892, and shall be glad to hear from those who are not supplied, so that they can be furnished.

THE CENTRAL ELECTRIC COMPANY have ready for distribution a handsome lithographed circular of the Bryant specialties, which have earned such a well-deserved reputation.

MR. C. A. BENTON, manager of the railway department of the Detroit Electrical Works, was a welcome visitor to Chicago last last week.

MR. N. P. SENAT, formerly connected with the *Street Railway Gazette*, of Chicago, has accepted a position with the *Chicago Herald*.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.

VOL. XIII. JANUARY 13, 1892. No. 193.

AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—I.

BY

Mary A. Henry

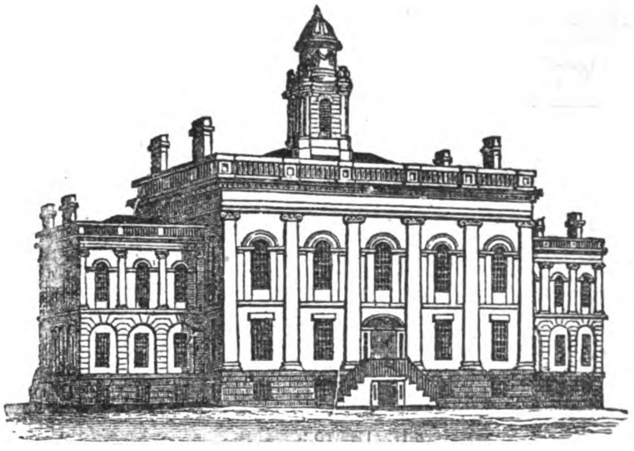
THE phenomena of self-induction and of mutual induction are closely connected, and indeed must be treated together as one whole in the modern theories of electricity and magnetism. After the discovery of self-induction by Henry, it seems to me but a step to the discovery of magneto-induction. This step was moreover made easy by the construction by Henry of electromagnets with great numbers of coils of wire. With a suitable galvanometer, also constructed with many turns of wire, there was sufficient residual magnetism in Henry's large electromagnets to give deflections of the galvanometer when the armature of the magnet was moved on or off the poles of the electromagnet, even when the latter was not excited by a battery.

MICHAEL FARADAY.

JOSEPH HENRY.

From a careful survey of the evidence presented, I believe that *Henry was the first to perceive the fluctuations of the galvanometer due to magneto-induction*, and that he had a conception of the relations of magnetism and electricity before Faraday published his first paper on the subject of magneto-induction. Henry has himself stated that he had perceived the phenomena of magneto-induction, and had been intending to study them further; but was prevented from pursuing the subject by unavoidable interruptions, and the desire to construct more powerful apparatus to continue his investigations. When we reflect that he had to insulate his wires with calico cloth, and to wind all his own electromagnets; that he was pursuing his investigations in Albany—then little more than a frontier town—while Faraday was at the Royal Institution, in the intellectual centre of the world, we feel that too much cannot be claimed for our countryman.—JOHN TROWBRIDGE.

IN the year 1774, a question of no small significance was presented as a subject for prize essays by the Academy of Bavaria. The subject was one which even at that early day had excited deep interest in the scientific world; it was no less than "the identity of the two great mysterious forces, electricity and magnetism." The essays received in the competition were so numerous as to make 13 large folio volumes of matter, but the report of the Academy nevertheless was to the effect that "although electricity and magnetism are by some experimenters proved to be the same in some respects, in other respects they are dissimilar, so much so that they must of necessity be as yet considered as distinct." In this indeterminate state the matter rested for 56 years, until 1819, when, by the deflection of a needle Oersted became immortal. While the Danish philosopher was one day lecturing to his class in the University of Copenhagen, an experiment occurred to him and he tried it then and there for the first time. It was a simple matter; nothing more than the passing of a galvanic current through a wire parallel to and above a magnetic needle. Oersted found that under these conditions, the needle, swinging upon its pivot, turned eastward, and at length came to rest at right-angles to the wire, its north pole pointing east. When the wire was held below the needle, the north pole turned westward, and settled pointing west. What had happened here? What was there in this mere swaying of a bit of steel through an inch of distance to bring fame to a philosopher like Oersted? The little needle was not a common needle, a mere unresponsive fragment of steel. Endowed with the mysterious principle of magnetism, it had as one might say, a soul, and as human soul answers to human soul, it was quick to respond to another magnetic soul. Had an ordinary magnet been brought to bear upon it, in obedience to the magnetic instinct, it would have excited no surprise, had it responded to its influence. What then, we ask again, had happened in the experiment of Oersted? The little needle was behaving exactly as if the wire traversed by the electric current possessed magnetic properties. Was this, in truth, the case? Had electricity produced magnetism in or about the wire? Or was electricity itself magnetism? Oersted published four quarto

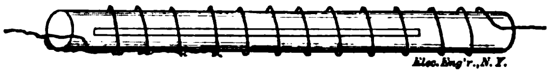


THE ALBANY ACADEMY, AS IT APPEARED IN 1826–32. FROM A CONTEMPORANEOUS WOOD-CUT.

pages on the subject;[1] the fame of his experiment spread with almost unexampled rapidity throughout the civilized world; it was repeated everywhere, and Schweigger seized upon the little needle to make of it the gavanometer,[2] so indispensable in the laboratory of the electrician from that day until this.

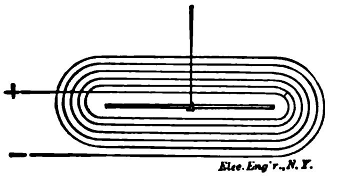
Very brilliant were the scientific men in the old world of that day, and about the year 1820 not a few of them were deeply interested in the question of the "identity of electricity and magnetism."

In the same year we find Arago and Sir Humphry Davy passing currents of electricity through wires and noting carefully the attractive power produced. Ampère caused two wires, each traversed by a current, to attract and repel each other, as if they indeed had been two magnets. Arago reached a result of no small importance; it was this: He placed a common steel sewing needle within a glass tube; around the exterior of the tube he wound a helical wire, through which the electric current was made to pass. The needle under these circumstances was found to become strongly magnetic.[3] Nature here asserted, in most unmistakable terms, that electricity could produce magnetism. Five years later we find Sturgeon bending a bar of soft iron into a horseshoe and by an obvious adaptation of Arago's method rendering it so strongly magnetic by means of a current of electricity, as to be capable of sustaining a weight of nine pounds.[4]



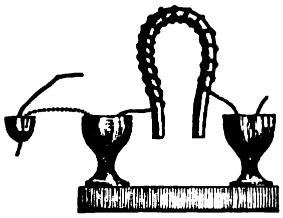
MAGNETIZATION OF STEEL NEEDLE BY ARAGO, 1820.

There is not the shadow of a doubt, after the year 1825, that electricity can produce magnetism; but the reverse, Can magnetism produce electricity? With ever-deepening interest as year after year goes by, the scientific world asks this question, but with all the most eminent men of Europe at work upon it, nature vouchsafes no reply, and so we come down to the last days of August, 1831, and to two men, one in the old world, the other in the new, at work upon the problem, each unconscious of the other, an ocean between them. One of these men is Michael Faraday, professor of chemistry in the Royal Institution of Great Britain; the other is Joseph Henry, professor in the Albany Academy in the State of New York. These two were destined to find the key to the problem; the answer to the question which had baffled the world of science for half a century.



SCHWEIGGER'S GALVANOMETER, 1820.

Copyright in *The Century Magazine*, April, 1888, by THE CENTURY CO.



STURGEON'S ELECTRO-MAGNET, 1826.

We say the last days of August, 1831, because at that date, the work of the two men nearly touch in point of time; but the actual discovery of magneto-electricity, the reader will see, if with kind patience he will follow our story, had been made by the one, that is, Henry, at least a year earlier, namely, in August, 1830, while it was not fully accomplished by the other until some thirteen months later, namely, the 24th of September, 1831; for this we shall find to be the date at which Faraday first fully recognized the phenomenon, and the principle by which it is controlled.

To understand properly the work of these two men, in reference to the discovery of magneto-electricity, it is necessary to know something of the circumstances in which they were placed. When Sir Humphry Davy was asked, which he considered his greatest discovery, he answered, "Michael Faraday." Entering the Royal Institution in an humble capacity in 1813, the flower of his genius growing and expanding under the fostering care of Sir Humphry, Faraday had attained a high position, and an enviable scientific reputation, in the great London institution. Director of the laboratory, he was surrounded by every possible facility for the prosecution of his investigations; and what was perhaps even more important, had unlimited time at his command in London, the great centre of scientific light. He was now forty years of age. Henry was nine years younger. When Faraday first entered the Royal Institution as an assistant, Henry was but thirteen. Counting the years of his age with those of the century, he had entered upon a course of original investigation as early as 1827, but amid such arduous duties as an instructor in the Albany Academy, that of all the twelve sisters of the year, he could only claim the month of August, the vacation time of the institution, as really his own. During four years he had been able to secure hardly more than as many months for regular scientific research. Could we look into his laboratory at this time, we would find, instead of the well-filled cabinets of the Royal Institution, only a few rude instruments made at great expense of time and labor by his own hands. Even the material for these rude tools was often difficult to obtain. Experiments, for instance sometimes stopped merely for the want of a scrap of zinc. We say "could we look into his laboratory," but we would seek in vain for a room which could properly be so called. Each series of experiments was necessarily carried on in the large hall of the Academy, which was available for Henry's use at no other time than during the summer vacation. Invariably all investigations came to a stop with the first of September, the beginning of the autumn session of the Academy, and were rarely resumed

FARADAY'S LABORATORY IN THE ROYAL INSTITUTION.

---

[1] A verbatim copy of Professor Oersted's original communication, in Latin, and a translation of the same may be found in *Journal of the Soc. of Tel. Engrs.*, v, 459, 464; together with a biographical sketch of Oersted by C. L. Madsden. [EDITOR.

[2] Schweigger's first galvanometer was a very simple affair, consisting of a small compass box, around which was coiled several turns of copper wire in a direction parallel to the meridian line of the dial. See *Schweigger's Journal für Chemie and Physik*, xxxi, 1-17. [EDITOR.

[3] Arago's experiments were published in *Annales de Chemie et de Physique*, xv, 93. Immediately afterwards, but before any account of Arago's experiments had reached him, Davy had also magnetized needles by the voltaic current, and by discharges of frictional electricity. He had also discovered the attractive effect of the conductor upon iron filings. His letter to Wollaston, recounting these experiments, is in *Philosophical Transactions*, 1821. It bears date Nov. 12, 1820. [EDITOR.

[4] *Transactions Society of Arts*, 1825, xliii, 38-52. The accompanying illustration is a fac-simile of that annexed to Sturgeon's paper.

until the month of August came again.[5] The invaluable stimulus of scientific intercourse and appreciation too, was wanting. Very different was the dull commercial town of Albany, from London, the intellectual metropolis of the world. A wide expanse of waters, not yet crossed by the swift ocean steamer, lay between Henry and all the culture of the old world, and in provincial America, little could be found to make good its place. Moreover, it must not be forgotten that Henry was the first who had undertaken a series of electrial experiments in America since the time of the immortal philosopher who first drew lightning from the clouds; "the mantle of Franklin"—said Sir David Brewster—"has fallen upon his young shoulders." Excepting Dr. Hare of Philadelphia, who was making notable improvements in galvanic apparatus, almost alone in the electric field, he stood to face the army of the old world.

Recalling the wide difference in condition surrounding the two, it is of no small interest now to see to what eminence each had at this time attained, the one during his eighteen years of culture and unimpeded work; the other in his few months of intermittent study, snatched at long intervals from the crowded days of four years of arduous professional labor. Constantly pursuing similar investigations, making many identical discoveries, Faraday and Henry seem like two competitors in a closely contested race, upon whose course we have suddenly come in these August days of 1831, and with curious eyes we scan the field to see how they are running. Bence Jones says:

> "If Faraday's life had ended at this time, when he finished his higher education, it might have well been called a noble success, but when we turn to the eight volumes of manuscripts of his *Experimental Researches* which he bequeathed to the Institution, we find that *his great work was just going to begin.*"[6]

Henry had begun his course with a series of original discoveries which might well weigh in the balance with anything Faraday had as yet accomplished, while in the particular field in which lay the "*great work*" of Faraday, which he was now "*just going to begin*" he had not only entered, but was already far ahead. The mysterious phenomena of the induction of electric currents, the reciprocal production of the magnetic and electric forces, were to him already old stories, intimately familiar, singularly well comprehended by him at this early date. He is in truth but amplifying the results which Faraday has just begun to seek, in these waning days of the summer of 1831. The younger man, as it were, had struck almost immediately into this particular path, and is now almost lost to sight in it, while the elder has only just come to the spot where his entering footsteps began.

Let us dwell for a moment upon the importance of the answer to the great question we have been considering, the value to the world of the discovery made by these two men.

It is not too much to say that it constitutes a veritable epoch in electrical science; upon it depend many of the most important applications of electricity to the uses of man, and new applications are developing day by day. Tyndall, the successor of Faraday in the Royal Institution, does not attempt to restrain his enthusiasm in the contemplation of it:

> "I cannot help thinking" (he says) "when I dwell upon it that this discovery of magneto-electricity is the greatest experimental result ever obtained. It is the Mont Blanc of Faraday's own achievements. He always worked at great elevations, but higher than this he never attained."[7]

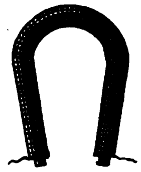
Edward N. Dickerson, the eminent advocate, said of Henry:

> "The towering heights that were scaled by the daring spirit of Faraday from the East, were at the same time surmounted from the West by our own countryman; both were climbing from opposite sides at the same time, and neither was conscious of the other's efforts till both stood face to face upon the summit."[8]

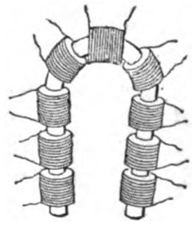
But the standard of the West had been floating many months upon these towering heights before the standard of the East was planted. It was Henry's foot, not Faraday's, which first touched the untrodden peak.

It was curious, that with such a host of the most brilliant minds of Europe at work upon the problem, the discovery which solved it was so long delayed. But there was a fact, which, it would seem almost with malicious or mischievous intent, successfully eluded all research. This fact was the necessary condition of *motion or change* for the production of the effect, and consequently the transitory nature of the phenomenon. If a magnet is thrust into the opening of a hollow helix of wire, electricity is manifested in the wire, but only for a brief instant, when the magnet is inserted and when it is withdrawn.

There is a fairy tale of a farmer's wife, whose heavy labors were lightened by a friendly gnome, who was never seen because he could never be caught at the moment he was at work. In all these years magnetism had been producing electricity under the very hands of these wise philosophers, but had never been detected in the act. *It was not caught at the moment it was at work.*



HENRY'S INTENSITY MAGNET.



HENRY'S QUANTITY MAGNET.

Let us see in what way Faraday and Henry, these two favored children of nature, ask of her the all-important question, so as to win at last a reply. Courtesy to the elder man and to the inhabitant of another country, would seem to suggest that we first go over the sea to Faraday; but this may not be, for we must look among Henry's own instruments for the stepping-stone to the great discovery, made by Henry's own hands to be a stepping-stone not only for himself but for Faraday.

Young Henry had before this time, as one of his friends has said, "made the lightning his familiar, his demon, his servitor; had lured it into his lecture-room from out of its cloud home in the thunder-storm, and tamed it so that he could bridle it, mount, ride it and spur it at will."[9]

He had taken the soft iron horseshoe of Sturgeon, with its spiral of loose uninsulated wire, an infant lifting but a few pounds at an inordinate expense of battery power, and had transformed it into a giant capable of sustaining fifty times its own weight, under the stimulus of a battery of a single pair of plates of copper and zinc, scarce a hand's breadth in area. He had made two magnets; his "intensity" magnet with a long single wire, and his "quantity" magnet with many short wires; the latter the stronger in actual physical force, but the former endowed with the subtle capacity which enabled it to respond to the electric influence at long distances; the magnet, in fact, which made the electric telegraph a commercial possibility instead of a philosopher's plaything. He had discovered and made plain the law governing the relation between the electric flow and the electric resistances in battery and magnet, and by this discovery had married, as it were, his magnets to their respective batteries; the "intensity" magnet of a long single wire to the "intensity" battery of many pairs of plates; the "quantity" magnet of many short wires to the "quantity" battery of a single large pair of plates; and had sent forth these children of his brain, through the pages of *Silliman's Journal*, to take their places as willing servitors in all the physical laboratories of the world; all this in the early days of this very year, in January, 1831.[10]

---

[5] The Albany Academy, in which Joseph Henry occupied the chair of Mathematics and Natural Philosophy from 1826 to 1832, is an institution which for three quarters of a century has been held in deservedly high esteem, not alone in the community in which it is situated, but throughout the United States. Among the oldest foundations of its kind in the country, "its venerable walls seem imbued with that subtle spirit of the past, that favors study, and that nothing but time can give." The Academy building, beautifully situated on the public square near the head of State street at the right of the Capitol, is a dignified and admirable architectural example of the classical or "colonial" type. In the words of the late Dr. Meads in his oration at the semi-centennial anniversary of the Acadamy in 1863:—"Time has not rendered it in any degree unfitted for its purposes, nor unworthy of its position among the public buildings of Albany. It seems to have had a power to charm down and repress even the proverbial destructiveness of youth, and it stands to-day, after the lapse of half a century, unmarred by any spoiling hand, in all its original freshness and beauty."

The room in which Henry prosecuted his memorable experiments in electricity and magnetism, during the vacations of the Academy, has remained almost unchanged since his day. It is a lofty, well lighted and spacious hall of admirable proportions. and chaste and classical decoration, and is in no respect unworthy of the interesting associations that cluster about its venerable walls. [7] *Faraday as a Discoverer.*

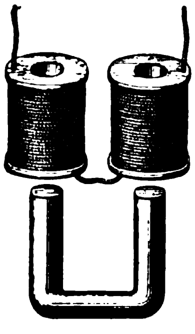
[8] *Joseph Henry and the Magnetic Telegraph*, p. 11.

[9] S. S. Cox, Memorial Speech in the House of Representatives Jan. 16, 1879.

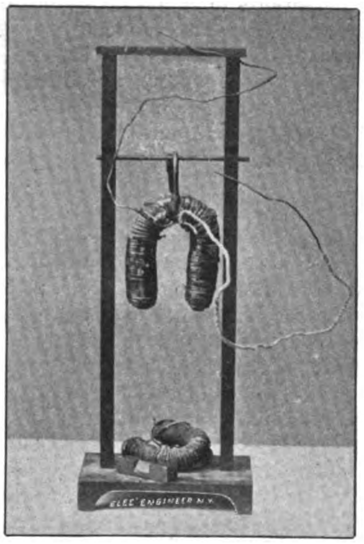
Prof. William B. Taylor says:

> "The importance of this discovery can hardly be over-estimated. The magnetic 'spool' of fine wire, of a length—tens and even hundreds of times as great as that ever before employed for this purpose was in itself a gift to science which really forms an epoch in the history of electro-magnetism. It is not too much to say that almost every advancement which has been made in the fruitful branch of physics since the time of Sturgeon's happy improvement; from the earliest researches of Faraday downward has been directly indebted to Henry's magnets. By means of the Henry 'spool' the magnet almost at a bound was developed from a feeble childhood to a vigorous manhood. And so rapidly and generally was the new form introduced abroad among experimenters, few of whom had ever seen the papers of Henry, that probably very few indeed have been aware to whom they were really indebted for this familiar and powerful instrumentality. But the historic fact remains that prior to Henry's experiments, in 1829, no one on either hemisphere had ever thought of winding the limbs of an electromagnet on the principle of the 'bobbin,' and not till after the publication of Henry's method in January, 1831, was it ever employed by any European physicist."



THE PRINCIPLES OF THE SPOOL OR BOBBIN, AS APPLIED BY HENRY TO THE ELECTRO-MAGNET.

> "But in addition to this large gift to science, Henry has the pre-eminent claim to popular gratitude of having practically worked out the differing functions of two entirely different kinds of electromagnet; the one surrounded with numerous coils of no great length, designated by him the 'quantity,' the other surrounded with a continuous coil of very great length designated by him the 'intensity' magnet. The latter and feebler system (requiring for its action a battery of numerous elements) was shown to have the singular capability, never before suspected or imagined, of subtle excitation from a distant source. *Here for the first time is experimentally established the important principle that there must be a proportion between the aggregate internal resistance of the battery and the whole external resistance of the conjunctive wire or conducting circuit.* This was a very important, though unconscious, experimental confirmation of the mathematical theory of Ohm, embodied in his formula expressing the relation between electric flow and electric resistance, which, although propounded two or three years previously, failed for a long time to attract any attention from the scientific world."
>
> "Never should it be forgotten that he who exalted the 'quantity' magnet of Sturgeon from a power of twenty pounds to a power of twenty hundred pounds, *was the absolute* CREATOR *of the 'intensity' magnet; and that the principles involved in this creation constitute the indispensable basis of every form of magnetic telegraph since invented.*"[12]



INTENSITY MAGNET MADE BY HENRY IN 1829; NOW IN THE CABINET OF THE COLLEGE OF NEW JERSEY.

It detracts nothing from Henry's independent and original discovery of the law of relation between the "electric flow" and the "electric resistance," that Ohm, in far-distant Munich, had a theoretical dream of such a law, which, with a sagacity little short of marvellous, he reduced to a concrete mathematical formula. Consider for a moment the distinction between the man who propounds a theory and the man who makes a veritable discovery; for precisely in these two attitudes stand Ohm and Henry in relation to this fundamental electric law. A theory may, it is true, be of inestimable value; but however ingenious, however founded upon intimate knowledge of the subject, it at the most can only suggest *what may be;* can only point out an intelligent mode of asking Nature a question. The theory may, or may not, prove to be true. A discovery, on the contrary, tells us *what is;* it tells us that a certain fact or a certain relation in nature actually exists. Of the theory of Ohm, now at the tongue's end of every schoolboy, but for a long time ridiculed, or at least unnoticed by the scientific world, Henry, in far-distant America, knew absolutely nothing. Five years later, in a letter written from Princeton, dated December 17, 1833, we find him asking Dr. Bache: "Can you give me any information about the theory of Ohm? Where is it to be found?" In another letter of about the same period: "Who is Ohm? What is his theory?" It was not until 1836, during his visit to London, that he sees at last Ohm's theory, and finds that, after all, it is in substance nothing more nor less than his own discovery, interpreted in the language of mathematical prophecy.

ASBESTOS PORCELAIN.

IN a recent communication to the Académie des Sciences, M. F. Garros called attention to a new form of porcelain brought out by him. He takes asbestos fibre and reduces it to a fine powder. If pure, it exhibits an exceedingly white apparence, but if traces of iron oxide are present there is a slightly yellow tint. In the latter case the oxide is removed by sulphuric or hydrochloric acid. The powder is then made into a paste, moulded into shape, dried slowly, and baked (1200° C.) from 17 to 18 hours. If placed in a very high-temperature furnace, a remarkably transparent species of porcelain is obtained. This "asbestos porcelain" has already been used for filtration and sterilization purposes, experiments showing that it is a more rapid and effective filterer than ordinary porcelain, and that the pores are less liable to become clogged up.

[10] Silliman's *Amer. Jour. Science*, Jan. 1831, xix, 404-5.

[11] "It is evident"—says Mr. Fahie—"that it was not until after the interview with Henry [on April 11, 1837] that Wheatstone recognized the applicability of Ohm's laws to telegraphic circuits, the study of which would likewise have enabled him to ascertain the best proportions between the length, thickness, etc., of the coils, as compared with the other resistances in the circuit, and to determine the number and size of the elements of the battery necessary to produce the maximum effect." [*History of Electric Telegraphy*, p. 515.] Yet Wheatstone—characteristically, it must be said—has not hesitated to claim Henry's discovery for himself. In a statement written by him in 1841, to be presented to the arbitrators in a disagreement which had arisen between himself and Mr. Fothergill Cooke, he says:—"These methods of completing the secondary circuits have lost nearly all their importance, and are scarcely worth contending about, *since my discovery, that electromagnets may be so constructed as to produce the required effects by means of the direct current even in very long circuits.* [*The Electric Telegraph; Was it Invented by Professor Wheatstone*, ii, 96.] In a subsequent portion of the same document he nevertheless says of himself:—"Wherever I have borrowed an idea from Ohm, Gauss, Steinheil, or any other person, I have, and shall always be ready to acknowledge it." Yet Henry's paper in *Silliman's Journal*, had then been published for some years, and Henry himself had explained to Wheatstone in King's College, on April 11, 1837, the construction and use of his "intensity" magnet. In later years, however, Wheatstone became somewhat more guarded in his assertions, for we find him writing to Cooke in 1856, in reference to the same matter:—"With this law and its applications, no persons *in England* who had before, occupied themselves with experiments relating to electric telegraphs, had been acquainted." The words which we have italicized are significant, and are only capable of construction as an acknowledgment—though not a particularly graceful one—of the priority of Henry. [EDITOR.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—I.

BY

Francis B. Crocker and S. S. Wheeler.

INTRODUCTION.

THE purpose of these articles is to set forth the more important facts which present themselves in the actual handling of dynamo-electric machines and electric motors, as a guide for those who use or study these machines. The authors do not claim for this treatment of the subject that it is anything more than a set of directions in which the various points are arranged under headings for convenience of reference.

The subjects considered are: Chapter I, General Principles of Dynamos and Motors; Chapter II, Directions for Selecting; Chapter III, Installing; Chapter IV, Starting; Chapter V, Running; Chapter VI, Stopping; and Chapter VII, Testing Dynamos and Motors; also Chapter VIII, Directions for Locating and Remedying Troubles in these machines.[1]

Heretofore writers on the dynamo or motor have usually treated these machines entirely distinctly, and books or papers on the dynamo usually contain nothing about the motor, or merely consider it briefly in a few special chapters, and books on the motor only refer to the dynamo incidentally. The authors have found that there is no necessity for this separation; in fact, nine out of ten statements which apply to the dynamo are equally applicable to the motor, and if the word machine is used instead of dynamo, the statement covers both and becomes doubly important and useful. Occasionally, of course, it is necessary to distinguish between the two machines, but, as a matter of fact, the difference in treatment required for dynamos and motors is often less than for different kinds of dynamos; for example, a shunt dynamo and series dynamo differ from one another much more than do a shunt dynamo and shunt motor.

CHAP. I.

GENERAL PRINCIPLES OF DYNAMOS AND MOTORS.

Definitions.—*A dynamo-electric machine is a machine for converting mechanical energy into electrical energy;* in other words, *it generates electric current when driven by mechanical power.* The term dynamo-electric machine is so long that it is usually and unavoidably shortened into "dynamo," which has exactly the same meaning. The name "electric generator" or simply "generator" is often applied to the dynamo, especially when used to produce current for electric railway or other motors, but this distinction is merely for convenience. An alternating-current dynamo is commonly called an "alternator."

An electric motor is a machine for converting electrical energy into mechanical energy; in other words, *it produces mechanical power when supplied with an electric current.* An electric motor is usually called simply a motor, and although motor might mean anything producing motion, it is very rarely used in any other sense and is perfectly definite in connection with electrical matters.

Principles of Action.—The dynamo is based upon the discovery made by Faraday in 1831, that an electric current is generated in a conductor by moving it in a magnetic field. The electric motor works on the principle that a conductor carrying a current in a magnetic field tends to move. Thus it will be seen from the above statements that the dynamo and motor are exactly the reverse of each other in their action.

Similarity of Dynamos and Motors.—The two machines are, however, very similar in their construction. In fact, the same machine can be used for either purpose equally well. In practice there are sometimes slight differences between dynamos and motors, as will be explained further on, but these are not very important. Hence, as already stated in the introduction, the two machines will be treated as one, except where some distinction is specially stated.

General Form.—We have seen that both the dynamo and motor depend for their action upon the movement of conductors in magnetic fields. Now it has been found as a result of scientific experiment and practical experience during the 60 years since Faraday's discovery, that the best way to carry out this principle is to arrange the conductors in suitable form and rotate them between the poles of a magnet, or magnets. This rotating part is called the *armature* and the magnet is called the *field magnet.* In alternating-current dynamos this plan is sometimes reversed, the field magnets being made to rotate and the armature being fixed.

Armature.—This usually consists of an *armature core* of iron on which are wound or attached the conductors which carry the current. This core should be split up or *laminated,* that is, made of discs, tape or wire, of iron separated by paper, varnish or rust, instead of one solid piece; otherwise it will have useless currents generated in it which would waste the power of the machine. This core is almost always made either in the form of a *drum* or a *ring* and hence we have these as the two principal types of armature.

Field Magnet.—This consists of one or more iron *cores* on which are wound the field *coils.* Attached to the field cores are the *pole-pieces* which form the magnetic field or space in which the armature revolves.

CHAP. II.

DIRECTIONS FOR SELECTING DYNAMOS AND MOTORS.

The choice of a dynamo or motor will, of course, depend largely upon the circumstances in each particular instance. There are, however, certain general facts which apply to almost all cases.

Construction.—This should be of the most solid character and first-class in every respect, including material and workmanship, both of which should be of the best possible quality. All the parts should be of adequate size and strength to ensure durability.

Finish.—What is called a fine finish on a machine is also very desirable, first, because it indicates good construction, and its absence indicates poor construction (there is no essential reason for this, but it seems to be a fact in most cases), and second, it usually causes a machine to receive much better treatment.

Simplicity.—The machine and all its parts should be as simple as possible, and any very peculiar or complicated part or attachment should be avoided. These are sometimes successful but should be well tried and proved before accepting.

Attention.—The amount of attention required by the machine should be small; for example, the brushes should be capable of being easily and securely adjusted, and the oiling devices should be effective and reliable, self-oiling bearings being very desirable. The screws, connections and other small parts should be arranged so that they are not liable to become loose, and the delicate parts should not be particularly exposed or liable to injury. The machine should be made so as to be easily and thoroughly cleaned.

---

[1] This chapter has already been published in the Sept., Oct. and Nov., 1891, issues of THE ELECTRICAL ENGINEER, under the title of "The Localization and Remedy of Troubles in Dynamos or Motors."

Handling.—The machine should be provided with rings or other means by which it can be easily lifted or moved without injury. It should be possible to take out the armature conveniently by removing one of the bearings.

Regulation.—Some form of regulator should be provided by which the E. F. M. or current of a dynamo or the speed of a motor can be reliably and accurately governed.

Armature.—This should turn very freely in the bearings, and should be perfectly balanced so as not to have any appreciable jar or vibration at full speed. There should be a uniform clearance of at least $\frac{1}{16}$ inch all around between the armature and pole-pieces. The armature should be capable of moving lengthwise in the bearings at least $\frac{1}{8}$ inch. It is not usually desirable to have the speed of an armature at its circumference more than 3,000 feet per minute. The ring-form of armature is especially suited to high voltage since the coils differing most in potential are at the greatest distance apart. A section of a ring armature can also be more easily rewound than in the case of a drum armature.

Capacity.—This should be ample in all cases. It is a very common mistake to underestimate the work required of a given machine, and, even if the machine has sufficient power at first, the demands upon it are apt to increase and finally overload it. No one is ever likely to regret choosing a dynamo or motor with a considerable margin of capacity, since these machines only consume power in proportion to the work they are doing. For example, a 30 h. p. machine would probably run with a 20 h. p. load more economically and satisfactorily than a 20 h. p. machine with the same load.

Form.—The machine should be symmetrical, well proportioned, compact and solid in form. If it is either very tall or very flat it is usually inconvenient and clumsy. No part of the machine should project excessively, or be awkwardly formed or arranged. The large and heavy portions of the machine should be placed as low as possible to give great stability. For the same reason the shaft should not be high above the base, nor should it be so low that there is not ample room for the pulley or other attachment. A horizontal belt, for example, will sag and strike the floor if the pulley is very low.

Weight.—The common idea that it is desirable to have a very light dynamo or motor is a mistake when it is for stationary use. There is no advantage in a light machine for stationary work, and it has the disadvantages of being less strong, less durable and less steady in running. A sufficient weight to make the machine thoroughly substantial is obviously a great benefit.

Cost.—It is also a mistake to select a cheap machine, since both the materials and workmanship required in a high quality dynamo or motor cost more than in almost any other machine of the same size and weight.

(*To be continued.*)

ONE WAY OF SAVING POWER ON ELECTRIC RAILWAYS.

BY LUCIUS ELLIOT MARPLE.

It is a well-known fact that much of the power generated at the central station of an electric railway is lost in overcoming the resistance offered by poor rail connections. Not only this; but there is consequently a much greater wear and tear on the machinery, and an undue heating of the motors because of the unsteady current resulting. As these are prominent features, it is of no small importance to the railway superintendent that there should always be the best possible connections between the car wheels and the rails.

The following instance, in which the writer was recently called in court to testify, shows that this may be the cause of annoyance in more ways than one:

A car happened to be stalled by dust on the track for a moment, when a "green" horse passing by took fright at it and stumbled, striking his head on the step of the car. It was claimed before the magistrate, and allowed, that a current of electricity from the car had, in some way, caused the animal's death. This decision was appealed from, and happily reversed in a higher court.

Several railways, have, however, overcome this trouble and effected quite a saving by applying water to the tracks in the proper manner.

The simplest and most effective way seems to consist in employing specially made carts, with wheels just fitting between the tracks. On each pair of wheels a large tank is placed six feet or more above the ground. By means of pipes, this delivers a stream of salty water with considerable force directly over either track.

By making several trips daily over each route, the tracks can be kept thoroughly clean and moist. Where this has been tried it has been proved that a very considerable amount of power may be thus saved.

To show the effect of a clean track, the instance may be cited of Nashville, Tenn., where the surface consists very largely of limestone rock. The writer has several times made careful note of the station output before and during a sudden heavy shower.

A reduction of from 900 to 600 amperes, or more than 30 per cent., was actually observed.

Probably the greatest effect will be felt in towns where the streets are unpaved and the travel is heavy enough to keep the rails continually covered with dirt.

THE EXPERIENCE OF CITIES WITH THE TROLLEY SYSTEM.

BY

S. W. Balch

The citizens of Yonkers have recently been discussing at much length the advisability of permitting the trolley system in their city, and the city council have finally decided to permit its use with certain restrictions. In connection with this discussion, one of the enterprising papers of the city, the Yonkers *Daily Herald*, addressed a number of inquiries concerning the trolley to the mayors of 108 cities in which it was understood to be in operation. Replies have thus far been received from 66 cities and towns. Sixty-two show a practical experience with the system and are, therefore, noted in the answers below.

The first question put to the mayors was as follows: "Do you consider that the trolley system has been operated successfully in your city?" All but five answer this in the affirmative. Three report that it is fairly successful, and two say that it has not succeeded.

The second inquires if the fault is believed to be in the system or in the management. From Toledo, O., where the Thomson-Houston and Westinghouse systems are used the answer considers the fault about equally divided. Zanesville, O., reports that good management is everything. Ottawa, Ill., reports that the management is a little lame. Akron, O., and South Bend, Ind., say that the electric cars are not a success on account of the management.

The mayor of Rockford, Ill., considers all overhead wire business bad and hopes that Edison will make a success of his two-track idea. He also remarks that the system is good when well carried out with double motor cars, revolving snow-brushes and heavy rails, and lays the faults to cheap equipment. Camden, N. J., reported that their system was not successful at first because the power generators were not suitable.

The third question inquired whether the system had benefited the business interests of the city. This question is answered affirmatively, and in many instances with emphasis, by all except South Bend, Ind., in which the answer to the question is omitted, and Buffalo, N. Y., where the use has not been sufficient to warrant an opinion. The mayor of Wilmington, Del., reports that the electric cars have infused new life into the people, and that a horse is too good an animal to put to a street car. The city electrician at Springfield, Ill., reports that there is a car every 15 minutes for those who live five miles from the centre of the city and that the great beauty is that the cars are on time.

The fourth question asks, Which system is used? As many cities use more than one system, or combinations of two or more systems it will, therefore, be seen why the numbers here given will sum up more than the number of replies which have been sent in. In 12 replies no answer, or an indefinite answer, is given to the question. From the others it appears that they are in use in, and endorsed as good by, the following places :—

	Used by	Approved by
Thomson-Houston..........	31	24
Sprague-Edison......	24	17
Westinghouse.......	5	4
Short.....	3	2
Van Depoele........	1	1
Detroit Electrical Works..........	1	1
Daft..............................	2	0

The fifth question asked the mayors if they consider their system the best. Their replies are incorporated in the above table, but as each appears to be contented with the system which he happens to have, his opinion does not appear to be much of an indication as to which one is the best. In several instances where two systems are used both are endorsed without preference. The mayors of Milwaukee, Quincy, Mass., and Reading, Pa., make no choice between the Thomson-Houston and the Sprague. On the other hand the mayor of Marlboro, Mass., has the latter but prefers the former. The Thomson-Houston system is also especially endorsed by the mayor of Peoria, Ill., and the city electrician of Springfield, Ill. The Sprague and Edison systems are endorsed by the mayor of Canton, O., and the Sprague and Westinghouse systems by the mayor of Wilmington, Del. The mayor of Lancaster, Pa., prefers the Edison to the Daft system.

The sixth question inquired if any persons had been killed by the electric current from the trolley line, and the seventh, how many. These are answered in the negative in every reply but one. This one is from Louisville, Ky., and reports five or six killed by carelessness of passengers. It is not thought from the answer that they were killed by the current. In Canton, O., a little girl was run over. Toledo, O., mentions two injuries. The mayor of Lynn, Mass., mentions accidents to carriages being run into, and Zanesville, O., reports the killing of several dogs. A number report no accident of any kind.

The eighth question asked if accidents from the current were very likely to happen. This was answered unqualifiedly in the negative in 40 of the replies, and no affirmative answer was received. The city electrician of Springfield, Ill., says : "On three occasions I have seen the entire current (480 to 510 volts) pass through a man. Of course he was burned but was at work again in 48 hours. Such cases as these are due wholly to the carelessness of the men while repairing hooks." Streator, Ill., reports that the current has been taken without injury. Johnstown, Pa., answers, "No, the current is not over 500 volts." And Camden, N. J., replies that the voltage is 220 and that fatal accidents are not looked for. The mayor of Milwaukee thinks an accident is possible upon contact with a live wire.

The mayors of several cities referred to their experts for the information sought. Saginaw, Mich., referred to W. J. Hart; Salem, O., to W. H. Wheldey, and Springfield' Ill., answered through Edgar L. Gross, city electrician.

The mayor of Aurora, Ill., sent a very interesting reply, of which the following is an abstract: "We have an elaborate and costly system of street railway propelled by the trolley system, and it operates successfully save when a snowstorm shuts it off short. Nobody has been killed by the electric current, but we have had some narrow escapes from death. Telephone wires are liable to break, and if they fall across the trolley wire it will kindle a fire in the office or residence, a mile away perhaps. One of the trolley wires fell recently in this city and knocked a horse down. If you are about to insert the trolley system, I suggest that you require the company to light the streets which it occupies without charge, placing a lamp on every second or third pole. The city of Providence, R. I., has been considering the granting of a franchise to a street railway company, and I recommend that you send to the Hon. H. Howard of that city for a copy of the pamphlet publication No. 8, of the Advance Club of Providence. It contains the contract which the city of Toronto has with its street railway company, which has many safeguards. The rate of speed should be regulated from time to time by the city authorities, and the company should be held to a rigid accountability for the condition of the street and road-bed which it occupies. A city should prepare its own ordinance granting the franchise, for if prepared by the company they will get the best of you and gain many little advantages by cunningly devised phrases which will hardly be apparent upon casual reading."

The mayor of Allentown, Pa., says that he considers the T rail better than the flange rail in every particular if wagon gauge is not required.

THE LAW OF MOTOR EFFICIENCY.

BY

C O Mailloux.

In the issue of The Electrical Engineer of December 16, Mr. H. Ward Leonard attempts to set aside my objections to his so-called law of motor efficiency. I will encroach upon your valuable space once again, not so much for the purpose of further argument with Mr. Leonard, as of straightening out certain questions of fact on which he does not appear to be as well informed as he might be. Mr. Leonard's statements, in fact, tend to strengthen the impression that he has neglected not only the theory but even the history of the "art to which his invention appertains."

It was in 1882 that Marcel Deprez first accomplished what Mr. Leonard now claims as his discovery or invention. He described his method in *La Lumière Electrique* (Oct. 3, 1885, pp. 6, 7). His experimentss have been freely quoted, among others, by Kapp, (Elect. Transm. 3d Ed., p. 89) ; and also repeated by others, (Thompson Dyn. Elec. Mach., 3d Ed., p. 539).

M. Deprez took a motor which was loaded artificially so as to give a constant moment of resistance, and consequently requiring a constant torque to make it turn. He applied to this motor a source of E. M. F. which he caused to vary from zero up to an extreme limit. He found that for any given load the current increased until it was sufficient to produce the torque needed to start the motor. Any further increase of the E. M. F. caused the speed (and therefore the counter E. M. F. of the motor) to increase so as to prevent the current from rising above the value at which the motor began to turn. He laid down and proved the law that for any load (torque) a certain current is required, and that this current will *automatically* be maintained constant, or very nearly so, at any and all speeds, it being independent of the speed. He also showed that the speed was controlled and governed for a given load, entirely by varying the E. M. F. of the source of supply.

In the original experiment the E. M. F. was regulated partly by varying the speed of the dynamo, and partly by a variable resistance in the circuit. He described later (Oct. 17, '85) a method of varying the E. M. F. of a generator (or motor) run at constant speed, by varying its magnetic field, which is the method of E. M. F. regulation found in Mr. Leonard's method.

Even the plan of separately exciting the motor was first made known and used by Deprez. It requires no extended comparison to see that M. Deprez's method accomplished all that Mr. Leonard's does and by exactly the same means, namely, by varying the E. M. F. of the source of supply. The only difference exists in the details and in the *theory*. Although Mr. Leonard effects his regulation solely by varying the E. M. F. of the source of supply just as M. Deprez did, yet he claims to have some control on the amperes, while M. Deprez made no such claim, but on the contrary recognized and admitted the fact that the amperes do and will control and take care of themselves automatically. The fact that the efficiency is more nearly constant when the E. M. F. is varied with the speed of a motor run at constant torque, has also not escaped attention. The table of tests of a ½ h. p. Immisch motor, quoted by Thompson, (Dynam. Elec. Mach., 3d Ed., p. 562) gives a sufficiently clear indication of it. Every one who has had experience with storage battery cars wherein the speed regulation is effected by grouping or varying the cells, has doubtless observed the fact. The present writer has many records of brake tests made in 1887, and subsequently, which show this very clearly.

In a later portion of his discussion in the same journal, M. Deprez gives (Oct. 24, '85, p. 158) an equation of efficiency which is an extension of that which I gave in my previous article, and which Mr. Leonard may find of interest.

According to M. Deprez, the efficiency depends on three things *only*: 1. The speed of the motor, *i. e.*, the counter E. M. F. 2. The ratio of the total circuit resistance to the motor resistance. 3. The ratio of the watts spent in heating the motor to the torque obtained by the current—which is what he calls the "cost of the torque."

These statements can be made to embrace almost any case of electric power transmission. The conditions and the rule which I gave for obtaining maximum efficiency are in harmony with M. Deprez's views.

So much for the facts as to the novelty of the method or the accuracy of the "law." Let us now see what are the facts in relation to the question of torque in the street car motors commonly used, *i. e.*, in plain series motors.

I quote :—"Mr. Mailloux is, I think, in error in stating that in the street car motors commonly in use the amperes vary as the torque. Such a condition could only be realized in a constant field and with the series field commonly in use, as a constant field is not realized under varying torques, although the commutation of the field is, of course, an endeavor to approximate to it."

The fact is that the amperes vary as the torque in all forms of motors, though not in the same way. In a shunt motor the curve of torque is nearly a straight line; in a series motor it is convex toward the axis of amperes, for the lower values. In both cases, for higher current values the line is either straight or slightly concave to the axis of amperes. The physical or mathematical reasons do not interest us now.

It is sufficient to know that the amperes do vary as the torque in series motors. For medium and high current values the series motor has the great advantage that it requires less amperes per unit of torque than does the shunt motor, and is not so likely to spark, because its load is constant, while that of the shunt motor will change with the current.

I do not regard a constant field as a condition *sine qua non* for accomplishing what Mr. Leonard's method does. A series motor used in place of his separately excited motor would operate quite as satisfactorily in most cases, and more so, in many cases. Mr. Leonard insists that when he groups the six motors in different ways, he varies the volts as the speed desired. Until his explanation is made intelligible however, or a more logical one substituted therefor, I must adhere to my previous opinion.

Mr. Leonard has also permitted himself to make the absurd statement that "there is no question that the current *will* be constant for all groupings, neglecting, of course, the slight effect of the losses in heat, etc." No question admits of more easy demonstration. In the abstract, one might ask, if the current is the same for all groupings, then since the direct E. M. F. is also constant, the electrical energy abstracted from the circuit, is constant. Where then would the energy come from which causes the increase of speed? In point of fact it must and does come from increase of current. Let us take a concrete case by assuming that each car requires for keeping it in motion on a given grade that the motors should each develop 200 pound-feet of torque or 1,200 pound-feet for the three cars constituting the train. This torque will, it is evident, be the same, at all speeds usually employed. Hence, each motor must furnish the same torque, no matter at what speed it runs, so long as the load and the grade remain the same. Starting with the six motors in series, a given current, say, 15 amperes is required to produce in each motor the desired torque of 200 pound-feet.

Let us now connect the six motors in two multiple series of three. Each series will again take 15 amperes to give the same torque. The line current will therefore be 30 amperes. If we connect the motors in three multiple series of two, the line current will be 45 amperes; with all the motors in parallel the current will be 90 amperes. The electrical energy supplied to the train, and, in consequence, the speed, will of course increase at each change in grouping. The change of speed will, in most series railway motors, cause a further complication from the fact that the same current will not maintain quite the same useful torque at all speeds, partly owing to changes in the coefficient of friction, and partly to armature reactions. For a given torque the current must be increased slightly as the speed increases. Mr. Leonard's emphatic statement is therefore without foundation. He has apparently confounded this case with one in which the motors remain always connected the same way.

Lastly Mr. Leonard's explanation of my abhorrence of commutators also falls to the ground, in view of the fact that in the method proposed by me the sparking was entirely obviated. There was also no rheostat. The voltage of the dynamo side of the converter was not expected to exceed at any time 25 volts for the function it was to perform. Its output would not exceed 2,000 watts at any time.

As for the question of weight, if Mr. Leonard can really make with 500 pounds of material a motor dynamo, having two distinct fields, of the watt capacity stated in his article, and running at reasonable speeds, and fair efficiency, he has done something that will produce a far greater and more lasting impression than his so-called "law" of efficiency.

RATHITE.

RATHITE is a new insulating compound, composed of vulcanized india-rubber and silk fibre. The idea is to apply this form of insulation in all cases where solidity rather than flexibility is wanted. The compound is due to MM. Waddington, Rath et Cie.

AN ELECTRICIAN'S APPEAL TO PORCELAIN MANUFACTURERS.

The subjoined appeal to porcelain manufacturers is from Mr. Francis W. Jones, the well-known electrical engineer and inventor, and now electrician of the Postal Telegraph-Cable Co., of this city. What Mr. Jones says on the matter of insulators is not only important but true, and it does seem to us that American porcelain manufacturers should have no difficulty in meeting the demand. It should certainly be worth their while, as the insulators used by the Western Union and Postal companies alone must run up into millions, with a steady consumption every year:

To the Porcelain Manufacturers of America:

Up to the present time in this country, glass has been chiefly used for the insulation of telegraph lines. In Europe, however, porcelain is the prevailing material and presents three or four times more resistance to the leakage of current than glass. The great cost of importation under a high tariff, coupled with a lack of knowledge of the advantages gained in Europe by the use of porcelain, are undoubtedly the reasons why glass has been so long adhered to in America, notwithstanding that great loss of business occurs during rains and fogs by the electricity leaking down the poles, rendering the wires inoperative. The insulating properties of porcelain depend on its quality. It requires a good smooth surface, must be perfectly vitrified throughout so as to be homogeneous, impervious to moisture and free from flaws; the glaze must be good. If such an article can be produced in this country, it sooner or later undoubtedly will replace all the glass in use, even should quite a difference in price exist in favor of glass. It would be an advantage if the shape could be made to conform to the present double-petticoat glass, but it may be thought best to adopt the English Post Office pattern. To convince you of the soundness of my views, see F. L. Pope's 1891 edition of "Modern Practice of the Telegraph," page 115. Also Preece & Sivewright's last edition on "Telegraph," page 267. Mr. Preece is electrician of the British postal lines. You will feel convinced, I am sure, that a field is open for your careful consideration and action. I shall be pleased to hear from you further on this (to me) important subject.

F. W. Jones, Electrician.

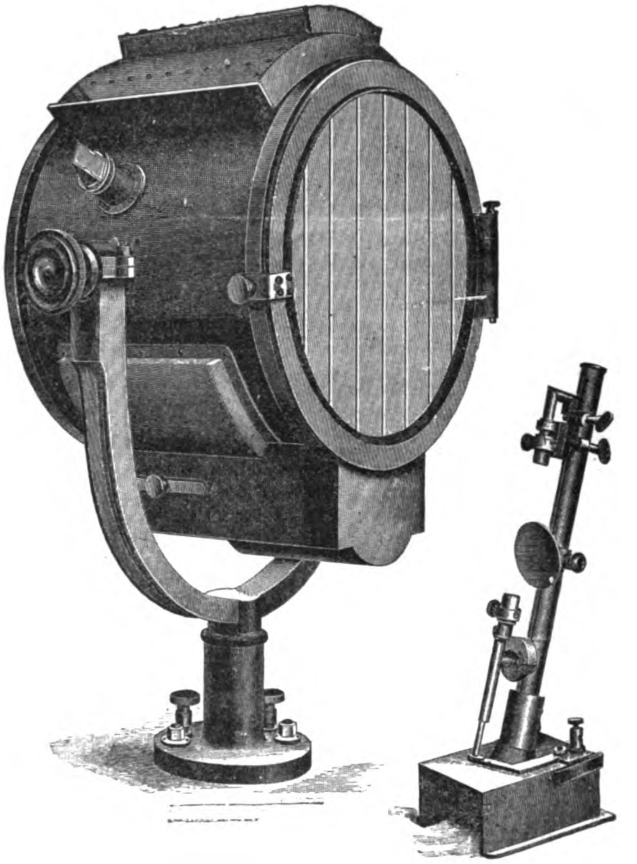
Postal Telegraph-Cable Company,
New York, Jan. 5, 1892.

THE ELECTRIC LAUNCH "ZURICH."

The following particulars from *L'Electricien* with regard to the electric launch, "Zurich," which attracted much attention at the recent Frankfort Exhibition, may be of some interest. The launch was constructed by MM. Escher, Wyss et Cie., of Zurich, and the Oerlikon Maschinenfabrik. The hull was of steel, and the boat was capable of carrying 100 passengers. The dimensions were: Length, 53 ft.; beam, 10¼; mean draught, 3½ ft. The screw, which was 28 in. in diameter, was coupled direct to a 10 h. p. two-pole Brown dynamo run as a motor at 350 revolutions. Power was supplied by a battery of 56 Schoop 31-plate gelatinous accumulators, having a capacity of of 450 ampere hours, and a maximum discharge current of 80 amperes, and weighing in all about 5 tons. The total weight of the electrical equipment was 6½ tons, that of the boat being 15 tons. The motor, when running at 365 revolutions, and absorbing 10 h. p. (102 volts x 75 amperes), propelled the launch at the rate of 8 miles an hour; when only 8 h. p. was absorbed the speed was still 7 miles an hour.

THE THOMSON-HOUSTON SEARCH-LIGHT ON BOARD THE STEAMER "FAIRFAX."

The electric lighting plant on the steamer "Fairfax," described last week in The Electrical Engineer, is, in many respects, a model marine plant. There are 243 16 candle-power lamps in use distributed in the various parts of the ship, those in the three lower decks having water-tight fixtures. The junction boxes, 75 in number, are of bronze, and water-tight, as are also the switches, 10 in number, and the wires are lead-covered waterproof. The lamps are on nine circuits controlled by cut-outs and switches in the dynamo-room, and the mains run to four distributing boxes, conveniently located in different parts of the ship, containing the branch cut-outs and switches.



Thomson-Houston Search Light, with Focusing Lamp.

The search-light or projector, shown in the accompanying illustration, is located on the mast forward of the pilot house, and is equipped with an automatic focusing lamp. The controlling device is placed in the pilot house so that the lamp can be moved vertically and horizontally. The projector takes 20 amperes of current, and is rated at 20,000 candle power.

PROF. AYRTON.

Prof. W. E. Ayrton, F. R. S., president of the Physcal Society, at the annual meeting of the Institution of Electrical Engineers was elected to the presidential chair of that body.

THE
ELECTRICAL ENGINEER.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JANUARY 13, 1892. No. 193.

The discoveries of great men never leave us; they are immortal; they contain those immortal truths which survive the shock of empires.—Henry Thomas Buckle.

BOODY BARBARISM.

It has become a fairly well recognized fact that public improvements or the erection of large engineering works must involve, to a greater or less extent, the loss of human life, and indeed in not a few instances this consideration has been made the subject of actual calculation in advance of the undertaking of such works. We might refer to hundreds of instances in which the erection of large structures has been accompanied by loss of life, and we need go no further than to select the Brooklyn Bridge as an instance in point. We have selected this particular example in order to show the fallacy of one of the arguments, if arguments they can be called, which Mayor Boody of Brooklyn has brought forward in connection with his veto of the resolution of the Board of Aldermen granting permission for the introduction of the trolley electric railways in that city. Mayor Boody believes that while "we are called upon to yield many of our present inconveniences for the public good, no citizen in time of peace can be justly asked to hazard life and limb; no amount of material benefit can compensate for the loss of one life!" Would Mayor Boody, we would ask, see Brooklyn isolated from the world because the erection of the Brooklyn Bridge involved a loss of life or because steam boilers on ferry boats have exploded or railroad accidents have occurred? The proposition is so absurd that it needs no further discussion. But we invite Mayor Boody to bring forward a single instance in which human life has been lost due directly to the electric current from an electric railway circuit. Persons have, it is true, been run over by electric cars in the same way as they have been for many years by horse cars and steam railways; but no one dreams of stopping these valuable adjuncts of traffic and returning to the omnibus and stage-coach because people are imprudent enough to cross the tracks upon the approach of trains. Another of Mr. Boody's reasons for vetoing the resolution is that no city of the size of Brooklyn has felt justified in adopting the trolley system. Considering the fact that New York and Chicago have granted trolley privileges within their limits, this part of Mr. Boody's objection is evidently based upon a lack of knowledge; but, aside from that, the reasoning in itself is about as convincing as would be the argument that, because a town of 10,000 inhabitants had adopted a railway trolley system, the method was not adapted to one of 20,000 inhabitants.

Somewhat more than a year ago the *Daily Advertiser*, of Boston, obtained the views expressed by the mayors of a large number of cities where electric railways operated by the trolley system were in operation, and the opinion expressed almost unanimously was, that the community was largely benefited by the increased comfort due to the introduction of the electric railway, and that the advance in the taxable valuation of property was of direct benefit to the taxpayers themselves. Considering that Brooklyn has permitted the erection of many miles of elevated railways, the attitude of its present mayor is hardly consistent, and we are glad to believe that his veto will be overridden by the city council. The more recent opinions of mayors after prolonged operation of electric railways will be found on another page, on which Mr. Balch gives a résumé of the replies received to inquiries emanating from the *Herald*, of Yonkers, N. Y., in which place the subject of electric railways is now being agitated. We are convinced that if the questions involved in the introduction of the trolley system were made a proper subject of study by the mayors and councils of such cities, no difficulty would be encountered in the obtaining of suitable franchises for their introduction.

STORAGE BATTERY WORKING.

It is about a year since Prof. Ayrton and his associates published a remarkably exhaustive paper on the behavior of the storage battery during charge and discharge, in which special attention was devoted to the examination of the changes which take place in the active material during these stages, a large number of analyses being made to determine the chemical composition at short intervals. In this issue we publish an abstract of an exceedingly interesting paper read by Dr. G. H. Robertson, in which particular attention has been paid to the investigation of the condition of the acid electrolyte and its effects upon the plates during the various stages through which the cell passes in charging and discharging. He recognizes distinctly the great influence of the "active oxygen," hydrogen di-oxide and persulphuric acid, and arrives at the conclusion that for improvements in the cell we must look more to the manner of its handling than to any change in the manufacture of the plates.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.

The large number of works which have appeared during the last ten years treating of the dynamo and motor have done much to make the principles and method of construction of dynamo-electric machinery matters of common knowledge among those interested in the science. But while these books have served an excellent purpose, it cannot be denied that almost without exception they have been wanting in so far as they lacked the details necessary for the practical operation of such machines. By practical operation we mean such a knowledge of the principles of operation as will enable one to select intelligently the machine best suited for his purpose, erect and operate it in the place best adapted for it, and in a manner such as to insure its steady operation under all conditions of use. That such a treatise was needed is evidenced by the fact that several of our large electric companies issue books of instruction intended to supply the information just referred to. But none of these go as deeply into the subject as its importance warrants, and hence we are led to believe that a thorough and systematic treatise on this subject will be welcome at this time. As such we present to our readers the first instalment of the work on "The Practical Management of Dynamos and Motors," by Prof. F. B. Crocker and Dr. S. S. Wheeler. Our publication some time ago of "The Localization and Remedy of Troubles in Dynamos or Motors," by the same talented authors, which may be said to form a part of this work, has given a foretaste of that which is to come; and we thus hope to place before our readers a work which will be of the highest practical value and which will form a fitting addition to the already excellent descriptive works available on the subject of electric machinery.

BLOCK SIGNALS FOR STEAM RAILROADS.

It has taken the public a long time to become fully awakened to the full extent of the parsimonious recklessness and callous indifference to the safety of passengers which has characterized the administration of America's self-styled "greatest railroad," but the past few days have given evidence that the campaign of education is making rapid progress. If anything further were needed to give point to the scathing, if not always intelligent, criticism of the public journals, and to add fresh fuel to the flame of popular indignation, it might have been found in an article which appeared a few days since in an afternoon journal, which, for reasons not necessary to particularize, has generally been regarded as in some sense the mouthpiece of the management of the railroad in question.

This apparently inspired article informs the world that "block signals get out of order continually and lead to delays and collisions. Much better"—the writer says—"is the service of living, faithful flagmen, and *the results have shown how pre-eminently best this system is*. The block system is not worth a cent in comparison." From which profound observation we are made aware that this pretentious ignoramus does not even know what the system is, which he is so swift to condemn. He actually does not know the difference between the block system itself and the special apparatuses which are frequently, though by no means necessarily, employed in operating it. He does not know—or wilfully suppresses the fact—that the "living, faithful flagman" is never dispensed with even under the block system. He asserts that "if the whole system of the Pennsylvania Railroad were to supplant the whole system of the Central, not a train a day would be on time, and accidents would be four times more frequent than now." The all-sufficient answer to this is a comparison of the records. The Pennsylvania, with a much heavier traffic than the Central, has been operated for many years between New York and Philadelphia, under the block system, without the occurrence of a serious collision involving a passenger train, while on the Central, the actual money loss from preventable collisions south of Poughkeepsie during the same length of time, not to speak of passengers slaughtered, has been enough to equip and maintain an efficient block system twice over.

GILBERT, THOMSON, HENRY.

It is with no little pleasure that we begin in this issue a series of articles on the work of Prof. Joseph Henry, by his daughter, Miss Mary A. Henry, who proposes, and gives evidence of her ability, to prove that her distinguished father made an independent discovery of the principle of magneto-electricity. Her charming narrative goes to show not only that Henry, in this, was abreast of the immortal Faraday, but even anticipated him by several months.

Our issue this week contains also a biographical sketch of Sir William Thomson, who has just been raised to the peerage of Great Britain; and since distinction in England takes this form, the honor thus conferred upon one so thoroughly entitled to it will be noted with warm approval by every American electrician and electrical engineer—not omitting Dr. Park Benjamin, who would prefer to see the recognition take some other shape than the award of an empty title. The description given by Mr. Shaw of his visit to the great and modest Scotch philosopher is full of interest and not less so because it is timely.

But we do feel that there is some warrant for the indignant outburst of Dr. Benjamin, in our columns this week, as to the neglect shown to the memory of William Gilbert, who was at once the Henry and Faraday of his remote times, and who enjoyed consideration while alive at least equal to that which we all have long delighted to pay to Sir William, now Lord, Thomson. Why is Gilbert allowed to fall into such oblivion, or if he be remembered, why are not the memorials of his life and work preserved with as much reverence as after ages will evince for the mementos of Henry and Faraday and Thomson? We will not find fault with our English friends in this matter, for our own pages this week show that it has become a duty to vindicate the memory of Henry; but it is at least safe to say that if they do not soon take the matter up it is one that American electricians will feel constrained to be active about.

WIPING OUT THE MEMORY OF GILBERT.

BY

Park Benjamin

It seems to me that it is about time to organize in this country a "Gilbert Society" for the purpose of preventing the wiping out of the memory of William Gilbert. That task was begun by Francis Bacon probably in Gilbert's lifetime, and repeated attempts in the same direction since then have not been wanting; as witness the stupid article concerning him in the ninth edition of the Encyclopædia Britannica. I suppose that such a magnificent tribute as was paid to Gilbert by Galileo would be sufficient to keep any man's memory green even during the 17th and 18th centuries; but towards the end of the latter period despite the praises of the great Italian, some one found it necessary to make a new and peculiarly insidious attack upon Gilbert; and this I happened to unearth the other day in a rather curious way.

Pretty much everybody who has written a biographical sketch of Gilbert within the last dozen or so years has alluded to his portrait as existing in the Bodleian Library at Oxford. It is well known that that portrait was painted at the order of Gilbert himself; that it represents him in about his 48th year, and depicts him in his doctor's robes standing with his hand on the "terrella," which was his artificial earth made out of a piece of loadstone. Upon the picture and above the figure there was inscribed, first, the word "*Terrella*," then the date "1591; *ætatis* 48," and also in the background and a little below his left shoulder were the words: "*Magneticarum virtutum, primus indagator Gilbertus.*"

A couple of years ago there came into my possession an old print purporting to represent William Gilbert, and tallying in all respects with the description of the ancient portrait except in the following very significant details: The inscriptions were totally absent, and for the terrella had been substituted an ordinary terrestrial globe with the usual signs on it. As it struck me that these omissions were certainly very remarkable, and quite in line with previous efforts to slaughter Gilbert's reputation, I took occasion last September when in England, to go to Oxford for the express purpose of seeing the picture, and if possible of having a photograph made from it. I found in the Oxford stationers' stores abundant photographs of every one of the other historical portraits in the famous library, but none of Gilbert; and so I addressed a courteous request to the librarian asking permission to make the photograph in question. That gentleman in reply asked me to call upon him, which I did, and once more proffered my request, expressing at the same time the great interest which all American electricians felt in the fame and reputation of William Gilbert. He heard me through patiently, and then with a half smile, remarked:

"Well, I should be very glad indeed to allow you to photograph the picture but for one reason, which I fear must be controlling."

"And that is"—I asked.

"There isn't any picture."

As this was rather staggering in view of the repeated statements by British writers living within a hundred miles of Oxford, including various professors, I ventured to suggest that perhaps the librarian was mistaken, or was confusing the portrait in question with some one of the many others hanging in the gallery. He smiled superior once more and proposed that I walk through the room and see if I could find that portrait, which, perhaps with more zeal than politeness, I did. Then I came back to him and asked:

"Well, where is it?

"Seeing that it was removed," he answered, "over a hundred years ago, I do not know."

"Who removed it?"

"I do not know."

"Why was it removed?"

"It got decayed. It was on board, and the board rotted."

"Might I ask the source of your information?"

"Certainly," he said.

And thereupon he went to the shelves of the library and brought me a copy of the "Histories and Antiquities of the University of Oxford" by Anthony A. Wood, dated 1796, opened it at page 96 of Vol. 2, and there appeared a brief paragraph describing the picture as I have described it above, terminating with the laconic statement "Decayed and removed."

"Is there no record," I asked, "that it was ever returned?"

"None."

"Is there any receipt in the archives from anybody who took it away?"

"None."

"Has any other picture been removed from this famous collection?"

"None that I know of or have any record of."

"It is a fact, isn't it, that there are a great many pictures here of far earlier date than that of Gilbert?"

"Certainly."

"Judging by the looks of those pictures, a number of them have been restored?"

He assented.

"Well, don't you think it is remarkable that such a thing could have happened in the most conservative institution in the most conservative town in the most conservative nation in the world?"

"Very."

Then I asked him if he knew of any picture of Gilbert, and he very obligingly went to the Department of Engravings and Prints and brought me a copy which he said was of a very rare publication, but which turned out to be the same print that I had myself.

Now, it is rather a singular coincidence that the date on this print, 1796, is the same date that is on Wood's book. The print was made by a London engraver. If he did not make it from the old portrait, what did he make it from? If he did make it from the old portrait, why did he carefully leave out of his copy every word and everything which could do credit to Gilbert as the great discoverer that he was? Who allowed Gilbert's portrait to be taken from the Bodleian Library without a word of record being left behind? How did its board come to be decayed when other panel pictures did not so become? And even if it had become decayed, what was to prevent the film of paint being taken from the surface of that board, as has been done in hundreds of instances in restoring the oil paintings of the old masters, almost invariably done on panel, and remounted centuries later on canvas after their original boards had almost fallen to dust?

Gilbert, when that portrait was painted, was at the zenith of his fame as a physician. He rose to higher eminence ten years later when his book appeared. He was a graduate of Cambridge, and therefore Oxford did not hang up his portrait merely as one of its alumni, but as that of a man whom it honored itself by honoring. It cannot be said therefore that his portrait represented some one of no importance, for even when it was stolen, Gilbert's reputation was ineffably above that of dozens of the noble nincompoops and nobodies who still smirk down from those venerable walls.

So much for the past. Some time ago there was organized in England a so-called "Gilbert Society," which, we were told, was very solicitous for the fame and reputation of the discoverer. In the announcement of its establishment there appeared a long list of eminent scientists as members headed by that of the distinguished philosopher recently degraded to the English peerage. This concern was going to translate Gilbert in the highest style of the art. It has, I believe, taken subscriptions on this side of the Atlantic for its forthcoming translation. It was going to conserve and promote the memory of Gilbert. I made some inquiries while in London recently, about that society and its work, but gleaned little information. In fact, it was not easy to demonstrate its existence, although, subsequently, I was informed that it still lived, but that the preparation of its translation of Gilbert's book was not being very actively pushed; a statement that made me regret that on learning of the superior ability to be devoted to the matter abroad I had laid down the pen with my own translation of the work half finished.

Meanwhile, still pursuing my quest, it occurred to me that if I could not get a photograph of a picture of Gilbert, perhaps I might get one of his tomb; and so I sent over to a friend in London asking him if that could be done. The tomb is in the parish church in Colchester. His reply, just received, after pointing out some difficulties (the monument is high up on the church walls, there is a deficiency of light in the interior, and it will perhaps be troublesome to arrange a camera) sets forth what I suppose is the most recent attempt to blot out the memory of Gilbert; and it is a little startling. "Gilbert's memorial," writes my correspondent, "narrowly escaped destruction some time ago, when the church was in process of restoration; but our friend, Mr. Laver, a scientific man, who was then one of the church wardens, fortunately happened to see one of the workmen *wheeling the monument off in a barrow* and rescued it from demolition."

As I said in the beginning of this communication, it seems to me high time that some action, in this country, should be taken to protect the memory of William Gilbert from British depredations. *Quis custodiet custodes?*

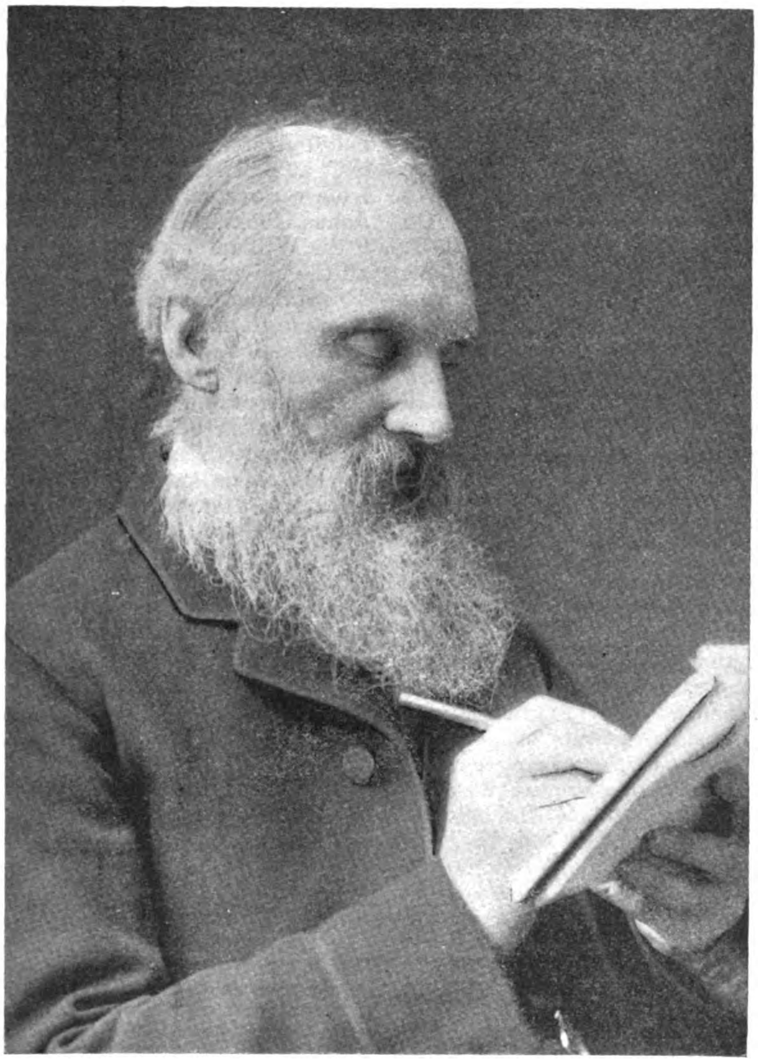
M. C. L. Weber, in an article recently published, gives the details of construction advocated for a small battery of accumulators. Two coils of lead wire, one above the other in long, thin glass tubes, is the arrangement shown. Such batteries would be used for laboratories or to charge electrometers.

WITH SIR WILLIAM THOMSON IN GLASGOW.

BY

A. C. Shaw.

The Atlantic cable has just brought to us the gratifying news that Sir William Thomson, the world-renowned electrician, has been raised to the peerage of England, and will hereafter be known to the world as Lord Thomson. Only a month or two ago Sir William was the recipient of high honor at the hands of his fellow-citizens of Glasgow, who, to commemorate the occasion of his election as president of the Royal Society, presented him with his portrait painted by the famous artist Herkomer, through the Right Honorable A. J. Balfour, then on a visit to Glasgow. At that time I had the good fortune to be sojourning in Glasgow, and had the pleasure of calling on Sir William first at his home in the University Yard, and afterwards at his laboratory, whence have come so many of those wonderful electrical instruments, which have served to win for him a world-wide reputation as the most eminent English electrician of the day, and have made his name a household word not only with scientific men, but among the people at large. Who, for instance, has not heard of the Thomson reflecting galvanometer and siphon recorder for cabling, or the sounding machine, enabling investigators to get accurate ideas of the nature of the ocean bed, or the Thomson mariner's compass, that wonderful instrument which seems to correct all errors in compass readings, and enables the mariner of to-day to make the trip from New York to Liverpool with as much accuracy as if the ship were guided on steel rails from one city to the other?



William Thomson
Glasgow Nov 28/91

It was, therefore, with feelings of profound gratification that I took the opportunity of a visit to Glasgow to call on Sir William and procure data regarding his life's history, which I now take pleasure in presenting to your readers, along with his portrait, which I may say, in passing, is an excellent likeness, and one which finds favor in Sir William's own eyes. As has been previously said, Sir William received me in his own home, in the University Yard, tendering me a hearty welcome and true Scotch hospitality. Being naturally interested in everything electrical, he then plied me with questions as to the *modus operandi* of the various systems of electric light and power in this country, being particularly interested in the wonderful and rapid development of electric street railway work. Practically there had been (with the exception of Leeds) almost no work of this kind in England, especially with the overhead trolley, and many were the pertinent questions asked as to the success and efficiency of such a system. Taking Boston for a text, and the West End Street Railway Company as an example, I assured Sir William that Americans had heartily endorsed the overhead system, and had found that electric railways were actually a necessity to the success of any enterprising city in the United States, and that though there had been severe opposition at first, the overhead wires were conceded to be much less of a necessary evil than the old antiquated horse cars. It may interest readers of THE ELECTRICAL ENGINEER to know that the city of Glasgow is at present considering seriously the question of adopting electricity as a motive power on its street railways, so that the subject was doubly interesting to Sir William at that time. On arriving at the laboratory I was presented to Dr. J. T. Bottomley, who has for so many years ably assisted Sir William, and who is himself well known to all electricians as the author of many familiar and valuable works. With Dr. Bottomley's assistance, I made a careful examination of many of the most recent inventions of Sir William, paying particular attention to his new standard electrical instruments for accurately measuring potential and current either in very small or very large quantities, and which are made by Mr. James White, of Glasgow, who has built all the Thomson instruments for the past thirty years. The most notable of these instruments are the standard direct-reading ampere balances, instruments founded on the mutual forces, discovered by Ampere, between movable and fixed portions of an electric circuit. These instruments are totally different from any other instruments in the market, and are absolutely accurate. Even more interesting than these, however, are the Thomson electrostatic voltmeters, which have the great advantage of being available as accurate measurers of potential on both direct and alternating circuits, and being electrostatic, use no current, and consequently require no temperature correction. These instruments are divided into three classes, the multicellular, the vertical and the electrostatic balance, and have a range of from 40 to 100,000 volts. It is needless to say that there were many other interesting and novel instruments to see, notably the latest invention, the Thomson wattmeter, and a variety of very large ampere-meters capable of measuring up to 100,000 amperes, without in any way heating—but I must hasten on to a short résumé of Sir William's life.

Sir William is an Irishman, by birth, though of Scotch descent, having been born in Belfast, in June, 1824. His father was educated at Glasgow University and afterwards became professor of mathematics in that college. Sir William, with his brother, James (now professor of civil engineering in Glasgow University) early took honors at the college, afterwards going up to Cambridge, where he graduated as second wrangler, in 1845, and first Smith's prizeman. At this early stage he was already noted for his success in mathematics, although other sciences had also great attraction for him, and at the same time he found leisure to devote himself to literature, music and even athletics. About this time he became interested in the study of magnetism and electricity, and gave birth to entirely new ideas on the subject of electric "potential," a subject at that time very imperfectly understood. In 1846, Thomson was elected professor of natural philosophy, in the University of Glasgow, which position he fills to-day with so much honor, having refused most tempting offers to go to English universities. In 1855 and 1856 he first gave his attention to ocean telegraphy and supplied the 1858 cable with the mirror-reflecting galvanometer, which first allowed the ocean cables to be successfully used commercially, and overcame the great difficulty of retardation. This was the first of the instruments which Sir William patented, much against his wishes, at the instigation of the Atlantic Company, as he was ready to give the public freely the fruit of his labors. Then followed the Thomson siphon recorder which was invented in 1867. This was generally brought into use three years later, and is the standard ocean cable instrument of to-day. The sounding machine and his mariner's compass were perfected about the years 1875 and 1876, and are both so well known that it is unnecessary to say anything about them. It is impossible to enumerate in this short sketch the many important points in Sir William's history, or the many useful instruments he has given to scientists, but it is interesting to note that he was in Philadelphia, in 1876, at the International Exhibition, and again in 1884 visited this country and delivered a course of lectures "On Molecular Dynamics," at Baltimore, to a class composed mainly of professors from various parts of the world, gathered together at the Johns Hopkins University.

Sir William has had honors presented to him from nearly all the universities of Europe. He is now president of the Royal Society, and ex-president of the Royal Society of Edinburgh, member of the Institut de France, the Academia dei Lincei at Rome, the Berlin Academy, the Amsterdam Koninklije Akademie and the American Academy of Sciences. He has attained almost every honor that scientific bodies can bestow on him, and, as has been already stated, has recently been recognized by the Queen by his elevation to the peerage. And yet with it all, what a modest, true-hearted, kind, genial man is there! A man whom it is an honor to meet, and yet who greets every one with a hearty frankness which at once dispels all sense of intrusion, and who inspires feelings of confidence, respect and love. Sir William, though now in his sixty-seventh year, is still as active as ever, intensely interested in all scientific work, beloved by his students, and honored by his fellow-citizens; and it is my sincere hope that he may yet be long spared to his sphere of usefulness, and the pursuit of these studies, which have yielded so much valuable fruit in the past, and which can form an ever-fruitful field of research to such penetrating genius as he so richly possesses.

SECONDARY BATTERIES.

MR. G. H. ROBERTSON'S paper, read recently before the London Society of Arts, brought out several interesting points relating to the chemistry of secondary batteries, or more particularly the chemistry of the acid, which are worth the careful study of those engaged in this specialty of electrical science. Referring to experiments with electrolytes, he says:

Although so many different modes of manufacture and preliminary treatment have been resorted to, all the batteries, so far as I am aware, which depend for their action on the couple formed between lead and lead peroxide in dilute sulphuric acid, exhibit the characteristic peculiarities noticed by Planté in his cell, namely: The high initial E. M. F. of a freshly-charged cell; the fall of E. M. F. on breaking the charging circuit, with corresponding rise on breaking the discharging circuit; the very rapid fall towards the end of discharge which occurs earlier, the more rapid the discharge is, and is not due to the exhaustion of the active material, as, after a rest, a fresh discharge can be obtained.

As the defects, namely, sulphating and buckling, which have retarded the introduction of reversible lead batteries, are also common to the two types, it appeared possible that they were due to the same causes which produced the variations in E. M. F.; therefore, as the work of Dr. Oliver Lodge[1] in 1883, and of Miesler[2] in 1888, had shown that the causes of the variation must be sought either on the lead plate or in the acid next it, and the chemistry of the plates afforded no explanation,[3] I last year, with Dr. Armstrong's advice and assistance, undertook the investigations of the reactions occurring in the acid.

[1] Cantor lecture.

[2] "Monatshafte für Chemie," viii, 713.

[3] For references and a summary of the principal work done on the cell, see the London *Electrician*, Vol. xxvii., No. 682, p. 165; No. 692, p. 487.

In 1878 Berthelot[4] discovered persulphuric acid ($H_2 S_2 O_8$), and brought forward evidence to prove that it is the primary product of the electrolysis of sulphuric acid solutions, and that the hydrogen dioxide—which, from Faraday's time, has been well known to be present in sulphuric acid after electrolysis—is really due to the action of this body on the acid. The products of electrolysis vary with the strength of the acid, 40 per cent. acid (density 1.300) yielding practically no hydrogen dioxide; while below and above that strength it is present in varying proportions. High current density and an electro-negative condition of the electrodes favor their formation.[5] Persulphuric acid is an unstable body, and begins to decompose as soon as the current which has given rise to it is stopped, and its decomposition is accompanied by the formation of hydrogen dioxide, unless the sulphuric acid is too dilute. Hydrogen dioxide is also unstable when concentrated, but a weak sulphuric acid solution of it is comparatively stable, and the stability increases the less hydrogen dioxide it contains; therefore this body is found in estimable quantities long after the persulphuric acid which gave rise to it has disappeared. Persulphuric acid is at once decomposed by spongy metal, such as platinum black, by heat with evolution of oxygen,[6] and resembles hydrogen dioxide in these reactions, and in releasing iodine from potassium iodide, but, unlike it, has no action on permanganate of potassium or peroxide of lead. The effect of electrolyzing a sulphuric acid solution of hydrogen dioxide is simply to increase the rate of the decomposition occurring spontaneously, if a weak E. M. F. is used[7]; but on increasing the E. M. F., though the rate of decomposition is increased, a little persulphuric acid is reformed. Subsequent workers have in the main confirmed Berthelot's conclusions. To the oxidizing oxygen in the products of the electrolysis of sulphuric acid, Berthelot gave the name of "active oxygen," and as they pass one into the other, and for most purposes connected with a battery it is not necessary to discriminate between them, I have retained it.

EXPERIMENTS AT THE GENERAL POST OFFICE.

That the nature of the electrolyte affected the behavior of the cell, was evident from information received from Mr. Barber-Starkey with respect to the effect of the addition of sodium carbonate, and it seemed possible that the different behavior of cells containing this substance was due to its catalytic action on hydrogen dioxide, which is known to be exceedingly unstable in the presence of a trace of alkali; and hence a comparative study of the reactions occurring in cells containing ordinary dilute sulphuric acid, and in those which had been treated on Mr. Barber-Starkey's plan seemed likely to elucidate the causes of the sulphating during rest, and the high initial E. M. F.—the two features most affected by this treatment.

Mr. Preece most kindly aided the investigation by allowing experiments to be carried out at the General Post Office, where one-half of the secondary cells contain 1 per cent. of sodium sulphate, and the other half ordinary dilute acid, density 1.180. He also put at my disposal the records of the behavior of the cells, and they proved that there was much less sulphating with sodium sulphate, as shown by the density of the acid never falling to the same extent as in the plain cells. The following readings, taken from short-circuited cells with badly broken plates, illustrate this. In two cells containing ordinary dilute acid, the density of the electrolyte had fallen to 1.100, while, according to the last readings before the short circuit occurred, it had been 1.170 and 1.180 respectively; while in two sodium sulphate cells the density had only fallen to 1.180 from 1.200 under similar circumstances. This was strong evidence in favor of the hydrogen dioxide formed in the working of the cell being appreciable in quantity, since if sulphating were only due to local action between the support and the paste, there does not appear any reason why the addition of sodium sulphate should affect it.

Whenever the cells were tested they were always found to contain "active oxygen," which was due to the presence of persulphuric acid and peroxide of hydrogen in varying proportions. During charge, persulphuric acid is the main constituent; during discharge the quantity of hydrogen dioxide gradually increases, while in a cell which has been at rest some time, there is very little except hydrogen dioxide to be found.

In addition to the tests made on the cells in the electric light and telegraph batteries, I studied the formation of the "active oxygen" during charge and discharge on some cells which were kindly set apart for my special use. The "active oxygen" forms at once on the passage of the current, decreases slightly, and then increases to a little above its first value. Starting either charge or discharge always causes an initial increase, except in the case of cells which have been long idle, when there is a diminution, due to the decomposition of the excess of hydrogen dioxide in the acid.

To test whether electrolyzed acid was able to reduce pure peroxide of lead, two equal lots of peroxide were taken by weighing one against the other, and put in two flasks. One to each, 100 cc. of acid, from next the positive plate of a cell at full charge, was poured, and this caused the evolution of oxygen, which continued slowly for some days. At the end of a fortnight the amount of peroxide of lead in each sample was estimated, and it was found to have decreased from 97.4 per cent. to 93.94 and 94.04 per cent. respectively. This appears to explain the well-known deleterious effect of rest on a cell, for although persulphuric acid itself does not reduce peroxide of lead, it forms hydrogen dioxide on standing, which is capable either of oxidizing the lead plate to litharge or of reducing the peroxide plate to the same substance. In each case the litharge is converted into sulphate by the sulphuric acid. In an ordinary cell in good order the amount of "active oxygen" is small, varying in quantity from about 0.01 grm. to 0.02 grm. per litre; but this means that in a 45-pint cell (the size used at the Post Office) there was always sufficient to convert from 3.25 grms. to 7.5 grms. of peroxide of lead into sulphate, or to undo the work of one to two ampere-hours' charge. The figures just given do not represent the total amount of "active oxygen," since the acid absorbed by the plates cannot be tested; but as the acid has more oxidizing power, the nearer you get to whichever is the positive plate, except at the commencement of discharge, and the total quantity of "active oxygen" increases rapidly soon after breaking circuit, it seems fair to assume that this increase is due to diffusion from the plates of acid which has more oxidizing power than that in the body of cell. This increase is followed by a decrease which is rapid at first, and then gradually gets very slow, and practically ceases while there is still a fair proportion of "active oxygen" left in the cell.

In the sodium sulphate cells the amount of the oxidizing agent was usually less than in the plain cells; and the amount of hydrogen dioxide was always so, unless the battery had been at rest for some time, when the conditions were occasionally found to be reversed. This, I suppose, is due to the proportion of "active oxygen" in the form of hydrogen dioxide, at the moment of stopping the current, being greater in the plain than in the sodium sulphate cells, while the latter contain more persulphuric acid. In both cells the hydrogen dioxide present at the time of stopping the current will be reduced on the plates, sulphating the surface, and more or less screening them from further action; but, as the sodium sulphate cell contains more persulphuric acid, the subsequent formation of hydrogen dioxide will be greater in it than in the plain cell. As far as I could discover, sodium sulphate has little or no action on the acid unless it is added during electrolysis, or to acid which has just been taken from a cell through which a current is passing.

The Effects of Hydrogen Dioxide on the E. M. F. *of a Cell.*—The presence of hydrogen dioxide having been thus proved, both directly and indirectly, its effect on the E. M. F. of the cell was tested. This was done by using strips of lead packed tight into small porous pots, with peroxide of lead to represent the peroxide plates, and using plain strips as the lead plates. A solution of pure sulphuric acid, density 1.180, was used as the electrolyte. The E. M. F. of the couple was taken by the deflection method, and then a drop or two of hydrogen dioxide was added to the acid, which produced a great diminution, or even reversal, of the E. M. F. The effect of introducing hydrogen dioxide into the body of the peroxide paste was also tried with a view of reproducing, if possible, the conditions of a cell which is started discharging directly the charge is completed, and in which the "active oxygen" would be accumulated at the positive plate, leaving the lead plate free, and I found that there was a slight increase in E. M. F.

Thus the variations in E. M. F. appear to depend on which plate hydrogen dioxide is formed at. When present at the peroxide plate it causes a rise, but when diffused through the acid and present at the lead plate it causes a lowering of the E. M. F.; and the rise in E. M. F., sometimes noticed on starting the discharge of a cell which has been at rest (mentioned in Prof. Ayrton's paper, J. I. E. E., 1890, p. 572), is probably due to the electrolysis and decomposition of hydrogen dioxide, for, in a cell which has been long idle, practically the whole of the "active oxygen" is due to this body.

CONCLUSIONS.

From the same faults appearing in batteries of such different construction, and judging also from the results of the experiments recorded in this paper, it would appear that the troubles occurring in batteries are due rather to causes arising in the working than in the manufacture. What is required is some substance which can be added to the acid to check the formation of the oxidized bodies in it, which cause sulphating, without at the same time injuring the plates in other ways. Nearly all the "forming" baths which have been introduced are baths in which hydrogen dioxide would he broken up as soon as formed, and, perhaps, in some modification of them the electrolyte of the future will be found; though, since the products of the electrolysis of sulphuric acid vary with the strength of the acid and the current density, no hard and fast rule can be laid down for the treatment of cells.

In cells containing acid below density 1.200, in which the proportion of "active oxygen" existing as hydrogen dioxide is high, the addition of one per cent. of sodium sulphate, or similar substance, is likely to prove beneficial, particularly if the work of the cells is intermittent. As the strength of the acid is increased, however, and the conditions are more favorable to the stability of persulphuric acid, less hydrogen dioxide will be produced, and there is more chance of the alkali released from the sodium sulphate during electrolysis damaging the plates.

[7] Berthelot. (*Compt. Rend.*, 85, 8–11.)

Also, Dr. Marshall has succeeded in preparing pure persulphuric acid, and has shown this year that it forms salts with the alkalies which are very stable; and what the effect on a cell of the formation of of sodium persulphate in it would be, is quite unknown. Although the formation of peroxides in the acid does not apparently account for the great gasing and sudden loss of charge sometimes observed, still we have seen that makers are reverting to Planté's process of manufacture, or modifications of it, and we may find that in this case also he was right, and that it is to the electrolyte we must look if we wish to find the means of materially improving the lead reversible battery.

LONG-DISTANCE TRANSMISSION OF POWER BY ELECTRICITY.[1]

BY FRANCIS R. HART.

GIVEN a point were power is best obtainable and another point where such power can be most advantageously used, the problem given to the engineer for solution is that of transmitting this power from the one point to the other. If the transmitting agent is electricity, the method is called one of *electrical power transmission.*

There are two general types of electrical methods that can be employed, (1) haulage, and (2) line transmission.

The first is comparable to the haulage of coal from the mine to a distant factory, there to have its stored energy utilized in mechanical work. The skeleton of such an electrical power-transmission system is shown in the following diagram:

TABLE I.

Source of Power, { Fuel. / Water. / Wind.

Engine, { Steam-engine. / Water-engine. / Wind-engine.

Mechanical-electrical Transformers, (Dynamos).

Storage Device, (Storage batteries).

Haulage System, { Carts. / Tramway. / Boats.

Electro mechanical Transformers, (Motors).

Machinery to be Driven.

More anolagous than the haulage of coal to this method would be a compressed-air system. If the steam-engine or turbine at the source of power drove air compressors which filled portable vessels with compressed air, and these vessels were transported and attached to air engines at a distant point, we have a system directly comparable with the electrical haulage plant.

The storage battery street car is an example of this method of electrical power transmission.

The other general type of electrical methods for distant delivery of power employs a line of conducting wires between dynamo and motor in place of the cumbersome system of haulage.

The second system has obvious advantages for long-distance transmission and I shall consider with you that only. There are conditions, however, where even for other than tramway work the haulage system may be the only or best system that can be employed.

I have given *fuel*, *water* and *wind* as the three power sources which may be employed to drive a power system. Some of the uses to which electrical methods of transmitting power may be put are shown in the following table:

Steam:
1. Large number small users obtain more economical power from one engine.
2. Local distribution from lighting companies.
3. Street railways.
4. To replace long shafts.
5. Special works (mines, etc.).

Water:
1. Locate mill with reference to shipping conveniences.
2. Concentration of small water-powers.
3. Carrying power into cities for factories, street railways, etc.
4. Continuous use of power (power during day and lighting at night).

Wind:
1. Pumping (mines and irrigation); wind-engine at best point and pump anywhere.
2. Lighting with storage cells.

The skeleton of the system is as follows:

Source of Power, { Fuel. / Water. / Wind.

Engine, { Steam-engine. / Water-engine. / Wind-engine.

Mechanical-electrical Transformers, (Dynamos).

Conducting Wires.

Electro-mechanical Transformers, (Motors).

Machinery to be Driven.

In practice, except for street railway and mining work, fuel is not an economical source of power for long-distance transmission plants. Ordinarily it is cheaper to deliver the coal at the distant point and obtain the power directly. In connection, however, with water-power the usefulness of an electrical power system can hardly be exaggerated.

Before describing to you the various systems that can be employed for line electrical power transmission I wish to call your attention to certain points concerning the efficiency of such a method and how far we can govern this efficiency. We call the mechanical efficiency of a system the ratio of the power delivered to the dynamo-electric machines at one end of the line to the power delivered by the electric motors at the distant end.

The commercial efficiency of a dynamo or motor, as I shall show you later, varies with its load. The maximum efficiency of good machines should not be under 90 per cent. and is seldom above 92 per cent. Under the most favorable conditions, then, we must expect a loss of, say, 9 per cent. in the dynamo and 9 per cent. in the motor.

The loss in transmission, due to fall in electrical pressure or "drop" in the line, is governed by the size of the wires, the other conditions remaining the same.

For a long-distance transmission plant this will vary from 5 per cent. upwards.

With a loss of 5 per cent. in the line the total efficiency of transmission will be slightly under 79 per cent.

With a loss of 10 per cent. in the line the efficiency would be slightly under 75 per cent. We may call 80 per cent. the practical limit of the efficiency with the apparatus of to-day.

The methods for long-distance power transmission by electricity may be divided into three general classes: (1) Those using continuous current; (2) those using alternating current; and (3) regenerating or "motor-dynamo" systems.

I have tabulated the subdivisions of each of these general classes as follows:

- Continuous current.
  - 2-wire.
    - Low voltage.
      - One machine.
      - Machines in parallel.
    - High voltage.
      - One machine.
      - Machines in parallel.
      - Machines in series.
  - 3-wire
    - 2 machines in series.
    - Machines in multiple-series.
  - Multiple-wire
    - Machines in series.

- Alternating current.
  - Alternating single phase.
    - Without conversions (1).
    - With conversions (2).
  - Alternating multi-phase.
    - Without conversions.
    - With conversions.

---

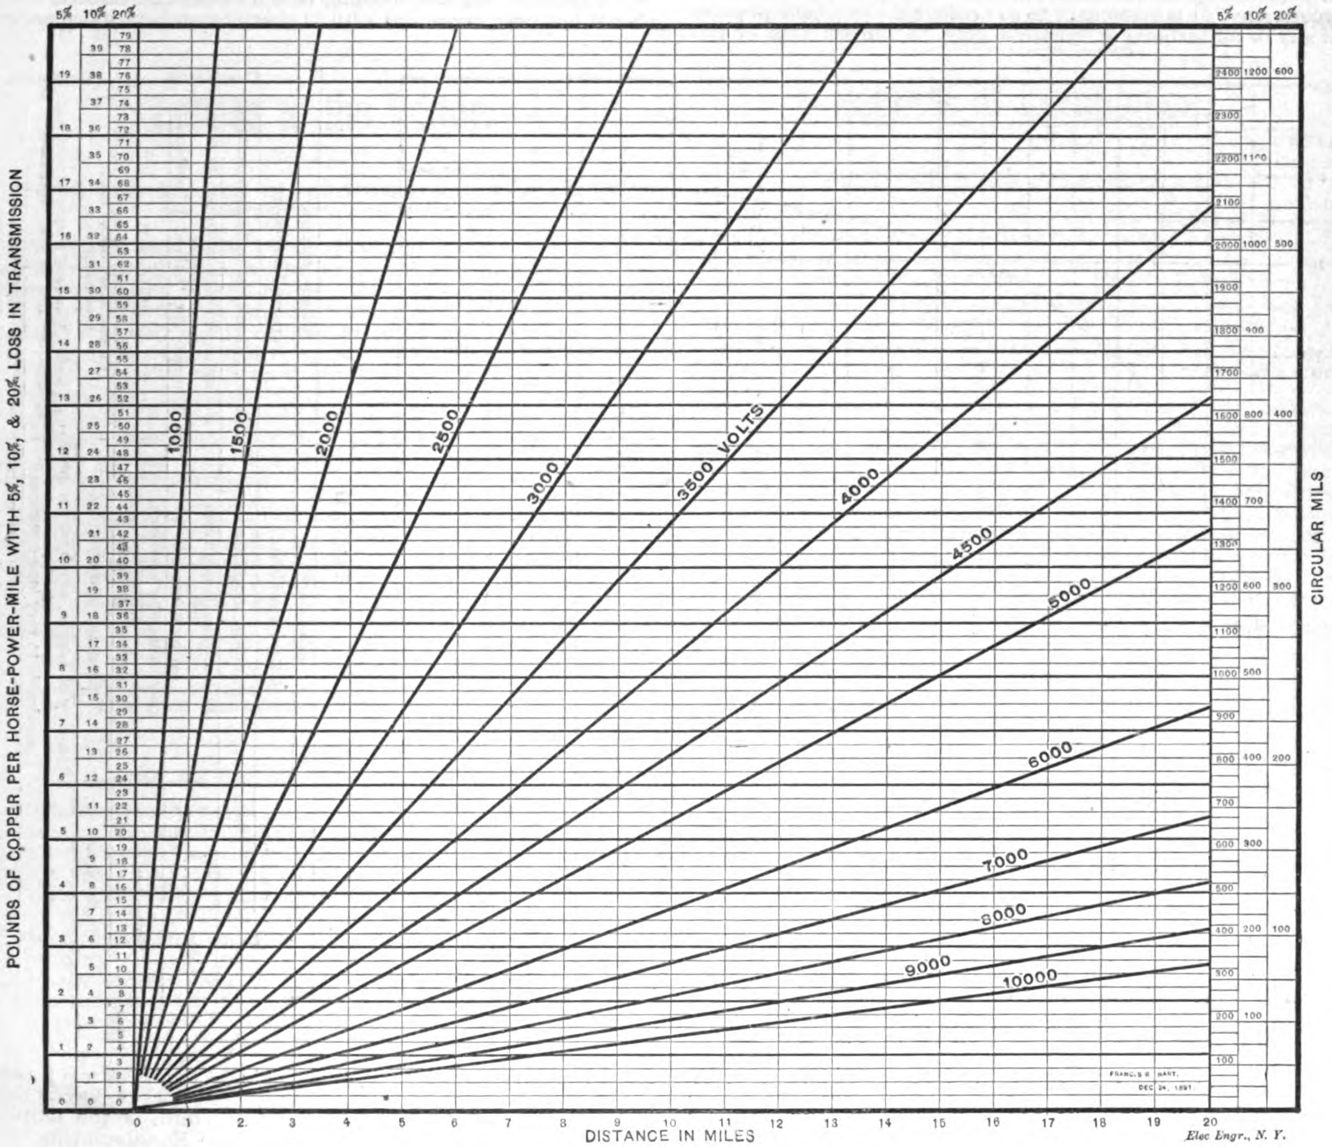
[1] A paper read before the Society of Arts, Boston, December 29, 1891.

Regenerating systems.
- **Alternating-continuous.**
- **Alternating converter; line converter; alternating-continuous.**
- **Continuous-continuous.**
- **Partial reconversion of any system.**

The relative advantages of these systems vary with each particular transmission problem, but in a general way may be tabulated as follows:

The system selected must (1) fill construction and operation conditions, and (2) give minimum cost per horse-power delivered. There are many factors which govern the selection of a system. For each problem considered there will be found certain fixed and certain unfixed conditions.

In general the fixed factors are as shown in Table II.



Elec Engr., N. Y.

FIG. 1.

1. Capacity of source of power; 2. Cost of power at source; 3. Cost of power by other means at point of delivery; 4. Danger considerations at motors; 5. Operation conditions; 6. Construction conditions, (length of line, character of country, etc.)

The partly fixed conditions are:

7. Power which must be delivered (*i. e.*, the efficiency of the system). 8. Size and number of delivery units.

The variable conditions are:

9. Initial voltage; 10. Pounds of copper on line; 11. Original cost of all apparatus and construction; 12. Expenses, operating: (Fixed charges, interest, depreciation, taxes, insurance, etc.) 13. Liability of trouble and stoppages; 14. Danger at station and on line; 15. Convenience in operating, making changes, extensions, etc.

Assuming that the cost of dynamos, motors, etc., will be approximately the same whatever the initial pressure, I shall show you the great variation in the cost of wire at different pressures. For convenience in working out such problems for rapid and approximate determinations, I have drawn a diagram on chart, Fig. 1, from which can be determined the pounds of copper required for transmitting any number of horse-power from one to twenty miles with an initial pressure of from 1,000 to 10,000 volts, at various losses in transmission. The scale of ordinates on the left gives the total pounds of copper required for one horse-power for each mile transmitted at 5 per cent., 10 per cent. and 20 per cent. loss in transmission. The scale of ordinates on the right gives the area in circular-mils of one of the two necessary wires at the same percentage losses.

To illustrate the use of the diagram, suppose we wish to know the weights of copper required for transmitting 100 h. p. 5 miles at 2,000, 3,000, and 10,000 volts and at 10 per cent. and 20 per cent. loss respectively. By inspection of the diagram we obtain the following figures.

Voltage.	Drop.	Total Pounds Copper.
2,000	10 per cent	33.6 × 100 × 5 = 16,800
	20 per cent.	16.8 × 100 × 5 = 8,400
3,000	10 per cent.	14.8 × 100 × 5 = 7,400
	20 per cent.	7.4 × 100 × 5 = 3,700
10,000	10 per cent.	1.24 × 100 × 5 = 620
	20 per cent.	.62 × 100 × 5 = 310

Very interesting mathematical deductions can be made showing conditions which give minimum cost, maximum efficiency, etc., but in practice these become of small value as almost invariably there are fixed construction or operation conditions which cannot enter as factors in a derived formula.

In the limited time left to me I can do no more than indicate to you the details of the construction and operation of an electrical power plant. I shall take as an example an installation where the source of power is water. We may separate the details of construction and operation into four heads—hydraulic, mechanical, electrical and financial. Under "hydraulic" come the improvement, control and care of the water privilege; the selection, placing and care of turbines, and the turbine regulation.

A good turbine, working at its proper load, will deliver from seventy-five to eighty per cent. of the total energy of the water. If over or under-loaded to any extent the efficiency is diminished. For the most efficient and economical working of a plant it is therefore necessary to exercise care and judgment in the management of the turbines.

Under the head of "mechanical" details of construction and operation belong the selection and care of shafting, gears, belts, clutches, etc. It is customary to so arrange the mechanical parts that any or all turbines or dynamos may be thrown into or out of use without affecting the running of the plant. That is, where possible, all like units should be interchangeable without interfering with the operation of the plant.

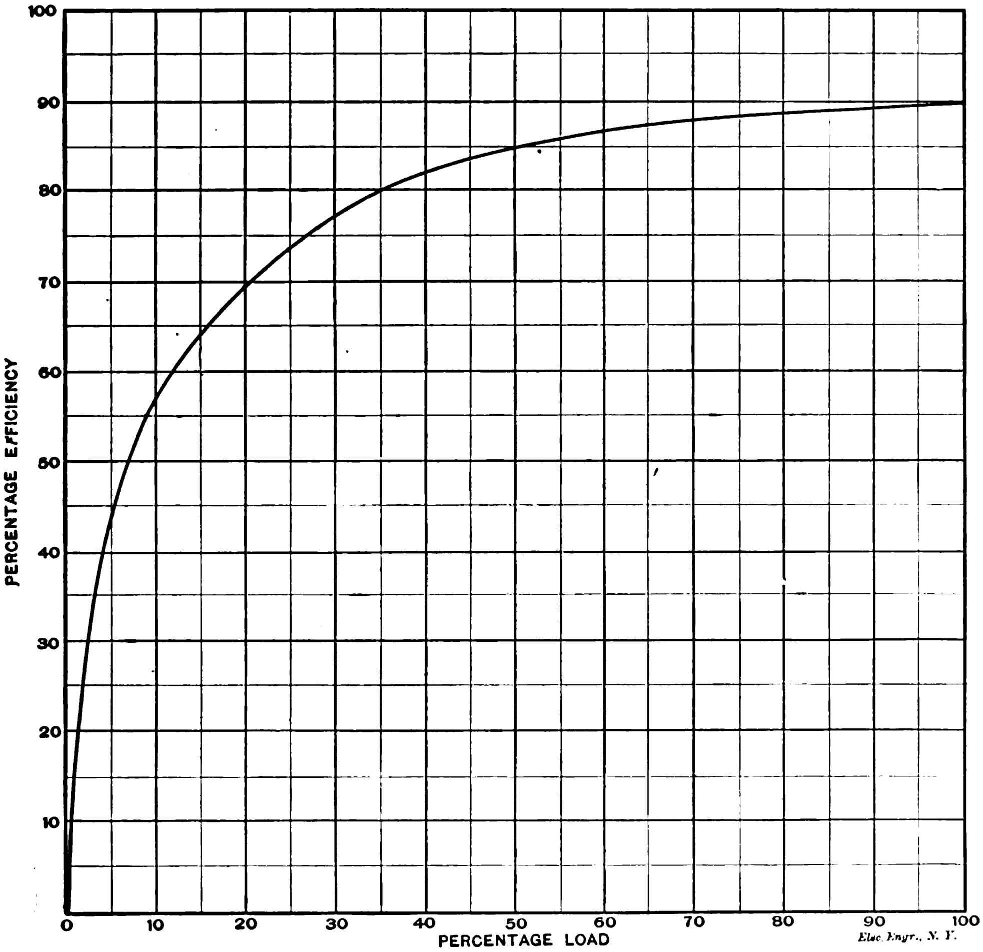


FIG. 2.

Under the head of "electrical" we have: Line construction and maintenance; machine construction, installation and maintenance; construction of switchboard, selection, construction and care of measuring instruments, lightning arresters, etc.; provision for extra parts of machinery and conveniences for rapidly making necessary changes.

The same care exercised in keeping the turbines at maximum efficiency should be applied to the dynamos. The curve, Fig. 2, shows the average variation in efficiency with load of dynamo-electric machines of from 25 h. p. to 75 h. p.

In all such plants complete records, in the form of daily reports, should be kept of pressures, currents, speeds, heights of water, time machines are started and stopped, etc. A monthly statement should be made showing the averages of the daily reports and all expenses for the month. It is convenient to deduce from each monthly statement for a uniform basis of comparison, the cost per horse power delivered for a stated time.

As the chairman, Prof. Cross, so kindly referred to the transmission plant at Cumberland Mills (Maine), which was designed and installed by the Massachusetts Electrical Engineering Company, a brief description of that plant may be of interest. The source of power is the Piesmuscot River. The turbines are vertical "Hercules" wheels working under a head of 12 feet. There are five eighty-horse-power dynamos at Saccarappa, and one mile away, at Cumberland Mills, are six motors, delivering power to the paper mills. The system is three-wire, with a maximum pressure of about eleven hundred volts. The wires are bare copper, with a sectional area each of 167,805 circular mils.

TABLE II.

	System.	Advantages.	Disadvantages.
Continuous.	2-wire { Low voltage.	Safety, simplicity.	Expense for copper.
	2-wire { High voltage.	Economy, simplicity.	Danger, difficulty of building machines.
	3-wire	Low voltage on machines and saving in copper.	Not saving enough in copper for long distances. Necessity for "balanc'd" system.
	Multiple-wire.	Low voltage at machines and saving in copper.	" " " "
Alternating.	Single phase.	Economy of copper.	Cannot start under load. Low efficiency.
	Multiphase.	Economy of copper, synchronous speed unnecessary, applicable to very long distances.	Complexity. Lower efficiency of terminal apparatus. Not as yet "standard."
	Motor-dynamo.	High voltage transmission. Low voltage delivery.	Expensive Low efficiency.

Society and Club Notes.

PITTSBURGH ELECTRIC CLUB.

AT the first regular meeting of the Pittsburgh Electric Club, after it had been organized with 71 charter members, officers were elected as follows: Morris W. Mead, chief of the Electrical Bureau of Pittsburgh, president; Eugene Ingold, of the Fort Wayne Electric Co., vice-president; James A. Rutherford, of the Railway Department, Westinghouse Electric and Manufacturing Co., treasurer; J. E. Hall, of the Fort Wayne Electric Co., secretary. H. McL. Harding and Ph. Lange, of the Westinghouse Co., E. B. Gawthrop and D. W. Dunn, of the Thomson-Houston Co., Isaac A. Silverman and E. B. Kettle, of the Edison Co., and W. N. Dillon, of the Brush Co., were elected a board of directors.

The club house is situated at 802 Penn avenue, in the very heart of the down-town portion of the city. It is equi-distant from all the railroad depots, and easily reached from any hotel. The building itself is three stories high, furnished throughout with antique oak. On the ground floor are two reception-rooms connected by a double folding door. In the rear of these rooms are the buffet, the dining-room, and the steward's quarters. On the second floor are the billiard-room, card-room and reading room, while on the third floor are three bedrooms. The place is fitted throughout with all the modern conveniences of a first-class club house.

The reception on the first of January was attended by about 500 people, and was a most enjoyable affair.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

The sixty-third meeting of the American Institute of Electrical Engineers will be held at the headquarters, 12 West Thirty-first street, New York, Tuesday evening, January 19th. A paper will be read by Mr. Chas. P. Steinmetz, of Yonkers, N. Y., on the "Law of Hysteresis." Advance copies of the paper are in preparation and will be forwarded to such members as desire them.

BUFFALO ELECTRICAL SOCIETY.

In order to increase the interest in the meetings of the Buffalo Electrical Society, and at the same time provide entertainment and instruction for its less advanced members, as well as for those more familiar with elementary branches, the Buffalo Electrical Society has taken up the study of physics as a class, devoting each alternate meeting to this purpose. Arrangements have been made for informal talks on this subject to continue through the season.

Letters to the Editor.

STANLEY AND KELLY'S ALTERNATING MOTOR—A REPLY TO MR. SWINBURNE'S CRITICISMS.

With your permission we would like to make a few remarks on the interesting comments by Mr. Swinburne in your last issue on our alternating current motor. As to hysteresis, we fail to see why this is more important in our motor than in any other in which the field is equally highly magnetized and the periodicity as great. With regard to danger from high potential we think there is none. The E. M. F. on field and condenser does not need to exceed 750 volts, and both field and condenser can be effectually protected from contact. Besides, it must be borne in mind that if through any cause a shunt were formed around either field or condenser, say, by a human body, the potential would at once fall, as the balance would be destroyed.

Mr. Swinburne's suggestion of a double-winding for the armature is another instance of his well-known sagacity and foresight. As a matter of fact, we adopted a multiple winding months ago. We are not quite prepared to enter into a detailed description of our motor yet, but not even Mr. Swinburne has foreseen the number of difficulties we have met, and we are happy to say, conquered.

W. Stanley, Jr.

Stanley Experimental Laboratory,
Pittsfield, Mass., January 8, 1982.

IRON ROOFS FOR CENTRAL STATIONS.

Referring to the article of Mr. Alfred E. Braddell and to your editorial on same, relative to iron roofs for light and power stations, we would state that this firm has built a large number of iron roofs not only for light and power stations, but for all kinds of work. We, of course, have not seen the roofs in question, but we think Mr. Braddell will find that there is no ventilator on the roof. Any iron constructed roof which is not ventilated at the peak will "sweat" or drop water from condensation, which is due to the outside changes in the atmosphere, condensing the moisture on the inside of the roof. Any ordinary kind of a ventilator in the peak will prevent this dripping or condensation taking place. The ventilator might be made circular or it might run the whole length of the roof like a monitor and be permanently opened or have movable slats so that it can be closed when it is desired to heat the building. We know that the inner roof of wood is not only unnecessary, but would add largely to the risk of injuring the iron in case of fire.

Milliken Bros.,
(Selling Agents of the Phœnix Iron Co.)

New York, Jan. 7, 1892.

INFRINGEMENT OF RAIL BOND PATENTS.

Calling attention to an item in your paper some months since in which you stated that Chas. A. Lieb had instituted suit against the Electric Merchandise Company for infringement of patent of rail bonds, we would be pleased to have you state in the columns of your paper that Judge Blodgett has to-day rendered a decision strongly and emphatically in favor of our company and against the claims of Lieb.

Electric Merchandise Co.
W. R. Mason,
General Manager.

Chicago, Jan. 4, 1892.

Personal.

MR. M. J. SULLIVAN.

We learn that Mr. M. J. Sullivan, of this city, has been called to Chicago to attach himself to the editorial staff of the *Street Railway Gazette*. Mr. Sullivan is a young man of much promise, and in his connection with the Edison Intelligence Bureau as well as in the journalistic line, has given evidence of great energy and ability. His many friends in the East will wish him abundant success in his new field of labor. It is understood that the *Gazette* will appear henceforward as a weekly.

Messrs. George H. Guy, H. L. Webb, and C. McL. Paine have resigned from their respective positions on the editorial and business staff of *Electricity*.

Reports of Companies.

NORTH AMERICAN PHONOGRAPH CO.

The reports current during the past few weeks as to an important reorganization of the North American Phonograph Co. have taken shape in a somewhat unexpected manner. The new Board of Trustees consists of Thos. A. Edison, Samuel Insull, J. N. Bush, Thos. R. Lombard, Scott Tremaine, W. Nolan and A. O. Tate, and the officers elected are: Samuel Insull, president; T. R. Lombard, vice-president; T. Butler, treasurer, and Mr. Walcott, secretary, as before. At a meeting held January 5, to organize, an executive committee was elected of Messrs. Edison, Insull and Bush. It is evident from these events that the North American Phonograph Co. has undergone a change making it very strongly Edison in complexion and control. It is stated that the offices will soon be moved from New Jersey to the Edison building in Broad street so that Mr. Insull may give the work his personal care without interference with his duties in connection with the Edison light and power interests. Outside of Mr. Jesse Lippincott's assignees there are no large creditors except Mr. Edison and the Edison Phonograph Works, and this arrangement has been carried through with the full accord of the Lippincott interests, as evidenced by the appearance of Mr. Bush in the new management. Beyond the above facts little can be elicited at the present time as to the plans that are to be followed up or the relations that will subsist with the various sub-companies. It is understood, however, that regular business is to be resumed speedily and that the apparatus is to be actively handled.

CALENDARS FOR THE NEW YEAR.

Our friends are still sending us a fine collection of calendars for 1892, and our sanctum is rapidly assuming the appearance of an art gallery. Among those last received are the following:

The Union Metallic Cartridge Company, of Bridgeport, Conn., send a calendar of very convenient form for long-distance work. It can be used by a whole family at once.

A decidedly copper tone pervades the sky, the fields and the potatoes in the work of art furnished by another well-known house, while the two aborigines in the foreground appear thankful for something. The picture is the "Angelus," and the publishers are the Eureka Tempered Copper Company, of North East, Pa.

The Bubier Printing Company present a little cottage in a snowstorm, from which it is to be inferred that they are in it, and that the temperature will be low when they get out.

The Moss Engraving Company's calendar contains a number of excellent half-tone engravings of stage favorites of assorted styles and all ages, from Fanny Davenport to "Little Tuesday."

"You have got to take cod liver oil" is the startling announcement made by a small boy and three smaller puppies that adorn Scott's Emulsion calendar. Why?

McIlroy & Emmet publish an attractive calendar embellished with a lithographic representation of four different kinds of giggles. A little jester with a big mandolin furnishes the music.

The Direct United States Cable Company's gift is of the pad variety, with a space on each leaf for memoranda. This is mounted on a heavy board back, and is both useful and substantial. The messenger boy appears to be running.

The Pope Mfg. Co. have sent a very compact little desk pad, each page of which has a blank space for memoranda and a short note upon cycling or some kindred subject, while the day of the week and month appears at the top in sufficiently heavy type to make the whole suitable for a paper-weight.

Legal Notes.

INCANDESCENT LAMP LITIGATION—THE UNITED STATES ELECTRIC LIGHTING CO vs. THE EDISON LAMP CO.—V.

ARGUMENT OF GEORGE H. CHRISTY FOR THE UNITED STATES COMPANY.—(*Concluded.*)

Mr. Christy next considered the question of abandonment. Mere delay, he said, was not abandonment; there must have been delay of that character which showed an intention to abandon. An inventor lost nothing in filing his application by mere delay, provided no intervening rights arose which would make it inequitable to assert a monopoly as against such intervening rights. The only equitable right that anybody could acquire would be a right to use, and no such right could even begin to exist until the thing in question had become capable of that use it was intended for, to wit, commercial use. But it had been proved by witnesses on both sides, as well as by Weston, that the incandescent lamp had not reached such perfection that it could possibly have been a commercial success until late in 1880. Judge Woodruff had said—and he was a judge who had been very careful in the matter of preserving the rights of patentees who seemed to be faithful and honest in their endeavors, and he would quote his exact language—"If an inventor, without substantial reason or excuse, abandons the use of his invention, and for nine years sleeps on his rights" till others do it, etc., it must have been without substantial reason or excuse. Now was it not an excuse and a substantial reason for Weston's delay that the invention could not have been made beneficial to the public earlier than 1880, or early in 1881? Was not that fact a substantial reason for his failure to proceed? Suppose Mr. Weston had gone to the Patent Office and had got his patent in 1877. Suppose, as the record shows, that he could not have got one iota of reward, in the use or sale of the product of the patented process, until four years of the protection which the law says an inventor is entitled to were gone; or suppose the incandescent lamp had not become a commercial success until 1891, instead of 1881; under the strict rule which his brother Betts was asking his Honor to apply, 13 or 14 years of the 17-year term of his patent would have expired and he would have been without his reward. Was a man bound to be diligent to his own injury, no one else being hurt? The public could take no rights until the invention became capable of public use; hence the public could not have been injured. If it were the policy of the law, that the inventor should have a period of 17 years, at such time as he might have a reasonable chance to get therefrom his reward, then by no rule of law or of equity could Weston have been required to go to the Patent Office earlier than he had gone. Was he not entitled to his 17 years as a matter of right? Was it not the duty of the court to construe the law so as to give him that right? The courts had been careful on all occasions, to protect the rights of inventors in contingencies like that. Judge Sage had said that when an inventor had gone to the Patent Office he had thereby "committed himself irretrievably to the provision that his invention was ripe for the public." Was he bound to go any sooner? He (Mr. Christy), contended that he was not; that under the Constitution and Act of Congress, Weston was entitled to all the equities that could apply to the case, and when it appeared, as it had done in this case, by the testimony of witnesses on both sides, that this 17 years' enjoyment could not have begun to run until the latter part of 1890, then he had been entitled to wait until that time before going to the Patent Office. In support of this proposition, Mr. Christy referred to the cases of *Hubel* vs. *Dick* (28 F. R., 132), and *Railway Register Co.* vs. *North Hudson Co.* (23 F. R., 293), in the latter of which cases Judge Nixon had said that an inventor was entitled as a matter of right, to his 17 years under a valid patent. He also referred to the case of *City of Elizabeth* vs. *Nicholson Pavement Co.* (97 U. S., 126), in which Judge Bradley had said:—"His monopoly only continues for the alloted period in any event, and it is the interest of the public as well as themselves that his invention should be perfect and properly tested before a patent is granted for it." Mr. Christy said he had cited this case simply to show that the decisions of the Supreme Court had been in line with the views which he had been presenting. All the cases which had been cited by his brother Betts on the question of delay had arisen with reference to inventions capable of immediate commercial use, and hence had no application to the present case. Cases in which the invention had been made in advance of the possibility of commercial use were comparatively rare. The principle had been illustrated in the case of *McDonald* vs. *Shepard* (4 F. R., 288), and *Johnson* vs. *Root* (1 Fisher, 351). His Honor had followed substantially the same ruling in the more recent case of *Harmon* vs *Struthers*, and had gone to the extent of holding that even an imperfect embodiment of the invention would not affect the right of the inventor to his patent when he got it. Substantially identical views had been expressed by Judge Wheeler in *Campbell* vs. *The Mayor* (47 F. R., 515); a case which had been commented upon in defendant's brief and cited in complainant's brief.

Mr. Christy said he came next to what was alleged to have been the first commercial success of the incandescent lamp. It had not been Edison's nor Sawyer and Man's success. It had been the success of a man who had disclaimed the invention, and hence had no right, nor any parties holding under him, to contest this invention with Weston. Maxim had been put in interference with Sawyer and Man and had been defeated. In that interference he had disclaimed the invention of Weston, and had taken a subordinate patent; hence it appeared from the record that Maxim had no equities. Mr. Curtis had testified that the Equitable plant had been put in upon an understanding that if it worked properly and was satisfactory it should be purchased. The test had been satisfactory, and for the first time in the history of electric lighting, so far as they knew, a successful lamp had been made and put into commercial use; but that success had not dated from the first of November, 1880, by any means. It had taken a considerable time to determine whether or not the lamps would stand; he thought it doubtful whether it could have been considered a commercial success until near the first of January, 1881, if not later.

The testimony of Curtis had shown how and when it was that the United States Company, the present complainant, and Weston had come together. All the other parties whose merits had been discussed, had been engaged in the business of making incandescent lamps, or trying to; Weston's company had been engaged on dynamos, arc-lights and electro-plating machinery. Not until the complainant company had acquired a controlling interest in the Weston Company, and had taken charge of its business, had Weston found himself in a position to manufacture incandescent lamps in a commercial sense, and then he had done it. His Honor would remember this point, when dealing with the equities of the parties. The defendants had no equities in this matter and never had. They had claimed equities by reason of the acts of Sawyer and Man and of Maxim, but such acts had been adverse. Maxim had no equity as an independent inventor, because over his own signature he had disclaimed the invention now in controversy, and had made no effort to introduce it until something or other had spurred him up to it. As to the Sawyer and Man defenses, he would say in a general way, that their record had been a history, and a sad history, of efforts, defeats and failures. They had tried hard enough, but they had not succeeded. In the slang phrase of the day they "did not get there." They had admitted that they had never sold a lamp. It was not pretended by anybody that they ever had. The utmost that Brother Betts could say was that they had made one lamp and had sent it to the Patent Office. Judge Bradley apparently had not thought that the making of one lamp which had not been used, constituted prior use. Mr. Christy then read extracts from Judge Bradley's opinion in the McKeesport case (40 F. R., 21), and continued:—In view of the testimony as to Sawyer and Man, and the findings of his Honor Justice Bradley, he thought he might safely pass Sawyer and Man, for they had no equity as against Weston. They had not solved the problem; they had not made a commercially successful lamp at that time and they had not done it yet.

His brother Betts had said a good deal about Weston having kept this invention to himself; that it was very singular if he had this great invention that he had not told some one about it. That had to do not with any question of fact, but with a question of mental philosophy. But he (Mr. Christy) would say that Weston did exactly what a man exercising ordinary prudence and good business judgment might have been expected to do. He had acted wisely in keeping what he had done to himself, so far as he could. His brother Betts had said that Mr. Weston was "an expert in the use of words," and so was Mr. Quimby; but was it any discredit to a witness that he should express himself with exactness and precision? that he should be able to tell what he knows, and to stop when he got to the end of his knowledge? Was it any discredit to Quimby that when a question was asked as to which he had no recollection, that he should say so?

(Here the court adjourned to December 11, 1891, 11 A. M., at which time the hearing was resumed).

It had been alleged by defendant—continued Mr. Christy—as against Weston, that there had not been sufficient proof as to the dates which he had testified to, to come within the requirements which his brother Betts had attempted to apply to it. Where the contest was between two patents, the plaintiff owning one and the defendant the other, the rule might be as defendant had stated, and that was the case which he had stated. But as between a patentee and an infringer, no such rule had ever been applied to his knowledge, in any court in this country. No presumption of law was to be made in favor of the infringer, nor could he set up in his own behalf any title under an alleged anticipating patent not owned by him. When the complainant can rebut a prior patent by carrying back his date, he may do it, proving it by drawings, models, sketches and conversation, in any manner satisfactory to the court, as regards the truth of the things to be proven. He (Mr. Christy) knew of no case in which a court had held that the party charged with infringement was in a position to demand that proof adduced in rebuttal should come up to any higher standard than that. But whatever the standard might be, he contended that Weston met the requirement; that he had made a case, as regarded the date of invention, abundantly ample to satisfy his Honor as to the truth of the things as to which he had testified. Mr. Christy then read from copious extracts from Weston's testimony, and said he thought his Honor would agree with him that it was a story which carried on its face all the ear-marks of truth. He also read from the testimony of Broadbent and contended that it was in exact accordance in substance, if not in detail, with that of Weston. Accordance in detail might sometimes show signs of collusion between witnesses, while substantial identity as regarded substance, omitting details, was one of the best tests of the credibility of a witness. Broadbent had testified that the new laboratory was ready in December, 1877; that he distinctly remembered seeing Mr. Weston do these things in the "church laboratory" before the removal to the "new laboratory." That was the very time Weston had said that he did it; and that statement of Broadbent tallied perfectly with Weston's recollection, that it was early in 1878 that he made the removal. There were in the testimony a number of what he might have called undesigned coincidences; for example, Mr. Quimby had said that at the time he saw Weston's experiments he was engaged in reissuing some of Weston's older patents. The date of the application of the only two reissues which appear at that time, showed that they had been filed in June and July, 1877. There were a number of other unexpected and undesigned coincidences—said Mr. Christy—some which he would proceed to point out. He said that he would refer to them, not as proving anything of particular value in the case, but as showing the truthfulness of the witnesses. It was the correlation of undesigned coincidences which contributed the most convincing evidence of the substantial truth of the testimony.

Mr. Christy said that he would not take time to argue upon the well-settled principle that the first to conceive was the first inventor, provided that from the date of conception to the date of completion, he exercised reasonable diligence. He thought he could show that Weston had exercised, not merely reasonable diligence, but more than reasonable diligence. What was diligence? It was diligence in trying. If a man was exercising reasonable diligence in trying, he was doing all that the law required; all that equity required. It did not make any difference whether anybody else came in in the meantime or not. That could not affect his rights. Weston had testified that his invention, as a method of treating carbons for incandescent lamps had been completed in 1877. He thought he had shown that that was true. That he had then learned how to make a carbon conductor better, with reference to its use in a lamp. What then was there for him to exercise his diligence on from that time? Clearly it was to invent a lamp in which he could burn it; and accordingly they would find, that that was the very thing to which he had chiefly devoted his attention from that time forward.

Weston did not have a company which was trying to make incandescent lamps, as Edison and Maxim and Sawyer-Man had; his company had been engaged in other lines of business, and although it was entitled to all his inventions, he had been compelled to give the manufacturing business the preference. The matter of diligence must be judged of by the circumstances under which the diligence had to be exercised. Mr. Christy then read extracts from Mr. Weston's testimony, describing the duties which he had to perform, and the difficulties with which he had been obliged to contend. He would repeat that the diligence required was the diligence in trying, and he might add, that diligence in trying sometimes became the greater when exercised in view of unexpected and unaccountable failure. Weston had had a great deal of trouble in getting a satisfactory vacuum pump, and he had finally obtained a pump which had given him the degree of exhaustion he required from the United States Electric Lighting Company. Mr. Christy added that he had argued a good many patent cases, but he thought this was as clear and good a record of diligence as he had ever presented to his Honor, or to any other federal court. He thought Mr. Weston's rights in the matter were unassailable.

Referring to the alleged anticipation contained in the Despretz article, Mr. Christy said he would call his Honor's attention to the fact that it set forth purely a scientific experiment. Carbon was known to be one of the most refractory substances in nature, and the object which Despretz had in view was to destroy the carbon, to volatilize it, to convert it into a vapor or gas. He had used the highest possible heat he could obtain. He had run against a snag in trying to do what he was after. What was that? To volatilize carbon. Despretz says that the carbon deposited over the thread, upon the clamps, and upon the whole apparatus in the few experiments which he had made. They were all experiment, and because they had been experiments they had given nothing whatever to the practical arts, for that was the test that the courts had applied to all these things. There was no instruction there to tell a man that he could get a building-up of the carbon at the weak points, and that uniformity of resistance from one end to the other, which was the central object of Weston's invention. There had been nothing to teach a skilled electrician or anybody else that the result which this invesntion calls for could be accomplished by that experiment—for that is all it was—an experiment which had been aimed at other purposes, designed for other results, and intended to destroy the thing operated upon, and not to improve it. If there was any utility in the use of carburetted hydrogen for the treatment of carbons, Despretz had not found it out. Neither had he found out that the resistance of the carbon could be rendered uniform, nor that carbon which had been so treated was of the least value as part of an incandescent electric lamp. The Weston application had been rejected on Despretz, and had been amended after it had been held that Despretz did not anticipate. It had been amended in order to make a more accurate statement of the invention.

A fact or two in this regard; not only had the rights of Sawyer and Man in this country been reviewed by a judicial tribunal, but the significance of Despretz's experiments had also been passed upon in the courts of Great Britain.

Mr. Christy then read from a decision of Justice Butt and of Lord Justice Lindley of the Court of Appeals, and observed that while of course decisions in England were not binding on his Honor, he nevertheless thought that they were, as Judge McKinnon had once put it, "strongly persuasive of the truth of the thing decided," namely, that Despretz had not anticipated the patented process.

As to the law on the subject of use, Mr. Christy said he would refer to the case of *Colgate* vs. *Western Union Telegraph*, in which Mr. Justice Blatchford had held that even though wire had been previously covered with gutta-percha, it was not an anticipation, it not appearing that its non-conducting powers had been known under the circumstances and conditions of such prior use. As regarded the *Scientific American* articles describing the Sawyer and Man invention, he contended that they were of no higher value than the Sawyer and Man patent. They had put forth the claim of adverse right, but as Weston had anticipated them on the record, it made no difference what they had done in the meantime, especially as the record had shown, and as Judge Bradley had said, their lamp had been a failure anyhow. Ten thousand failures could not make one success.

In conclusion Mr. Christy said he would call attention to a few other points in defendant's brief. Defendant had said: "There is not the slightest evidence that the carbons of the Edison Company were of an imperfect character." Why then had they treated them? The very fact that they had treated them showed that they had been imperfect or not suitable for use, and that they had treated them to make them suitable.

Mr. Betts here observed that what he meant was that there was no proof that the carbons of the Edison Company differed in resistance at different points, not that one carbon may not have differed from another; but the point which Mr. Christy had made with regard to Despretz, that he did not show the building up of the carbon to make it of even resistance, was a good point, and if the claim had been limited to that Despretz would probably not beat it. But if it was limited to that, then he contended that there was no proof of infringement.

Mr. Christy replied that Despretz had nothing to do with the case before his Honor. If Despretz had said that he was trying to make an incandescent carbon, and if it had appeared that the only difference between Weston's carbon and Despretz' carbon was that one was stronger than the other, or that one made smoke and the other did not, then Mr. Betts' criticisms might be correct. But Despretz gave nothing whatever to the art, and hence it did not lie in defendant's mouth to say that the only differences between Despretz and Weston were differences that they did not use. Another point; defendant says—if he correctly understood his brother Betts—that the sale of a patent or the grant of a license under it was putting that invention into "public use" or "on sale" within the meaning of the statute. No decision to that effect had been cited; it was like many other legal propositions contained in defendant's brief; no judicial opinion could be found to sustain them. He asserted that neither the peddling of a patent—not the thing made under it, but the patent itself—nor the granting of licenses under it, was a working of the invention under the meaning of the act of Congress. The statute had specified four things which were patentable: first, "any new and useful art that was a process"; second, "any machine"; third, "any manufacture"—like a poker or a toothpick—and fourth, "any composition of matter." As he understood it, "public use" related to any or all of them, but more particularly to the art or process, and "on sale" related to machines, articles of manufacture and compositions of matter, which were the results, the things, the articles patented. A man could not create a public use by going round and peddling rights under his patent.

In conclusion Mr. Christy said he would submit to his Honor that all the equitable rights which he had started in to talk about belonged to the complainant; that the legal rights had come to it through Weston, and that defendant had nothing under either, and that defendant had wholly failed to show that anybody other than Weston and the parties holding under him had any legal title whatever.

Mr. W. L. Adams has been appointed secretary and treasurer of the Electric Merchandise Co., of Chicago, vice Mr. A. H. Englund, resigned.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED DECEMBER 29, 1891.

Accumulators :—

Secondary-Battery Plate, H. G. Morris and P. G. Salom, 466,138. Filed July 5, 1890.

A battery plate consisting of a compound of sulphide of lead from which is formed the spongy lead active material. A negative plate composed of a compound of sulphide and oxide of lead, and a positive plate consisting of a compound of sulphide of lead and lead peroxide.

Alarms and Signals :—

Fire or other Alarm, H. M. Browne, 465,829. Filed Dec. 24, 1890.

An alarm bell having an automatic pneumatic circuit-breaker.

Means for Transmitting Signals Electrically, T. A. Edison, 465,971. Filed May 23, 1885.

A system employing elevated induction plates for transmitting signals to distant points.

Signal-Transmitting Apparatus and System, H. A. Chase, 465,989. Filed May 4, 1891.

Has for its object to increase the efficiency and cheapen the cost of construction and maintenance of a fire-alarm system.

Signal-Transmitting Mechanism, H. A. Chase, 465,999. Filed July 10, 1891.

A signal system for use in connection with a fire-alarm system.

Electric Signaling Apparatus, F. W. Cole, 465,991. Filed Jan. 6, 1890.

Has for its object the sending of signals of different kinds to be received on any desired one of several instruments; the signal being always the same but having a different meaning according as it is received upon one or another of different instruments.

Electric Signaling Apparatus, B. J. Noyes, 466,053. Filed Nov. 4, 1890.

A multiple signal transmitting apparatus operated by a signal wheel.

Electric Annunciator, F. C. Colville, 466,063. Filed Mar. 26, 1891.

A small and compact annunciator operated with very little current.

Annunciator, W. C. Dillman, 466,159. Filed July 10, 1891.

An electric annunciator for use in connection with speaking tubes.

Electric Fire-Alarm System, H. E. Jacobs, 466,306. Filed Mar. 23, 1889.

An electric fire-alarm system comprising an electric signal, a visual signal, a thermostat and low-resistance magnet in circuit with the battery, a high-resistance magnet in shunt with said circuit, and a motor for operating said signals.

Clocks :—

Electric Pendulum Clock, H. Phillips, 466,011. Filed Mar. 11, 1891.

Conductors, Conduits and Insulators :—

Covered Electric Conductor, T. L. Reed, 465,888. Filed Nov. 18, 1890.

Insulator, G. S. Albanese, 465,961. Filed Apr. 3, 1891.

An insulator in which the line wire is held in position by a bent wire clamp on the principle of a bottle stopper.

Electric Conductor, J. W. Marsh, 466,250. Filed Sept. 30, 1890.

A conductor consisting of two wires arranged in opposite sides of a non-conducting frame and held in position by a perforated strip of fibrous material surrounding both frame and wires.

Electric Cable, W. A. Connor and J. W. Marsh, 466,268. Filed Feb. 10, 1890.

A cable consisting of a number of conductors to be used in pairs, the two wires of each pair being separated from each other by a greater distance than the adjacent wires of adjoining circuits.

Distribution :—

System of Electric Distribution, T. H. Hicks, 465,854. Filed Dec. 26, 1890.

A system of distribution for high potential alternating currents whereby the current is first reduced by a converter to the desired voltage and then changed to a continuous current.

Dynamos and Motors :—

Electric Machine, T. H. Hicks, 465,853. Filed May 9, 1890.

Provides means whereby multipolar generators can be made to furnish continuous currents of high E. M. F. without danger of short-circuiting between the sections of the commutator.

Alternating-Current Dynamo, T. H. Hicks, 465,855. Filed Jan. 3, 1891.

Employs an armature having coils arranged in pairs each coil having convolutions forming a central opening, the two coils of each pair crossing each other at the ends of the armature and occupying an arc of its circumference equal to the width of two field poles and two field spaces and extending the length of the armature.

Armature Connection for Motors or Generators, T. A. Edison, 465,970. Filed Mar. 26, 1891.

Has for its object to prevent sparking at the commutator at the instant of a break in the local circuit.

Armature for Dynamos or Motors, T. A. Edison, 465,973. Filed Mar. 23, 1891.

Claim 3 follows:

An armature for dynamos or motors consisting of a core wound with two wires said wires being connected at intervals and one of said wires only being connected to the commutator.

Alternating Current Dynamo, T. H. Hicks, 465,994. Filed Mar. 9, 1891.

Somewhat similar to No. 465,855.

Governing Device for Electric Motors, W. Baxter, Jr., 466,028. Filed Apr. 14, 1891.

Has for its object to obviate the end thrust of a governor applied to a motor shaft and to improve the bearing of the contact pieces actuated by the governor.

Galvanic and Thermo-Electric Batteries :—

Galvanic Battery, S. Miller, 466,177. Filed Oct. 16, 1891.

Has for its object to provide a primary cell convenient in use, economical and very efficient in action.

Lamps and Appurtenances :—

Controlling Apparatus for Incandescent Lights, W. J. Kelly, 466,245. Filed Aug. 7, 1891.

A controlling apparatus for scenic effects in theatres, etc.

Lamp Socket, J. L. Hinds, 465,238. Filed July 23, 1891.

Has for its object the manufacture of a simple and effective socket possessing maximum efficiency and durability, and made at minimum cost.

Lamp Socket, J. L. Hinds, 466,289. Filed July 23, 1891.

Similar in its object to 466,288.

Lamp Socket, J. L. Hinds, 466,290. Filed July 23, 1891.

Similar in its object to 465,289.

Metal Working:

Sliding Clamp for Electric Welding Apparatus, H. Lemp, 465,866. Filed Jan. 19, 1891.

Art of and Apparatus for Heating Metal Articles by Electricity, E. E. Angell, 466,131. Filed Mar. 16, 1891.

Method of electrically heating metal articles preparatory to tempering.

Electric Forge. E. E. Angell, 466,132. Filed Mar. 18, 1891.

Electric Forge, E. E. Angell, 466,133. Filed Mar. 23, 1891.

Electric Heating Tool, G. W. Blanchard, 466,266. Filed April 3, 1891.

An electric heating device consisting of tongs having insulated handles and means for connecting electric conductors to their jaws, for the purpose of heating rivets etc.

Miscellaneous :—

Door Bell, F. M. Winters, 465,909. Filed June 1, 1891.

Combination of an electric door bell and clock.

A door bell operated by a small magneto-electric machine operated by the bell pull and connected with lock work which is used for ringing the bell.

Electric Cane, A. W. and A. H. Roovers, 465,949. Filed Mar. 13, 1891.

Lightning Arrester, A. Wurts, 465,958. Filed Oct. 5, 1891.

Consists of two discharge plates one of which is movable in reference to the other; these plates being so located that they will pass at the moment of a neutral point in the wave phase of the electromotive force.

Phonograph, T. A. Edison, 465,972. Filed Nov. 18, 1889.

Electrical Pyrotechnics, P. C. E. Champion, 465,981. Filed May 15, 1891.

Cut-Out, H. W. Fisher, 465,983. Filed Mar. 2, 1891.

A spring-actuated electric cut-out.

Electrical Switch, G. B. Martratt, 465,997. Filed Dec. 6, 1890.

Comination of an electric switch with a fusible cut-out.

Brake for Electric Motors, A. J. Shaw, 465,999. Filed Sept. 21, 1891.

A magnetic brake.

Electrically-Operated Elevator, F. E. Herdman, 466,037. Filed Feb. 24, 1891

Electric Plug Circuit Closer, J. L. Kimball, 466,052. Filed Jan. 22, 1891.

Has for its object to prevent the twisting of the conducting wires when the plug is screwed into its socket.

Electric Game Register for Pool Tables, C. A. Erikson, 466,068. Filed Aug. 24, 1891.

Temperature-Regulating Device for Electrical Circuits, E. Weston, 466,087. Filed June 4, 1891.

Maintains constant electrical resistance in a circuit despite changes in temperature.

Electric Switch, W. J. Kelly, 466,244. Filed June 29, 1891.

A circuit-controlling switch, simple and cheap in construction and efficient in action.

Railways and Appliances :—

Electric Railway, J. Emmner, Jr., 465,844. Filed Oct. 30, 1890.

Has for its object to simplify the construction of conduit electric railways to insure perfect contact and prevent leakage or short circuiting.

Electric Railway, H. S. Pruyn, 466,886. Filed June 25, 1890.

A strong, light elevated structure which will deaden the sound of passing trains.

Electrical Railway Switch, M. Kerstein, 466,101. Filed May 16, 1891.

An electrically actuated railway switch and means whereby it may be readily operated by the attendant on the car.

Electrically Driven Locomotive, E. H. Morgan, 466,180. Filed Mar. 9, 1891.

Method of converting an ordinary steam locomotive into one driven by electricity by the use of storage batteries.

Electric Railway Trolley and Support, W. A. Stevens, 466,196. Filed Sept 22, 1890.

Employs a top-bearing trolley wire at one side of the track.

Electric Car Brake, La M. C. Atwood, 466,212. Filed Jan. 10, 1891.

A brake actuated by a rack segment engaging a pinion on the armature shaft of the motor.

Telegraphs :—

System of Synchronism for Telegraphy, G. A. Cassagnes, 465,832. Filed June 26, 1891.

Maintains synchronism between trailers rotating on the contact distributers at two distant stations.

ELECTRICITY IN CARCINOMA.

A PAPER was read some time since before the American Electro-Therapeutic Association in Philadelphia, by Robert Newman, M. D., of this city, on the cure of cancer by electrical treatment. This paper has been published by the American Medical Press Company, of Philadelphia, and is most interesting even to a layman.

To quote the author's opening sentence: "It is a very ungrateful task to write a paper on the treatment of cancer, while pessimists insist that cancer is incurable and the profession look with suspicion on any report of a successful case, and still more hazardous to say that electricity has cured; nevertheless, it *has.*"

Dr. Newman then gives his experiences, and cites many instances to substantiate his statements, with the hope, he says, of drawing the attention of electrical experts to the subject, in order that some method of treatment may be systematized and perfected.

MR. E. E. BOYNTON, electrical engineer, has resigned his position with the Elektron M'f'g Co. of Springfield, Mass., and has entered the employ of the Thomson-Houston Electric Co., at Lynn.

TRADE NOTES AND NOVELTIES

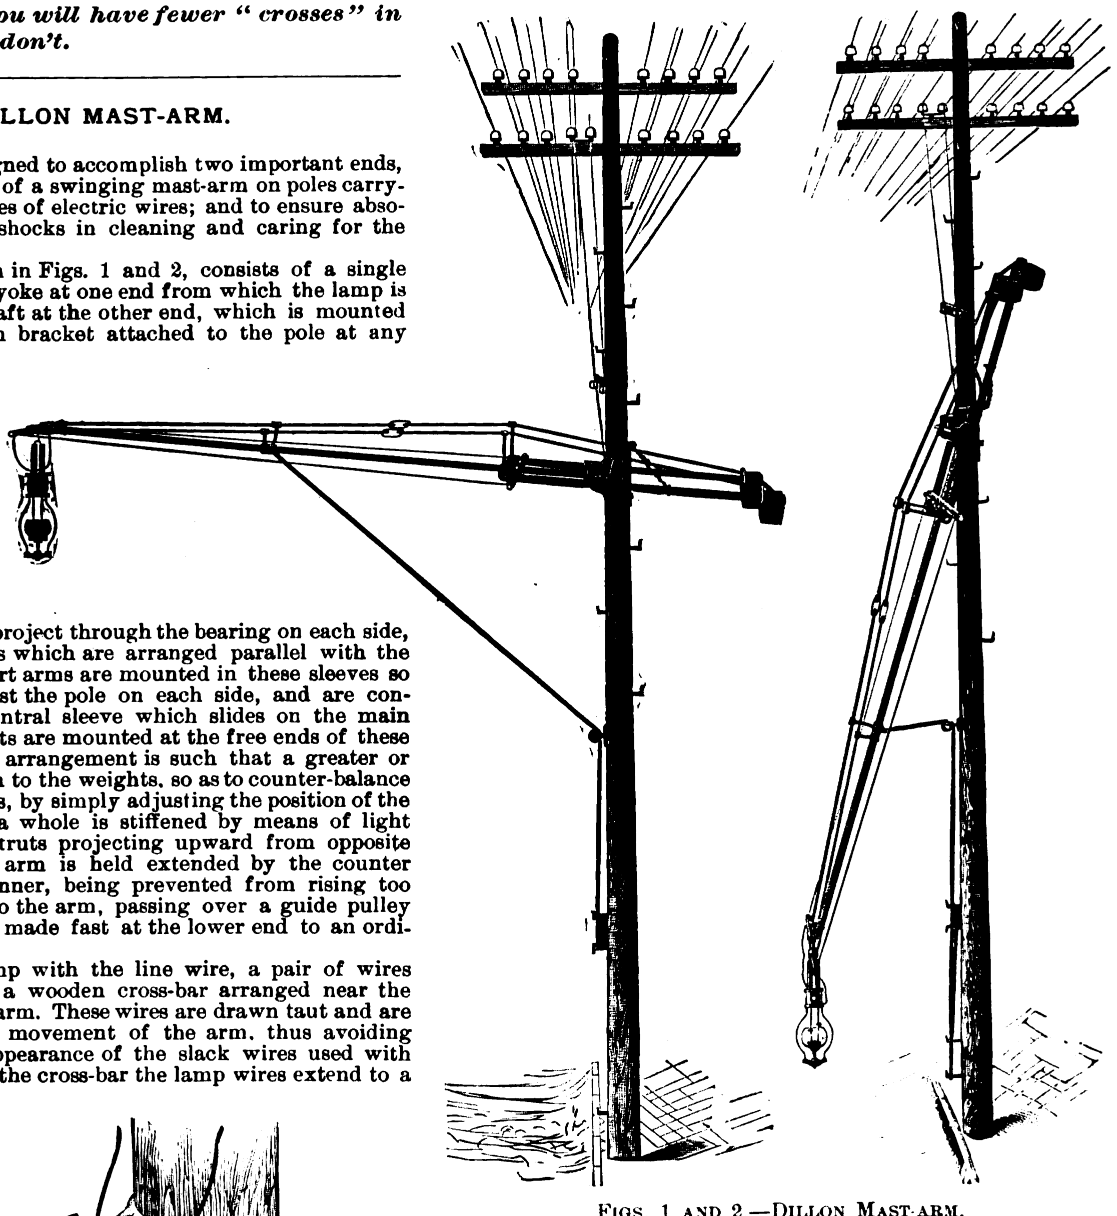
AND MECHANICAL DEPARTMENT.

If you advertise you will have fewer " crosses " in business than if you don't.

THE DILLON MAST-ARM.

This mast-arm is designed to accomplish two important ends, namely, to permit the use of a swinging mast-arm on poles carrying at the top ordinary lines of electric wires; and to ensure absolute safety from electric shocks in cleaning and caring for the lamp.

The arm proper, shown in Figs. 1 and 2, consists of a single piece of tubing, having a yoke at one end from which the lamp is suspended, and a short shaft at the other end, which is mounted in bearings in a cast-iron bracket attached to the pole at any height desired.



Figs. 1 and 2.—Dillon Mast-arm.

The ends of the shaft project through the bearing on each side, and carry a pair of sleeves which are arranged parallel with the main arm. A pair of short arms are mounted in these sleeves so as to extend backward past the pole on each side, and are connected at one end to a central sleeve which slides on the main arm. The counter weights are mounted at the free ends of these short arms and the whole arrangement is such that a greater or less leverage may be given to the weights, so as to counter-balance lamps of different weights, by simply adjusting the position of the short arms. The arm as a whole is stiffened by means of light truss-rods, passing over struts projecting upward from opposite sides of the arm. The arm is held extended by the counter weights in the usual manner, being prevented from rising too high by a rope attached to the arm, passing over a guide pulley attached to the pole, and made fast at the lower end to an ordinary belaying-cleat.

In connecting the lamp with the line wire, a pair of wires extend from the lamp to a wooden cross-bar arranged near the shaft which supports the arm. These wires are drawn taut and are never slackened by the movement of the arm, thus avoiding entirely the unsightly appearance of the slack wires used with other mast-arms. From the cross-bar the lamp wires extend to a pair of binding-posts attached to two copper segments mounted on the supporting shaft, but insulated therefrom.

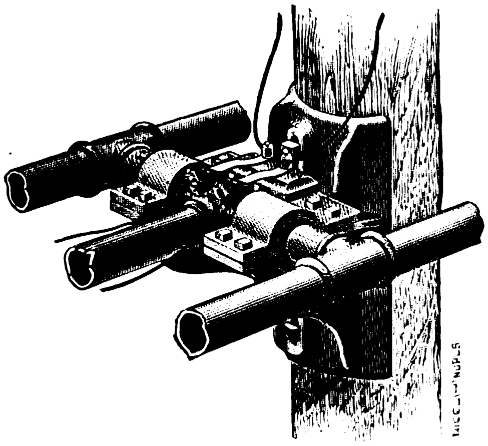


Fig. 3.—Dillon Mast-arm.

The ends of the line-wire terminate in a pair of binding-posts mounted on the bracket which supports the arm, but insulated from it, and these binding-posts are attached to a pair of terminals which rest at their free ends, when the lamp is in position for lighting, on the segments to which the lamp wires are connected, as shown in Fig. 3, so that the current passes from one portion of the line to the first segment, thence through the lamp and off through the other segment to the line again.

The segments to which the lamp wires are connected are of such length that, when the lamp is lowered, they pass out from under the line terminals and become wholly disconnected, the terminals then resting upon a second pair of like segments, also mounted on the shaft, but insulated, and connected by a short bar cast integral therewith, thus forming a short circuit wholly independent of the lamp. By this arrangement, the act of lowering the lamp for the purpose of trimming, separates it from the line circuit, and renders an accident impossible ; and the lamp is automatically put in circuit by the raising of the arm.

This device is manufactured by the Dillon Mast-Arm Co., 126 S. Pennsylvania street, Indianapolis, Ind.

A Striking Picture.—One of the neatest and most novel advertising devices is one recently brought out by the Thomson-Houston Electric Co. It is composed of a very handsome lithograph picture of the Masonic Temple, in which all the windows are cut out, leaving open spaces, which is then placed in a handsome frame supporting several incandescent lamps behind it. When the current is turned on, this gives a most beautiful luminous effect and shows the building as it appears when the lights are running. This company have a picture of the Masonic Temple of Chicago arranged in this manner in their Western office on Michigan avenue, which is excessively attractive in appearance, and which catches the attention of every passer by.

THE JOHNSTON DISCONNECTOR FOR ELECTRIC RAILWAY CIRCUITS.

It is now conceded that the overhead trolley system is the most economical and practical method of propelling street cars; and while many apparent and a few real objections have been made to this system in our large cities, a recent invention of Mr. A. Langstaff Johnston, C. E., of Richmond, Va., removes all of these real and imaginary objections. It is being introduced by the Johnston Safe Automatic Electric Co., of Richmond, Va.

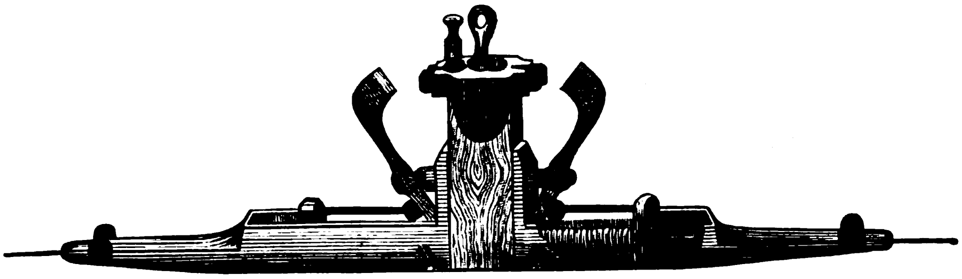
Mr. Johnston, the inventor, is a well-known civil engineer, an associate member of the American Institute of Electrical Engineers, and a member of the American Society of Civil Engineers. He has constructed several of the principal electric railways in this country, and has devoted many years to the study of the subject.

It can be truly said that this invention is an important event in the progressive development of the electrical trolley system, and will popularize the same, as it makes the trolley wire perfectly safe.

This device, when applied to the trolley wire or any wire bearing a current of electricity dangerous to life and property, will, in the event of the rupture of the wire from any cause, thoroughly cut off all electric current, and the wire will fall to the ground uncharged and can be handled with impunity.

It offers special advantage and facility for repairs to any portion of the electric wire line, without interference with the service of any section of the line except that section where repairs are to be made, and without in any manner interfering with the machinery at the power house, a constant flow of electricity being kept up to all other parts of the line by means of the various feed wires.

It is confidently asserted that this device will be of the greatest use to all overhead systems, and a perfect guarantee of safety to the public, as by it the current can be cut off on any section of the electric line without affecting any other portion thereof. It will also prove of great value and convenience in case of fire along the line.



The Johnston Disconnector for Electric Railways.

It is applicable to electric light wires or to any heavily-charged wire; or to wires which cross each other, especially where they are led off into other wires.

The instrument is self acting and perfectly simple. If a wire breaks in a storm or from any cause, the same may be picked up without the slightest fear of receiving a shock, and the wire instantly repaired without interference with travel on any part of the line, except where the break occurs, and there only for a few minutes while the broken wire is being reunited.

The device has been put to a practical test on the Richmond and Manchester electric railway line, where it has been in constant use for some time, and the railway officials say it has proven more than satisfactory and accomplishes all that is claimed for it. With the trolley wire thus made perfectly safe, and the other objections removed by the use of this device, why should not the overhead trolley system be used in all cities?

At least as many as five of the devices per mile are necessary, or wherever a feed-wire is placed, they take the place of the ordinary insulator and thus prove no additional incumbrance to the line.

As will be seen, the device is simplicity itself. The jaws seen in the cut are held together in circuit by the tension of the live wire. When that tension ceases by the breaking of the wire, the jaws are thrown outward by the recoil of the springs disconnecting that section until the restoration of live tension pulls them into circuit again.

A THOMSON-HOUSTON FACTORY FOR CHICAGO.

The following is from the Chicago *Interocean*:

"It is probable that the Thomson-Houston Company will select a site and erect a large factory at Pullman, at least negotiations with that end in view have been under way for some days, with every indication of reaching a favorable conclusion within a short time. Mr. Pullman, Norman B. Ream, President H. A. Pevear, C. A. Coffin, Vice-president, Captain Eugene Griffin, the second vice-president of the Thomson-Houston Company, and B. E. Sunny, the Western manager, visited Pullman December 31, with a view to selecting a location. The grounds were looked over, and the advantages of the different sites that might be selected discussed, but no choice was made at the time. From its extensive interests and its importance, and especially from the amount of capital required and controlled by this company it will be one of the most important acquisitions to Chicago's already large number of industrial institutions. The details have not yet been considered, but a general statement is made by one of the company that about $500,000 will be expended in buildings and a plant and about 500 to 1,000 men will be given employment. The concern, should it established here, will manufacture a full line of electrical goods, including equipment for electric railroads, and will have no connection whatever with the Pullman Company."

LUNCHING WITH THE W. S. HILL CO.

Those of the New York electrical people who were not aware that the W. S. Hill Co., of Boston, had opened a branch office in this city, were apprised of it in a fetching way, Monday, Jan. 4, by a neat invitation signed by the company, requesting the pleasure of their presence at an "At Home" at the office of the company, room 518 Electrical Exchange Building. A handsome lunch was prepared for the consumption of the hungry electricians, and while chicken salad was being washed down with punch, General Manager George H. Poor, Mr. W. S. Hill himself and their New York representative, Mr. E. A. Des Marets, stood ready to explain to those interested points regarding the Hill motor and Hill switches. The Hill motor is remarkable for the comparatively small amount of iron used in its construction and its consequent small weight, besides a very low speed. Electrical offices in lower Broadway, Cortlandt and Liberty streets were generally deserted while the lunch was in progress, and while Mr. Hill had a most excellent opportunity of renewing his old acquaintances in New York, Messrs. Poor and Des Marets improved their time in making new ones. The occasion was also brightened by the presence of ladies.

We believe the W. S. Hill Co. has shown wisdom in opening an office in this city, and we venture to predict for the company the increased and increasing business for 1892 which its specialties merit and its management would seem to guarantee.

RECENT SALES OF BALL ENGINES.

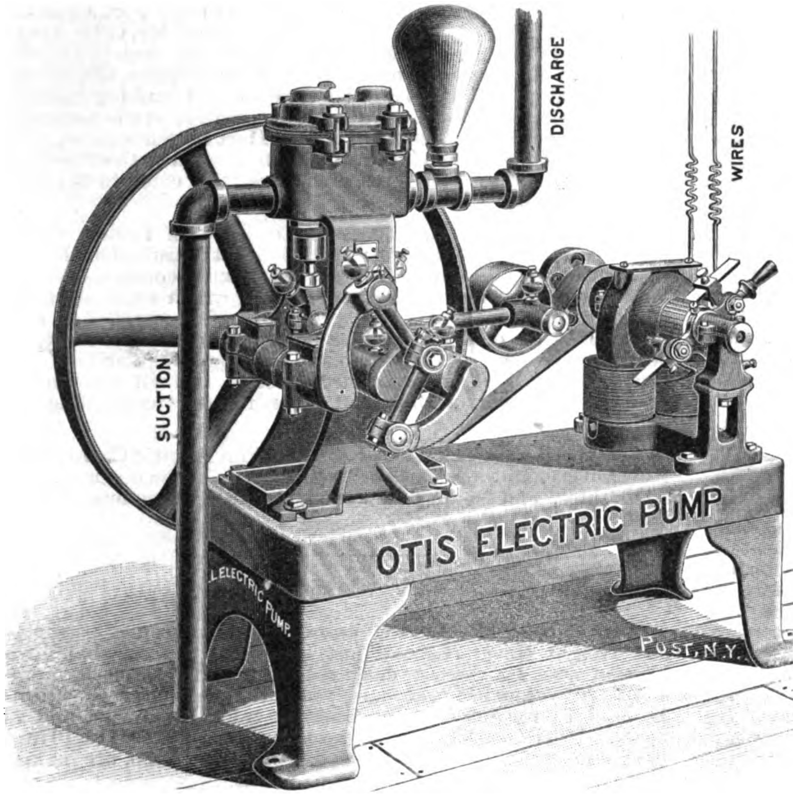
The Ball Engine Co. of Erie, Pa., reports the following sales: Palace Hotel, San Francisco, Cal., one 200 h. p. cross-compound. H. C. Hawks, Boston, Mass., one 35 h. p. single cylinder. The Linderoth Ceramic Co., Chicago, Ill., one 25 h. p. single cylinder. Ohio Baking Co., Cleveland, O., one 80 h. p. single cylinder. Lawrence Gas and Electric Light Co., New Castle, Pa., one 150 h. p. single cylinder. L. H. Goodnow, Fitchburg, Mass., one 35 h. p. single cylinder. Attica Electric Light Co., Attica, N. Y., one 80 h. p. single cylinder and one 50 h. p. The Colonial Club, New York City, two 50 h. p. single cylinder. Citizens' Electric Light Co., Braddock, Pa., one 150 h. p. single cylinder. Youngstown Electric Light Co., Youngstown, O., one 350 h. p. cross-compound. Pittsburgh and Birmingham Traction Co., Pittsburgh, Pa., one 50 h. p. single cylinder. California Electric Light Co., San Francisco, Cal., one 300 h. p. cross-compound. Sauquit Silk Mfg. Co., Scranton, Pa., one 35 h. p. single cylinder. Claremont Electric Light Co., Claremont, N. H., one 80 h. p. single cylinder. Johnstown Electric Light Co., Johnstown, Pa., one 200 h. p. single cylinder. Abington and Rockland Electric Light Co, North Abington, Mass., one 100 h. p. tandem compound. Edison Gen. Elec. Co., New York, two 50 h. p. single cylinder. Wrought Iron Casting Co., South Boston, Mass., one 100 h. p. single cylinder. Cleveland Hardware Co., Cleveland, O., one 50 h. p. single cylinder. Union City Electric Light Co, Union City, Tenn., one 80 h. p. single cylinder. Brush Electric Light Co., Cleveland, O., one 35 h. p. single cylinder. Loraine Electric Light Co., Loraine, O., one 100 h. p. single cylinder. Masonic Building, Richmond, Va., two 60 h. p. single cylinder.

THE OTIS ELECTRIC PUMP.

WITH the marked improvement of the electric motor, and rapid extension of electric power lines, there has grown a popular demand for electric machinery of all kinds. Principal among these is the electric pump. To supply this demand, and to fully meet the exacting requirements of this service, Otis Brothers & Co. have just brought out their latest improvement in this class of machinery, viz., the "Otis Electric Pump."

This pump is constructed to operate upon a novel principle, the water being moved with a continuous and unvarying flow, entering at the suction, and passing through valved pistons, thence out at the discharge. The advantages of this principle of action are many; prominent among which is its entire freedom from the shock, jar, or water-hammer; another is the economy in power naturally resulting from the constant motion of the column of water, as it does not require as much power to keep a body in constant motion as it does to move it with an alternate starting and stopping motion.

Another advantage arising as a natural result of the continuous action is the even distribution of the work at all points of the revolution of the pump, thereby creating a uniform resistance to the action of the electric motor. Besides, the continuous-acting principle, upon which all of these pumps are constructed, avoids the noisy and unsteady operation common in steam pumping machinery in general.



OTIS ELECTRIC PUMP.

For domestic use, and other light services, they are eminently adapted to supersede all of the old troublesome and objectionable devices (with their disagreeable features), such as steam, gas, oil, hot air engines, etc., wherever it is possible to connect with the lines of the electric lighting or power circuit.

The pump is automatic in its action. There is placed at the tank, and in the electric circuit, a switch, which is operated by the action of a float, as it rises and falls with the water; for instance, when the tank has filled to the desired height, the float acts to cause the switch to break the circuit and stop the pump until the water-level is lowered by drawing from the tank; the float then descends and causes the switch to again complete the ircuit and start the pump, to again fill the tank.

These pumps are particularly adapted to furnishing water for omestic use, for office buildings, for irrigation, for watering live ock, for protection in case of fire, operating elevators, as well as many other purposes.

CROCKER-WHEELER DIVIDEND.

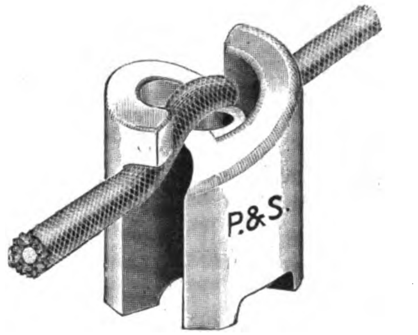
A DIVIDEND of 5 per cent. was paid the stockholders of the ker-Wheeler Motor Company, Nov. 15th. A reserve fund at the same time created, and the balance of the profit was aside for this fund.

ELECTRIC GAS LIGHTING COMPANY.

A VERY complete and well-arranged catalogue is that issued by the Electric Gas Lighting Company, of 195 Devonshire street, Boston. In addition to electric gas lighters of every description, the catalogue comprises a very complete assortment of miscellaneous electrical supplies.

THE NEW PASS & SEYMOUR WIRING INSULATOR.

WE illustrate herewith a very interesting new form of wiring insulator, from Pass & Seymour, the manufacturers of china for electrical purposes, at Syracuse, N. Y. This new insulator does away with the unsightly "tie wire" and does not injure the insulation or make any short kinks in the wire. It will be noticed that the wire passes through the centre of the insulator. This effectually prevents the insulator from turning and throwing slack into the wire, as is the case when the wire is fastened to the side of the insulator. The screw required to fasten it is less than half the length required for other insulators of this class, and when the wire is in position it is hid. Wiring can be done very rapidly with it. The insulators are fastened to the ceiling, the wire is passed under one lug and drawn taut, and then passed under the other lug, the slight bend in the wire holding it taut. The wire is also held a good distance from the ceiling, which prevents the deposit of dust. Such an insulator as this is destined to enjoy a large sale.



PASS & SEYMOUR WIRING INSULATOR.

NEW ENGLAND NOTES.

THE WAINWRIGHT M'F'G CO. OF MASSACHUSETTS report the following sales during the past month: Grand Trunk R'y of Canada, one 600 h. p.; Powers Hotel, Rochester, N. Y., two heaters, 300 h. p.; Barnett & Record, Minneapolis, Minn., two heaters, 350 h. p.; Pomeroy & Middleport Electric Co., Pomeroy, O., one heater, 125 h. p.; Goshen Electric Light Co., Goshen, N. Y., one heater, 125 h. p.; Newport News Electric Light Co., Newport News, Va, one heater, 200 h. p.; Wilmington City R'y Co., Wilmington, Del., one heater, 1,000 h. p.; Fraser & Chalmers, Chicago, Ill., 1 heater, 800 h. p.; American Spool, Bobbin & Shuttle Co., Boston, one heater, 150 h. p.; Derby Street R'y Co., Derby, Conn., one heater, 125 h. p.; Russell & Co., Massillon, O., seven heaters, 885 h. p.; Pittsburgh, Allegheny & Monongahela Traction Co., Pittsburgh, Pa., one heater, 400 h. p.; Buckeye Engine Co., Salem, O., three heaters, 280 h. p.; Stearns M'f'g Co., Erie Pa., one heater, 100 h. p.; Mount Morris Electric Light Co., New York, N. Y., one heater, 200 h. p.; Mahoney, Shenandoah, Girardville & Ashland Street R'y Co., Rappahannoek. Pa., one heater, 200 h. p.; Johnson Wheel Co., Freeport, Ill., one heater, 100 h. p.: Geo. F. Blake M'f'g Co., E. Cambridge, Mass., 3 heaters, 210 h. p.; Montana Electric R'y Co., Helena, Mont., one heater, 250 h. p.; Hughes Steam Pump Co., Cleveland, O., 3 heaters, 180 h. p.; Edward Simon & Bros., Newark, N. J., 1 heater, 100 h. p.; Arbuckle, Ryan & Co., Toledo, O., 3 heaters, 285 h. p.; Phœnix Iron Works Co., Meadville, Pa., 1 heater, 500 h. p., and 35 small heaters amounting to 1,550 h. p. Among the sales of expansion joints the following large orders appear: Pabst Brewing Co., Milwaukee, Wis., 91 joints; Delaware, Lackawanna & Western R'y, Jersey City, N. J., 14 joints; Grant Locomotive Works, Chicago, Ill., 12 joints; Blue Island Engine & Steam Heating Co., Blue Island, Ill., 3 joints; New York Central & H. R. R. R., New York, N. Y., 4 joints; U. S. Government cruiser, "Detroit," 2 joints; U. S. Government cruiser, "Montgomery,"2 joints.

The Electric Gas Lighting Company, of Boston, are out this year again with another interesting catalogue, replete with useful devices for the electrical trade. The frontispiece, this year, is a masterpiece of art, and if one were to deduce any moral therefrom, it would be that the Electric Gas Lighting Company were doing a very "*driving*" business, with a good charioteer at the reins. The catalogue embraces, as usual, all the various forms of gas lighting apparatus, hand and automatic, with their various attachments in the way of switches, cut-outs, keys, etc. Samson, their never-failing champion in the battery line, comes in for his usual share of attention, and is rated as a formidable opponent to all rivals. Electric bells of all kinds, annunciators, including the "Tirrell" gravity drop, next receive attention, the new "Hub" needle indicator, designed for less expensive work, being also well described. All kinds of push buttons and pulls are next set forth, and then follows the Thaxter electric lock, the W. T. door opener, battery supplies, various instruments, tools, alarm clocks, telegraph instruments, etc., electric light supplies and other useful commodities. The Porter electric motor is also given considerable prominence, which it has well merited, having achieved a wide and favorable reputation for itself since its introduction little more than six months ago. Lastly, there is enclosed a sheet giving a full list of discounts, so that the exact price of any article enumerated in the catalogue can be readily and easily deduced.

The Holtzer Cabot Electric Company, of Boston, have recently issued their new catalogue for 1892, embracing a number of novelties introduced by them in the past year. The catalogue commences with their well-known jack-knife switches, single and double pole from 30 to 1,000 amperes; and special mention is made of their switch with movable connections, specially adapted to motor work. This company are also making a specialty of slate switchboards, specially for central station work, and they are present building a very large and complete one for the Brookline Gas & Electric Light Company, of Brookline, Mass. The catalogue illustrates their well-known pressure indicators, automatic controllers, switches, cut-outs, magneto testing machines of special design, sockets, the H. C. ceiling rosette, insulators, insulating joints, and all kinds of fixtures of their own manufacture. The new "Bonnie Breeze" fan motor, brought out during the past year, deserves special mention. There is also a most complete list of tested fuse links and fuse wire, for electric light, power and railway work. Besides these specialties, the catalogue contains a list of numerous articles for which the Holtzer-Cabot Company are agents, and concludes with very useful and comprehensive tables of dimensions, resistances, carrying capacities and weights of commercial wire, carefully compiled by their electrician, Mr. J. Harly Craig. Altogether it is a book well worth preserving.

The Jewell Belting Company, of Hartford, Conn., have just completed a sixty-inch double belt, 185 feet long, for the Newark Rapid Transit Company, of Newark, N. J., which is one of the handsomest belts that they have ever made. This company have had orders for eighteen belts, double and three-ply, within the last month, a large proportion of them for electric light and power work, of which the following is a list: 100 feet of 42 inch double, 190 feet of 32-inch double, 135 feet 60-inch double, 69 feet of 30-inch double, 79 feet of 30-inch double, 115 feet 30-inch double, two belts 103 feet each of 48-inch three ply, 115 feet of 48-inch double, 115 feet of 48-inch double, 40 feet of 48-inch double, 90 feet of 30-inch double, 86 feet 32-inch double, 88 feet 32-inch double, 111 feet of 30-inch double, 57 feet 30-inch double, 123 feet 40-inch three-ply. The Jewell Belting Company are paying special attention to the exacting requirements of belts for dynamos and power generators. They put in the very best of material, and have achieved a well-earned success. Their driving belt department is full of work, both for wide and narrow belts, and they are now better equipped than ever to turn out the best of work in the shortest possible space of time.

The New England Butt Company, of Providence, R. I., report very satisfactory business during the past year, with a marked increase of export trade both to Europe and South America. During the year they have brought out several novelties in braiding and winding machinery, and at present business is quite brisk in all its departments.

The Consolidated Electric Motor Company, of Boston, have secured the control of the Hubbell portable primary battery, the invention of Mr. Charles J. Hubbell, of New York. This small battery derives its power from zinc and carbon, using the ordinary dilute sulphuric acid. The carbon is connected, however, to the bottom of the battery and the zinc is connected at its central point, by which, it is claimed, a much greater current is obtainable. Four of these cells will light up a small lantern, while 8 will run a 10 c. p. lamp continuously for 12 hours, or will run a sewing-machine or fan. The battery possesses several novel features, and is extremely clean and free from smell. The Consolidated Company intend putting them on the market at an early date.

The Eddy Electric Manufacturing Company, of Windsor, Conn., have installed a power plant of of 385 h. p. in the factory of the Encaustic Tiling Company, at Zanesville, Ohio. This plant embraces two generators of 100 h. p. each, driven by Jewell belts from a New York Steam Safety Company, engine, and 12 motors varying from 5 to 35 h. p. distributed in different parts of the factory. They have also installed a 50 h. p. generator and seven motors driving Blackman ventilating fans in the New York State Capitol at Albany, N. Y., and have installed a central power station at Kalamazoo, Mich., consisting of a 60 h. p. generator and 80 h. p. in motors.

The Hart and Hegeman Manufacturing Company, of Hartford, Conn., have recently become incorporated with a paid-up capital of $21,000. Mr. G. W. Hart is president, Mr. G S. Hegeman, vice-president, and Mr. A. H. Pease has been appointed treasurer. Mr. Pease is a new-comer to the company, but is well known in Hartford and vicinity as a bright and pushing business man, and he will form a valuable acquisition to the company. They will continue to manufacture the Hart switches in all sizes up to 100 amperes, and it is gratifying to learn that their business has largely increased and prospered since they came to the East to manufacture.

The American Circular Loom Comhany, of Boston, manufacturers of the well-known "canvas jacket" insulation, have a neat little folder descriptive of their new flexible conduit, designed for the interior wiring of buildings, one of which every electrical engineer ought to possess. This conduit can be supplied on reels in any lengths, does not require any jointing, and owing to its flexibility can be easily fitted to any existing irregularity of surface. It is well worth a careful inspection, and will be found to save a great deal of time and labor in the "conduiting" of buildings.

Mr. George E. Claflin, of the Franklin Electric Company, of Kansas City, Mo., was in the city this week renewing many old friendships, and looking after the interests of his company in the East.

NEW YORK NOTES.

Otis Bros. & Co., the well-known manufacturers of passenger and freight elevators, have just completed a somewhat novel piece of work for the new cable road in this city. The car-house at 129 3d avenue has been equipped with a very large elevator to be used in raising the cars from the tracks to the 1st and 2d floors. The dimensions of the elevator platform are 44 ft. 10 in. x 10 ft. with a capacity of 30,000 lbs. Otis Bros. & Co. are making a specialty of electric elevator installations.

Buffalo, N. Y.—The specifications for the new building of J. N. Adam, of Buffalo, N. Y., call specially for the installation of 90 Ward arc lamps. The electrical equipment will be a very large incandescent plant. When complete this will be the largest and best lighted drygoods house in the city of Buffalo. The Electric Construction and Supply Co. have lately been receiving a large number of Ward lamp orders since the beginning of the year.

The Engineering Equipment Company, of this city, have fected arrangements with the Syracuse Tube Co. whereby t are to control the entire sales in the Atlantic Seaboard State their "tubular" or pipe poles for street railway use. The fa ties of the factories have been increased at least double th former capacity, thus ensuring the prompt filling of all orders.

Mr. H. D. Emerson, of the Creaghead Engineering Co., C cinnati, was in town last week. He reports that the comp has more engineering work on hand than it can attend to.

Prof. J. P. Barrett, chief of the Department of Electricit of the World's Columbian Exposition, spent a few days in the last week. His visit was entirely of a personal nature.

☞ ***Departmental items of Electric Light, Elec. Railways, Electric Power, Telegraph, Teleph New Hotels, New Buildings, Apparatus Wan Miscellaneous, etc., will be found in the adverti pages.***

THE
Electrical Engineer.

Vol. XIII. JANUARY 20, 1892. No. 194.

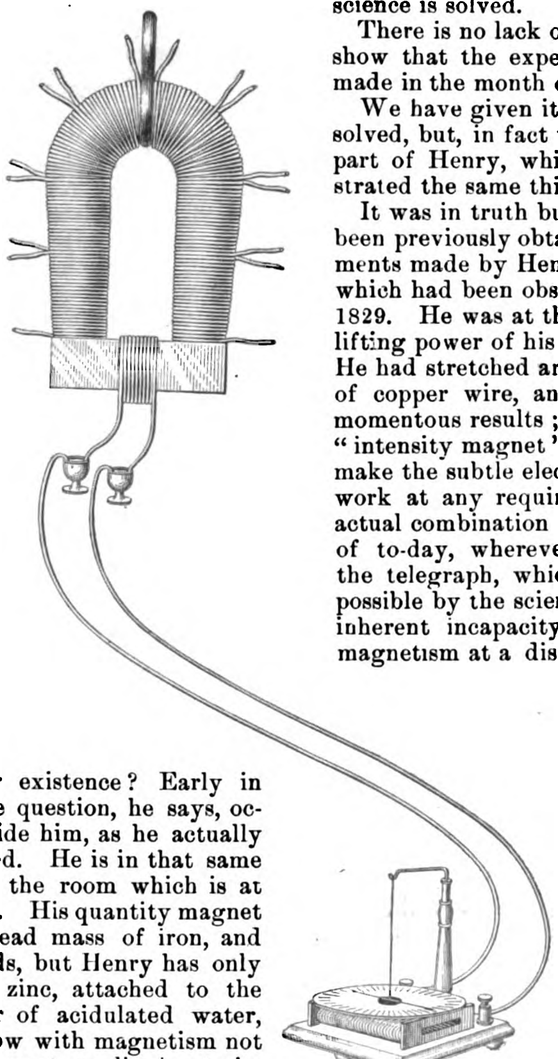
AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—II.

BY

Mary A. Henry

LET us now return to the great discovery which is the subject of our story. The permanent artificial steel magnet, up to this time the sole instrumentality available for interrogating Nature in regard to the point in question, is, as we know, always a magnet. Steel once endowed with magnetism, retains it, at least in some degree, forever, but soft iron has no such capacity. The electromagnet of soft iron remains a magnet only so long as the electric current traverses the wire encircling its core. The electric current is its vital principle; when this ceases its magnetism dies. Springing to intense life in an instant; as quickly losing almost every vestige of energy, these magnets of Henry, not only by their enormous power, by their ready capacity for instant change, were well calculated to betray the great secret which Nature had hitherto so jealously hidden from philosophic eyes.

If electricity can produce magnetism, may not magnetism produce electricity? Surely this was but a natural question for Henry to ask. He had compelled electricity to endow his magnets with their great force; could he do the reverse —compel these, his wonderful children, to produce the electricity to which they owed their existence? Early in the making of the magnets the question, he says, occurred to him. Let us stand beside him, as he actually asks the question and is answered. He is in that same room in the Albany Academy; the room which is at his disposal only during vacation. His quantity magnet stands there in its frame. A dead mass of iron, and copper and wood, it is as it stands, but Henry has only to dip the plates of copper and zinc, attached to the ends of its wires, into a tumbler of acidulated water, and the electric current will endow with magnetism not only the iron horseshoe but the armature clinging to its poles. Around the middle of this armature, Henry winds a thin copper wire, the ends of which he connects with the coil of a galvanometer, forty feet away. Now if this magnet can produce electricity it will, when awakened to life, produce electricity in this wire, and the sensitive galvanometer will betray its presence; *its needle will swerve.* He holds the metal plates suspended over the tumbler; his assistant intently watches the distant needle. What a moment of interest, as he stands there ready to ask the momentous question! He was of an especially reverent nature; he was accustomed at such times to pause a moment and say to himself: "I am about to ask a question of God." The plates are dropped into the tumbler; the electric current begins—the magnet is instinct with living power, and it *does* produce electricity in the wire around its armature, for see—*the needle of the galvanometer swerves.* The question is answered *Magnetism can produce electricity*, but—most important but—only at the instant of the making and breaking of its galvanic circuit. The gnome has at last been caught at work; the great problem of electrical science is solved.



Arrangement of Apparatus in Henry's Crucial Experiment of August, 1830, in which Electricity was First Produced from Magnetism.

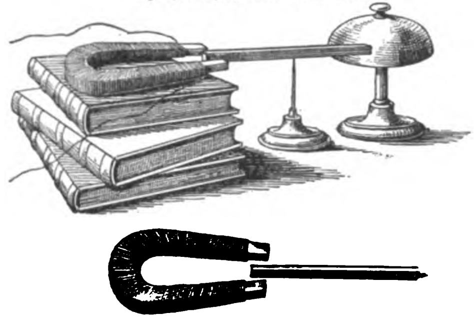
There is no lack of evidence, as we shall hereafter see, to show that the experiment we have described was actually made in the month of August, 1830.

We have given it as the one by which the problem was solved, but, in fact this was not the first experiment on the part of Henry, which, when properly interpreted, demonstrated the same thing.

It was in truth but a logical sequence of results which had been previously obtained. It occurred in a series of experiments made by Henry to investigate a curious phenomenon which had been observed by him a year earlier, in August, 1829. He was at that time, in this very room, testing the lifting power of his magnets with different lengths of wire. He had stretched around its bare walls, one-fifth of a mile of copper wire, and had made a discovery fraught with momentous results; the discovery that by connecting his "intensity magnet" with an "intensity battery," he could make the subtle electric force effective to do mechanical work at any required distance. He had in fact made the actual combination which constitutes the electric telegraph of to-day, wherever found and under whatever name; the telegraph, which had been hitherto pronounced impossible by the scientific world, by reason of the seemingly inherent incapacity of the electric current to generate magnetism at a distance. He made his magnet, excited by the intensity battery through that long wire around the room; ring a little bell to announce that the electric telegraph was an accomplished fact; and then the time came, when as usual, he was compelled to give up the room. Many times, during the busy years that followed, Henry rang his little bell, by means of the electric current, for the edification of the Academy students. He was deeply interested in the experiments which led to this important result, but in the course of them a brilliant and unexpected *spark* had flashed under his eyes from a break in the circuit of a long coiled wire, with which he had united the opposite poles of his battery. Nature, like a coy maiden, had lifted her veil for a moment to lure him in a different direction, and so it happened that when vacation came round again in August, 1830, he had taken up the investigation of this new phenomenon, which he called "electrical self-induction in a long helical wire connecting the poles of a galvanic battery." [13]

It was in the prosecution of this new series of researches that Henry obtained, as we have related, the phenomenon of magnetic electricity. From the self-induced currents in his long coiled wire to the production of electricity by his magnet, was only a natural and logical step. Henry, from the first, had considered the two phenomena as manifestations of one and the same principle, and later referred to them as such, in his paper on the subject in Silliman's *Journal*. The world of science has of late years come to the same conclusion. In view of this fact, we may say that the discovery of magneto-electricity was really made by Henry in 1829, when he first obtained sparks from the inductive action of the extra current.

Copyright in *The Century Magazine*, April, 1888, by The Century Co.



Henry's Demonstration of the Principle of the Electro-Magnetic Telegraph, 1829.

Many other important results were obtained, which cannot be enumerated here, but the inexorable first of September came all too quickly; the academic year of treadmill work; of drilling noisy boys from the rising until the setting of the sun—almost literally, since one of his classes assembled at six in the morning. And so we come down to August, 1831—the August we have dwelt upon so persistently, and very interesting it is now to see what Henry was doing, when Faraday, far away across the sea, is about to enter upon his great work. Spurred to enthusiasm by the brilliant results of the labors of the past year, Henry, to use his own words, is "making preparation for an exhaustive series of experiments upon the identity of electricity and magnetism," and is constructing for the purpose a still larger magnet. But he is not only making this larger magnet, he has constructed a great "reel" wound with a mile of wire. With the magnet we saw him using, and the wire around its armature, he had been able to move a needle forty feet away. What is he doing with this larger magnet and this great reel of a mile of wire? He is making an instrument capable of powerful work. Now look at the picture of a modern "dynamo." What is its essential feature? A reel, wound closely with wire, made to revolve within the influence of a great magnet.

We do not know in what way Henry intended to revolve his reel within the influence of his magnet, but this does not matter. What he is doing in these August days of 1831, is literally *making a dynamo*, in the modern acceptation of the term. Surely, it was not too much to say that Henry was already almost lost to sight in this particular path in which Faraday is only just about to enter. But the first of September came too soon for the completion of his preparations. His room must be given up, as usual, for the ordinary requirements of the Academy.

The great magnet must remain unfinished, and all experiments must cease, not to be resumed until the last two weeks of June, 1832. A glimpse we have of the unfinished magnet standing in Henry's room, in a letter, yellow with age, written by him to Prof. Cleveland, under date Albany, November 6, 1831:

> I have lately had forged a large horseshoe weighing 101 lbs. which I intend fitting up for some contemplated experiments in the identity of electricity and magnetism. It will be more powerful than any heretofore made, being almost double the weight of the Yale College magnet (59½ lbs).

Prof. Silliman hears of the new magnet and writes March 5, 1832, from New Haven to Henry:

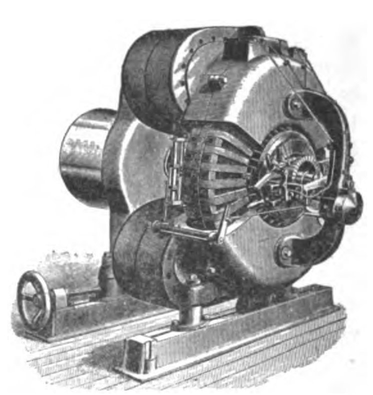
> "I have been told that you have constructed a larger galvanic magnet than those of which notices have been published. I write to inquire if there is anything that you would like to have published in the *American Journal* for April, as to any extension or new application of your discovery. I am informed that you have applied it to the separation of fragments of magnetic iron from the mixtures of other things." [14]

And Henry in his reply of March 28th, 1832, says:

> "In answer to your inquiries as to my further experiments in magnetism, I have little definite to communicate at the present time. I have not entirely abandoned the subject, but have been prevented by circumstances from prosecuting a series of experiments, which were commenced on a very extensive plan. I had partially finished a magnet much larger than any before made, and have constructed a kind of reel on which more than a mile of copper wire was wound. I was obliged to abandon the experiments on account of the room in which my apparatus was erected being wanted for the use of the Academy, and it has not been convenient to me to resume them during the winter."

Other yellow letters tell of the varied occupations of Henry's busy life, which allowed no place for the intensely interesting researches, commenced on so grand a scale and interrupted so opportunely. They were, as we have said, resumed in the latter part of the following June. What was it that set Henry at work at that time? A paragraph in a periodical, announcing that Faraday too had made the great discovery that magnetism could produce electricity. The notice was brief; it showed that electricity in one wire might be made to generate electricity by induction in another wire, and it gave this experiment:

> "In a coil of wire a permanent magnet was inserted, and Faraday found that electricity was produced in the wire when the magnet was inserted in the coil, and when it was withdrawn."



A Modern Dynamo Electric Machine.

Was this the experiment; the one by means of which Faraday made the discovery? We shall see. It should be remembered that this notice conveyed to Henry all the knowledge he had of Faraday's efforts. It impressed upon him the immediate importance of publishing his own results. Although the notice of Faraday's experiment had been published in April, it did not come under Henry's eyes until the following June. He thereupon immediately set to work; repeated the experiments mentioned in the notice, added some others of his own, and hastily prepared a paper for the July number of *Silliman's Journal*, giving—a fact much to be regretted—only a few of the many interesting and important results he had obtained.

---

[13] This constitutes the discovery of the extra current made by Henry in 1829, by Faraday in the summer of 1831. M. A. H.

[14] It is a matter of more than casual interest, that this, the earliest industrial application of Henry's electromagnet, should have been the means of directly bringing about the rotary electric motor, as we have it to-day. It was at the Penfield Iron Works, near Crown Point, Lake Champlain, N. Y., and the village at that place still bears the name Port Henry, given to it at that time in honor of the philosopher. In The Electrical Engineer of Jan. 7, 1891, the story of the visit of the Vermont blacksmith, Thomas Davenport, to the Penfield Works, and how he was led to purchase the Henry magnet and to employ it in the construction of an electric motor, has been graphically told by Franklin L. Pope. It is worthy of note, also, that the separation of the constituents of pulverized iron ore by means of magnetism, has within the last year or two attracted great attention, and seems likely to become of vast industrial importance. [Editor.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—II.

BY

Francis B. Crocker and S. S. Wheeler.

Chap. II.—Continued.

The Various Kinds of Circuits on which dynamos and motors are commonly used, and the best type of machine in each case, is as follows:

CONSTANT POTENTIAL.

(*Circuits on which potential or voltage is kept constant, machines, lamps, etc., run in parallel.*)

Circuits intended for—	Potential.	Dynamo should be—	Motor should be—
Incandescent lighting.......	110 volts (2-wire sys.) 220 volts (3-wire sys.)	Plain shunt or compound wound.	Plain shunt wound.
Electric railway. Power circuits....	500 volts.	Plain shunt or compound wound.	Series wound for railway. Shunt wound for stationary.

CONSTANT CURRENT.

(*Circuits on which current or amperes are kept constant, machines, lamps, etc., run in series.*)

Circuits intended for—	Current in Amperes.	Dynamo should be—	Motor should be—
Arc lighting.... Power circuits..	6.8 9.5 or 18	Series wound with current regulator.	Series wound with speed regulator.

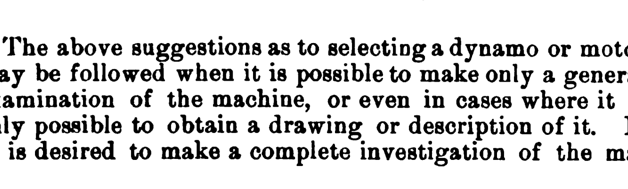


Fig. 1.—Base Frame.

The above suggestions as to selecting a dynamo or motor may be followed when it is possible to make only a general examination of the machine, or even in cases where it is only possible to obtain a drawing or description of it. If it is desired to make a complete investigation of the machine, it is, of course, necessary to make a thorough test and measure exactly its various constants. This can be done as completely as may be required by following the Directions for Testing, which are given in another chapter.

A satisfactory test cannot usually be made, however, until after the machine is set up in place; and, moreover, it is not generally necessary if the machine is obtained from a reputable source.

Chap. III.

DIRECTIONS FOR INSTALLING DYNAMOS AND MOTORS.

Setting up.—The place selected for a dynamo or motor should be dry, clean, cool, away from all pipes if possible, where the machine is in plain sight and is easily accessible and taken care of. Avoid particularly any dusty, wet or hot location. Any place near which grinding, filing, turning or similar work is likely to be done, is very undesirable for a dynamo or motor, as the dust and chips produced are liable to injure the bearings, commutator and insulation of the machine. A firm and level foundation should be provided in any case, and larger machines of 20 h. p. or more should be set on solid stone, brick or timber foundations. It is well, particularly in the case of high-voltage machines, to have them placed upon an insulating base-frame of wood, the pores of which should be filled with paraffine or well varnished to keep out moisture. If a wooden belt-tightening base is used this will answer the purpose, but if iron tracks are used they should be placed on a wooden base-frame. Fig. 1.

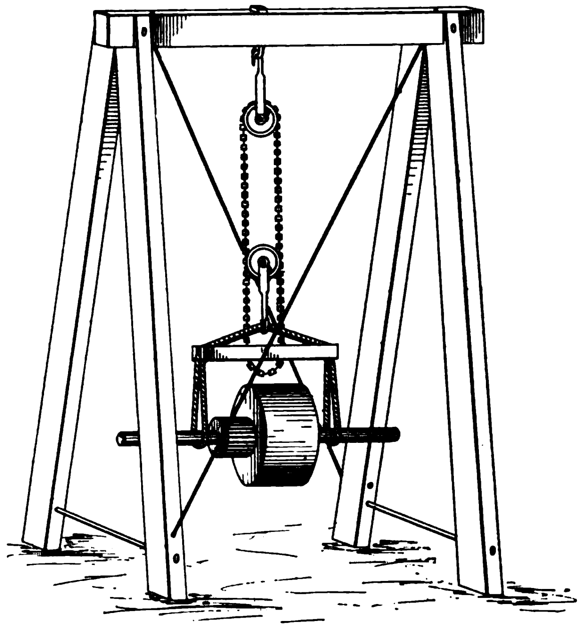

Fig. 2.—Sling for Handling Armature.

In unpacking and putting the machines together the greatest possible care should be used in *avoiding the least injury to any part*, in *scrupulously cleaning each part* and in *putting the parts together in exactly the right way.* This care is particularly important with regard to the shaft, bearings, magnetic joints and electrical connections from which every particle of grit, dust, chips of metal, &c., should be removed. It is very desirable to have machinery put together by a person thoroughly familiar with its construction, and in the absence of such a person no one should attempt it without at least a drawing or photograph of the complete machine as a guide. An exception may be made to this rule if the machine is very simple and the way to put it together is perfectly obvious, but in no event should the installation or management of machinery be left to guess-work. The armature should be handled with the greatest possible care in order to avoid injury to the wires and their insulation, as well as to the commutator and shaft. Handle and support the armature as far as possible by the shaft and avoid any strain on the armature body or commutator. If it is necessary to lay the armature on the ground, interpose a pad of cloth, but it is much better to rest the shaft on two wooden horses or other supports. A convenient form of sling for handling armatures is shown in Fig. 2.

Pulleys.—A dynamo or motor is usually furnished by the maker with a pulley suited to it. In the case of a dynamo, do not use a smaller pulley, and with a motor do not use a larger one without consulting a competent electrical engineer. The size of pulley required on the other machine or counter-shaft to which the given machine is to be connected is found by multiplying the revolutions per minute of the dynamo or motor by the diameter of its pulley expressed in inches and dividing by the revolutions per minute required of the other shaft, which gives diameter of pulley in inches. The proper speed for a dynamo or motor should always be obtained from its manufacturers, and this speed should not be departed from without their approval. A simple rule for determining the sizes and speeds in any belt or gear transmission is that the speed of one pulley or gear wheel multiplied by its diameter must be equal to the speed of the other multiplied by its diameter. An allowance should be made of one or two per cent. loss of speed in the driven pulley owing to the slip of the belt. In fact, the usual result is that the speed actually obtained in practice is less than is expected and this often makes a change of pulleys necessary.

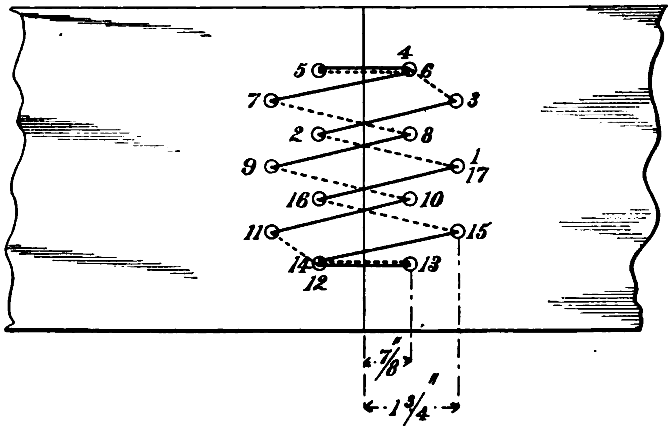

FIG. 3.—METHOD OF LACING A BELT.

Belting.—The kind of belting selected is somewhat a matter of taste but "light double" leather belting is applicable to most cases and is generally satisfactory. The width of belting is usually made about half an inch less than the face of the pulley on the dynamo or motor. The common rule for determining width of belt is that "single" belt will transmit 1 h. p. for each inch in width at a speed of 1,000 feet per minute. If the speed is greater or less, the power is correspondingly increased or decreased.

This is based upon the condition that the belt is in contact with the pulley around half its circumference or 180°. If the arc of contact is less than half a circle the power transmitted is less, as shown in the accompanying table:

Arc of contact of belt.	Fraction of circle.	Power transmitted, *C*.
180°	½	1.00
157½	7/16	.92
135	3/8	.84
112½	5/16	.76
90	¼	.64

The complete formula is, therefore, $\text{H. P.} = \frac{w \times s \times c}{1000}$

that is, the horse-power transmitted by a belt is equal to the width of belt in inches (w) multiplied by the speed of belt in feet per minute (s) and by the figure depending upon the arc of contact (c) and divided by 1000. For example, a belt six inches wide traveling at 1,500 feet per minute and touching three-eighths of the circumference of the pulley will transmit:

$$\frac{6 \times 1500 \times .84}{1000} = \frac{7560}{1000} = 7.56 \text{ h. p.}$$

"Double" belting is expected to transmit twice and "light double" one and one-half times as much power as "single" belting.

The smooth side of a belt should be run against the pulley as it transmits more power and wears better. An endless belt should be used for dynamos and motors since they usually run at high speeds. If an endless belt is not used, the joint should be very carefully laced so as to make it as straight and smooth as possible. In lacing belts, two rows of oval holes should be made with a punch as indicated in the diagram, Fig. 3. The nearest hole should be three-quarters inch from the side, and the first row seven-eighths inch from the end, and the second row 1¾ inch from the end of the belt. In large belts these distances should be a little greater. A regular belt lacing (a strong, pliable strip of leather) should be used, beginning in the middle holes and being careful to have lacing straight on the side next to the pulley, the diagonal parts being on the other side. A six-inch belt should have seven holes on each part; other widths in proportion. Be very careful to measure correctly the length of belt required, as it is very awkward to have it too short or even too long if it be an endless belt. If the machine has a belt tightener, measure for belt when position of tightener makes belt the *shortest* in order to allow for stretch, which is considerable in some belts.

Avoid short or vertical belts as they are much more apt to slip than long or horizontal ones. If it is absolutely necessary to connect pulleys at different levels, make the belt as nearly horizontal as possible. The distance between the centres of two belt-connected pulleys should be at least three times the diameter of the larger pulley, and it may well be four times if the space permits.

Make belt just tight enough to avoid slipping without straining the shaft or bearings. A new belt will not carry as much power as one which has been properly used for a few months.

The dynamo or motor shaft and the shaft to which it is to be belted should be placed exactly parallel and the centres of the two pulleys should be exactly opposite each other in a straight line perpendicular to the shafts. The machine should then be turned slowly by hand to see if the belt tends to run to one side of pulley, in which case the machine should be slightly moved until the belt runs in the middle of the pulleys and does not tend to work to one side.

PRIMARY BATTERY LIGHTING.

THE subject of lighting a small private house with a primary battery is treated in *Cosmos* by M. de Contades in a somewhat novel way, illustrated in detail. The writer describes, apparently from an existing installation, an arrangement for charging secondary batteries from two large sulphate of copper cells with an automatic switch for cutting the secondaries into series. These light 10 lamps, each of .5 ampere, at 50 volts, for seven hours a day. The capacity of the charging cell, working for the other 17 hours, is 1,020 ampere-hours.

BERLINER "ELECTRODES."

BY

John A. Barrett,

Having just received, amongst others, a copy of the patent of Mr. Chas. Cuttriss, No. 464,959, for a telephone transmitter, *sans* "electrodes," my attention is attracted to the scope of his first claim and its relations to certain early forms of transmitters.

The matter seems to be the more worthy of remark, since such a type of instrument has been editorially noticed as a possible circumvention of the Berliner "electrode" patent, and has been otherwise discussed in various superficial aspects.

On page 144 of the 1890 edition of Prescott on the Electric Telephone, in a chapter devoted to Edison's Telephonic inventions of 1877, is introduced a section on "Short-Circuiting Telephones;" and on page 145, Fig. 100, is given an illustration of a transmitter with the following description:

"Still another form of short-circuiting telephone is shown in Fig. 100 (devised Nov. 1, 1887). A spiral spring, 'w,' is wrapped around a cylinder, the diaphragm pressing against the last turn, so that, in vibrating, the convolutions approach or recede from each other. A very slight motion of the diaphragm is sufficient to cause the first few coils to come together; and, in general, the number of coils that thus touch each other is dependent upon the amplitude of the diaphragm's motion. The wire is included in the primary circuit of an induction coil, so that the resistance of the circuit fluctuates as the diaphragm vibrates. This wire has also been used as the primary of the induction coil itself with better results."

The first claim of the present patent is as follows:

"In a telephonic transmitter the combination with a diaphragm of a resilient conducting strip included in the circuit by the connection of its two ends to the diaphragm and stationary terminal support respectively; the said strip being bent or wound upon itself spirally in such a manner that by the vibrations of the diaphragm its convolutions will be closed upon themselves and to a greater or less extent in accordance with the amplitude of such vibrations as set forth."

As to the claims in which the short-circuiting spiral is specified as of carbon material; on page 144 of the same work, Fig. 97, is shown a "short-circuiting" transmitter, in which a metal lever attached to a diaphragm and acting in connection with a strip of carbonized silk, which forms a part of the transmitter circuit, in the course of its vibration cuts out of the circuit parts of the carbon strip.

The definition of those claims, based upon the limitation of the short-circuiting spiral to carbon as a material, would probably raise some nice legal points as to the degree of invention involved in the combination of the material of one instrument and the mechanical arrangement of the other; the material in question performing radically the same electrical functions in both forms.

Aside from questions such as these, as to the scope and validity of the Cuttriss patent, questions which may, perhaps, be regarded as mainly personal to those interested in this particular patent, there is a broader field of inquiry opened in this connection, in which lie the roots of the whole telephone transmitter problem.

What are Electrodes in a Microphone Transmitter? And what unquestionable distinction with respect to the radical function of the Variable Resistance may be set up between the electrodes of the Berliner and the absolute continuity of the short circuiting or Cuttriss type?

I shall not attempt to lead to any undebatable conclusion with respect to these questions; but I propose to show that the apparent distinction of types may possibly be superficial merely, and that there is room for an argument which might bring back the Cuttriss departure into the fold as a true "Electrode" Transmitter within the reach of the Berliner patent.

With regard to the term "electrode," as employed in the Berliner patent, it is always dangerous to use a technical term descriptively outside the scope of its conventional significance; not so dangerous, perhaps, to the one who first so employs it, as to those who come after him.

In the present instance the term electrode in its technical sense conveys decisively the idea of the separation, or at least the separability of the two terminals of a metallic electrical circuit. Strictly, there are usually understood to be two electrodes, which are the ends respectively of the metallic portion of an electric circuit, and their separability in service is a functional condition of their existence as electrodes.

A provision for establishing an uninterrupted mutual contact between the two terminal portions—or bodies, if they are so represented—for the purpose of enabling them to accomplish an object, which in a separated or separable condition they could not accomplish, terminates for the time and purpose their function as electrodes.

Electrodes in constant contact with each other are technically an anomaly.

But a special appropriation of the term has been made in Berliner's patent to a matter not within its strict technical acceptance, and a sufficiently intelligible definition for the purposes of the patent is given in the specifications of the patent itself, so that in all discussion of Berliner's patent and its relation to other patents, the term electrodes must be divested of its technical sense, and employed simply to designate those parts of the transmitter, to which Berliner has applied it in his specifications. It is emphatically important not to allow the term in itself to convey any significance of the essential form, arrangement, or offices, of those parts, but to be merely a symbol of reference to the drawings and specifications. The radical function and the principle of action of the parts marked electrodes must be determined by an examination of the entire patent, in connection with certain accepted propositions with regard to the subject at large.

Broadly speaking the parts—those specially designated as electrodes—are certain metallic elements, between the several portions of which a constant contact is maintained. This contact is specifically stated to be constant; that is, continuous and never to be interrupted by the normal service of the transmitter, and means are provided for preserving this contact unbroken within the limits of such sonorous vibrations as the instrument is adapted to.

It is upon this very point of the absolute continuity of the electric circuit through the transmitter system that the courts have shut out the Reis telephone from being held to be a genuine speech transmitter. Berliner states directly that any interruption of the circuit produces independent sounds foreign to the normal operation of the instrument. This is the distinction upon which Reis has been counted out, and it is upon this ground that Berliner expects to be supported for the full scope of his claims.

This, then, may be stated as an accepted theory of action of the speech transmitter, namely, that the circuit must be maintained permanently closed during normal use; a theory which has been generally confirmed by experts, adopted by the courts and accepted by the public.

It now becomes important to inquire in what way the parts designed for that purpose—the parts named electrodes by Berliner, and under that term described and illustrated and claimed by him—may be understood to perform their functions.

These functions are twofold, to wit, to cause the current occupying the circuit to fluctuate by the infinitesimal progressions constituting the undulatory curve, and at the same time always to maintain an unbroken continuity of the circuit.

Berliner says that when the pressure at the points of contact is varied it produces a variation of resistance and a corresponding variation in the current. The essential feature is the Point of Contact, which must offer a resistance to the current, but must not be entirely broken.

It is necessary to discuss this Point of Contact somewhat carefully, as herein is probably the essence of the whole question.

I do not suppose that a mathematical point can have any electrical conductivity, so that it is necessary to hold that the point of contact in its full meaning is more accurately an area of contact.

Now, an area of absolute contact between two portions of conductor has *per se* infinite conductivity and reciprocally no resistance, since it is a plane or series of planes, and, as a path to the current, has no length. In this respect it is identical with a hypothetical area of cross-section of a homogeneous conductor.

But if the clean surfaces of two metallic bodies are brought lightly together so as to establish an electrically-conducting circuit between them, a considerable resistance, properly enough called *contact resistance*, is observable. It is probable that however lightly the surfaces may touch each other, a plurality of planes of absolute electrical contact are established of limited and indeterminate area. It should be carefully noted, nevertheless, that the contact resistance should evidently be referred to the length and cross-section of the paths along which the electrical current must converge through the conducting bodies towards the planes of contact. An increase of pressure between the two bodies by increasing the total area of the planes of contact makes the sum of the converging paths shorter and broader until a point may readily be reached when the contact resistance becomes inappreciable.

This conception of contact resistance and the method of its variability is probably useful and accurate in determining the principle of action of all microphonic transmitters from Reis to the latest improved "Hunning." It is obviously a principle comprehended within the Berliner claims; not to give it the greater distinction of being the sole fundamental principle to which those claims must be limited.

The second essential requirement of the variable resistance medium of the speech transmitter is that it should not interrupt the electrical circuit during normal service. In order to fulfil this requirement, if a variable contact is employed between the surfaces of two or more physically separable and individual conducting bodies, those individual bodies must be so attached to each other in fixed and absolute continuity of contact, that the normal operation of the instrument will not at at any time completely separate them. They must be so joined together electrically as to present a unified conducting organism for the purposes of the instrument. It is no longer consistent with their operative function of maintaining a continuous conductivity, to regard them as separable and individual pieces or bodies. Physically they may be separable into a plurality of parts; but functionally in the transmitter they are essentially inseparable and constitute a continuous electrical conductor as absolutely as if they were riveted or amalgamated or welded together.

It is reasonable to argue, therefore, that the so-called electrodes of Berliner are not, in fact, the surfaces respectively of a plurality of individual-conducting bodies acting against each other, but that the term is more broadly applicable to different portions of the surface of a continuous conductor brought into relations of mutual contact; both the continuity of the conductor and the variability of surface contact being stated as essential by Berliner.

It is possible to confirm such a position by other concurrent arguments, but as the purpose and limit of the present article were to raise a question and not to reach a judicial conclusion, it is unnecessary to diverge upon them.

In accordance with this theory of action, then, it may be held that Berliner's claims would surround any transmitter in which the continuity of the conductor is maintained, while the electrical resistance is increased through an elongation and constriction of the conducting path by the separation of short-circuiting areas of contact between mutually respective surfaces of portions of the resistance organism, and decreased by the reverse action.

It is consequently not to be confidently asserted that the spiral-spring continuous-conductor short-circuiting transmitter is a distinct type not infringing the Berliner claims.

THE EXPRESSION FOR THE WORK DONE BY MOTORS.

BY

Albert L. Arnet

In Mr. Thorburn Reid's formulæ for motors in The Electrical Engineer of Dec. 23, 1891, occurs this formula for the work done by the motor, a two-pole series machine:

$$W = C e \qquad (4)$$

where W is the work available at the motor pulley; C the current strength, and e the counter E. M. F.

Now supposing the motor to be supplied with current from a source of constant E. M. F., E, the energy imparted to the motor is given by

$$W^1 = C E;$$

so that we have for the efficiency of the motor at a given speed the expression

$$\text{Efficiency} = \frac{C e}{C E} = \frac{e}{E};$$

or the efficiency is the ratio of the counter E. M. F. to the E. M. F. of the mains. This agrees with Prof. S. P. Thompson, Dynamo Electric Machinery, p. 521. It does not agree however with Kapp, Electrical Transmission of Energy, p. 186. For the work available at motor pulley Kapp gives the following expression:

$$W = (C - c)\, e$$

where C = the current strength,
c = the current required to run the motor at best speed without load,
e = counter E. M. F.

On the basis of this Kapp gives some tabulated results of experiments with a certain motor whose most economical speed was 1,010 revolutions. The resistance of armature and line was .2 ohm. To run the motor at 1,010 revolutions, unloaded, required 4 amperes of current. The E. M. F. of the mains is 100 volts.

One table is as follows:

No.	Speed.	e	C	Com. Effic.
1	1010	91	45	82.8
2	1065	96	20	76.7
3	944	85	75	80.0

The especial point of interest to me has been to reconcile these efficiencies with Joule's law. As yet I have not succeeded, and I offer this in the hope that some one will kindly explain the matter. In case (3) of the table above, the energy lost as heat $C^2 R = .2 \times 75^2 = 1125$ watts; while in (2) $C^2 R = .2 \times 20^2 = 80$ watts. Now Kapp tells us that in (3) the motor is more efficient than in (2), notwithstanding the fact that the amount of energy lost as heat in (3) is 14 times greater than in (2).

If I interpret correctly the formula of Mr. Reid, the efficiencies of the motor for the three cases cited should be respectively 91 per cent., 96 per cent., and 85 per cent. I am disposed to think that these values are nearer the truth than those in the table quoted from Kapp.

THE NEW TELEPHONE EXCHANGE FOR ATLANTA, GA.

THE telephone exchange of the Southern Bell Telephone Co. of this city, at Atlanta, Ga., now has nearly 1,300 subscribers on the Law system, and the business is in such excellent condition, with promise of increase, that the company has decided upon building a new exchange headquarters. In fact the work has already begun, ground having been broken for a fine edifice that is to be completed by the fall of 1892. Our illustration of the new exchange is made from an admirable engraving published by the *Atlanta Constitution* in a recent historical sketch of the local development of the telephone industry. The building will stand at the corner of Pryor and Mitchell streets, Atlanta, and will cost at least $70,000 exclusive of the land. It will be built of fine Georgia granite. No part of it will be rented, but it will be devoted wholly to the purposes of the company. The operating-room, or exchange proper, will be on the third floor, and the whole of the switchboard apparatus, etc., will be entirely new, provision being made for three or four thousand subscribers. The second floor will be occupied by Mr. John D. Easterlin, the district superintendent at Atlanta for a large section of country, while Manager W. T. Gentry will have the ground floor for his suite of offices. The basement will be devoted to material and supplies. The absence of a wire cupola on the roof, and of wire supports, is noticeable. The reason of their disappearance is that Mr. D. I. Carson, the secretary and general superintendent of the Southern Co., has made arrangements for placing all the wires underground, an ordinance to that effect having passed the city council. It is intimated that cement-lined pipe may be used for the conduits. A large sum of money is to be spent on this work. Mr. James A. Wotton, the electrician of the company, will have charge of a fine laboratory and repair shops, and of the electrical work in general. Altogether the new departure in Atlanta is one of importance, as the exchange is the first of its magnitude and completeness in the South. It is expected that the central office will be moved next December, when Atlanta will have a service worthy any city in the Union.

NEW ATLANTA TELEPHONE EXCHANGE.

A COMBINED ACCUMULATOR AND GAS BATTERY.

BY

F. A. LaRoche

THE escaping bubbles of gases from a storage cell during the operation of charging will attract the attention of the most casual observer, and no doubt cause speculation as to the amount of waste energy of which the elimination of these gases is significant. A long association with the construction and practical working of electrical accumulators, with their ever-escaping gases constantly in view, prompted a desire to utilize this waste. The ideal electrical accumulator would embrace among its features the return of all the energy expended in its charging. After much careful thought and many preliminary experiments with this end in view, the results to follow were noted. It is needless to wade through each successive step leading up to the final experiment, since all previous efforts culminate in the last. Therefore it is sufficient to commence with a discription of the completed cell.

This cell was a curiosity; the container was made of a section of wrought iron steam pipe 4 inches in diameter and six inches in length, with a cap screwed upon each end. The internal arrangement of the cell required much care and careful calculating—the plan of this cell was a combination of the Wollaston gas battery with the usual accumulator. Therefore it was necessary to have two separate compartments, one within the other, and the large one twice the capacity of the other. The smaller of the two compartments contained the + plate while the — plate was placed in the larger. The reason for this arrangement is as follows: Water, when a current of electricity is passed through it, is electrolyzed and its constituent gases eliminated upon the metal conductors at the point of contact with the water. Now water (H_2O) is composed of 2 volumes of hydrogen and 1 volume of oxygen. The oxygen is liberated at the positive pole; therefore this pole is placed in the smaller compartment. This precaution is necessary because it is essential to have equal pressure within the cell to maintain the acidulated water of the battery at a common level. The sides of the cell were protected from action of the battery liquid by an impervious coating. The small compartment was made by securing an inverted porous cup to the lid of the cell; this cup was partly coated with pitch, so that the portion above the level of the liquid was made impervious, while that portion opening beneath the liquid retained its porosity.

The battery plates were made of two small sheets of lead, each two inches square; these plates had been previously filled with litharge and carefully formed; their electrical capacity was accurately ascertained in the open before being closed in the cell. When everything was made ready the cell was closed and hermetically sealed. A pressure gauge was next fitted to the cell as a precautionary measure; also an escape cock. By this arrangement the escaping gases were kept separate and confined under pressure, oxygen within the porous cup, hydrogen outside in the larger compartment.

Wollaston proved that oxygen and hydrogen when separated by a partition, always enter into combination, and produce a current of electricity, provided the gases are in contact with one liquid conductor and that the gases and liquid are traversed by metallic conductors connecting only outside of the battery. This is the principle underlying the present experiment. It was hoped that by keeping the evolved gases under pressure, they would, to a large extent, be condensed and held either in solution or suspension within the battery fluid and thus be brought into more extensive contact with the metallic conductors. The result, it was reasoned, would be an increase of ampere capacity only, for the chemical affinity between oxygen and hydrogen is such, that, under the most favorable conditions, not more than two volts E. M. F. can be expected from their reaction. The combination of the gas battery supplied but the same chemical agents. The small battery plates used, gave on the test, two volts full, but no more. These facts went to confirm the belief that the only possible gain would be in quantity and that the voltage would remain unchanged.

Finally all arrangements were completed and with anxious expectancy the terminals were screwed fast in the binding-posts, and the current switched on.

A current of five amperes was used for charging the cell. Presently the index on the pressure gauge began to register, steadily the hand went around the dial until, after three hours had passed, the current was cut off and the gauge indicated 300 lbs. to the square inch.

The test of the cell was performed as follows: The terminals were connected with a small motor with an amperemeter in circuit; the voltmeter used in the previous test was connected across the terminals.

The most remarkable feature in the whole occurrence was the fact that the voltmeter persisted in registering a fraction over three volts. Contrary to all reasoning the unexpected had happened; nevertheless, the fact remained, because a calibrated instrument still registered with certainty the three volts and a trifle more. Several hypotheses have arisen to account for this, but without making any effort to explain the phenomenon, we will simply state the fact and go on with the remainder of the test as follows:

Time.	Volts.	Amperes.	Watts.
1 hour.	3	3.5	10.5
2 hours.	$2\frac{7}{10}$	3.2	8.64
2½ hours.	2	3.	6.

After 2½ hours' discharge, equivalent to 25.14 watts, the E. M. F. fell rapidly and the battery was then recharged for a second test. This varied a little but not materially from the figures given in the first test. In a later trial the pressure gauge ceased to register and the charging was continued until suddenly a flaw in the metal was developed, whereupon the contents of the cell were spurted across the room. With this disaster ended a series of remarkably interesting experiments.

THE VAN VLECK DISCONNECTIVE TRIPLE EXPANSION NON-CONDENSING ENGINE FOR CENTRAL STATIONS.

Note has already been made in these columns that the Edison Illuminating Company of this city in extending its present plants, and in the installation of its new ones particularly, had contemplated the adoption of large units embodying generators driven direct by multiple-expansion steam engines of the latest type. Where the loads on the station permit of the employment of large units the installation of dynamos direct connected permits of the highest economy, a fact which has so often been pointed out as to need no further comment at this time.

As a first step in this progressive movement, the company have within the last few weeks installed in their Twenty-sixth street station a 1,000 h. p. triple-expansion engine, designed by Mr. John Van Vleck, which, we believe, will attract more than ordinary attention in electrical engineering circles. Our engraving, Fig. 1, shows the engine as it now appears in the station; while Figs. 2 and 3 give respectively a detailed view of the side and end elevations.

This engine is probably the first large triple engine intended for direct connection to multipolar dynamos in any American central station, and it is interesting, both on this account and because it possesses several advantages that are of vital importance in a generating plant, in which economy and reliability are the most important factors.

The engine is of the three-crank inverted cylinder type, and will generate from 600 to 1,000 h. p. according to steam pressure, and only occupies about one-tenth of a square foot of floor space per horse power. The three cranks employed produce a very steady rotation of shaft which is very important in a direct-connected electrical generator.

The engine is designed to run non-condensing, which may surprise some American engineers who seem to associate a triple engine with a condenser, and who do not seem to agree with certain European engineers who claim that steam pressure above 160 or 180 pounds makes condensing undesirable, and under some conditions, even an expense. At present, however, this engine is being operated under a pressure of 125 pounds, and gives excellent results even when partially loaded, although it should be remembered that the high-load factor necessary to supply a district in New York with light and power will permit of running engines of this size up to their full capacity, and that they need rarely run on partial load.

The engine is furthermore interesting in that it is probably the first triple-expansion land engine ever set up, at least in this country, which possesses the feature that any of its three cylinders can be disconnected and thrown out of gear without preventing the engine from running; in fact, it can be run as a triple or compound, or even a single-cylinder engine, at will. The engine is, therefore, not one "unit" but three separate "units" combined, any one of which may be disconnected in case of trouble with any one of them. As far as we know, this principle has only been applied by one or two English engine builders in the construction of their tandem quadruple engines.

The general construction of the Van Vleck engine is such that it can be applied to a triple or quadruple engine of any size from 500 h. p. upwards, while this cannot be said of that class of engines having centrifugal automatic governors on their main shafts which cannot very well, with slow speed, control several large-size valves, which, to be tight, must take power to operate them. In this case the valves are "positive driven" by means of the Joy valve gear controlled by a hydraulic governor. In this way even the greatest amount of valve friction cannot in the least affect the speed of the engine.

All the regulating and valve gear is placed on the front of the engine, where it can all be seen and operated from

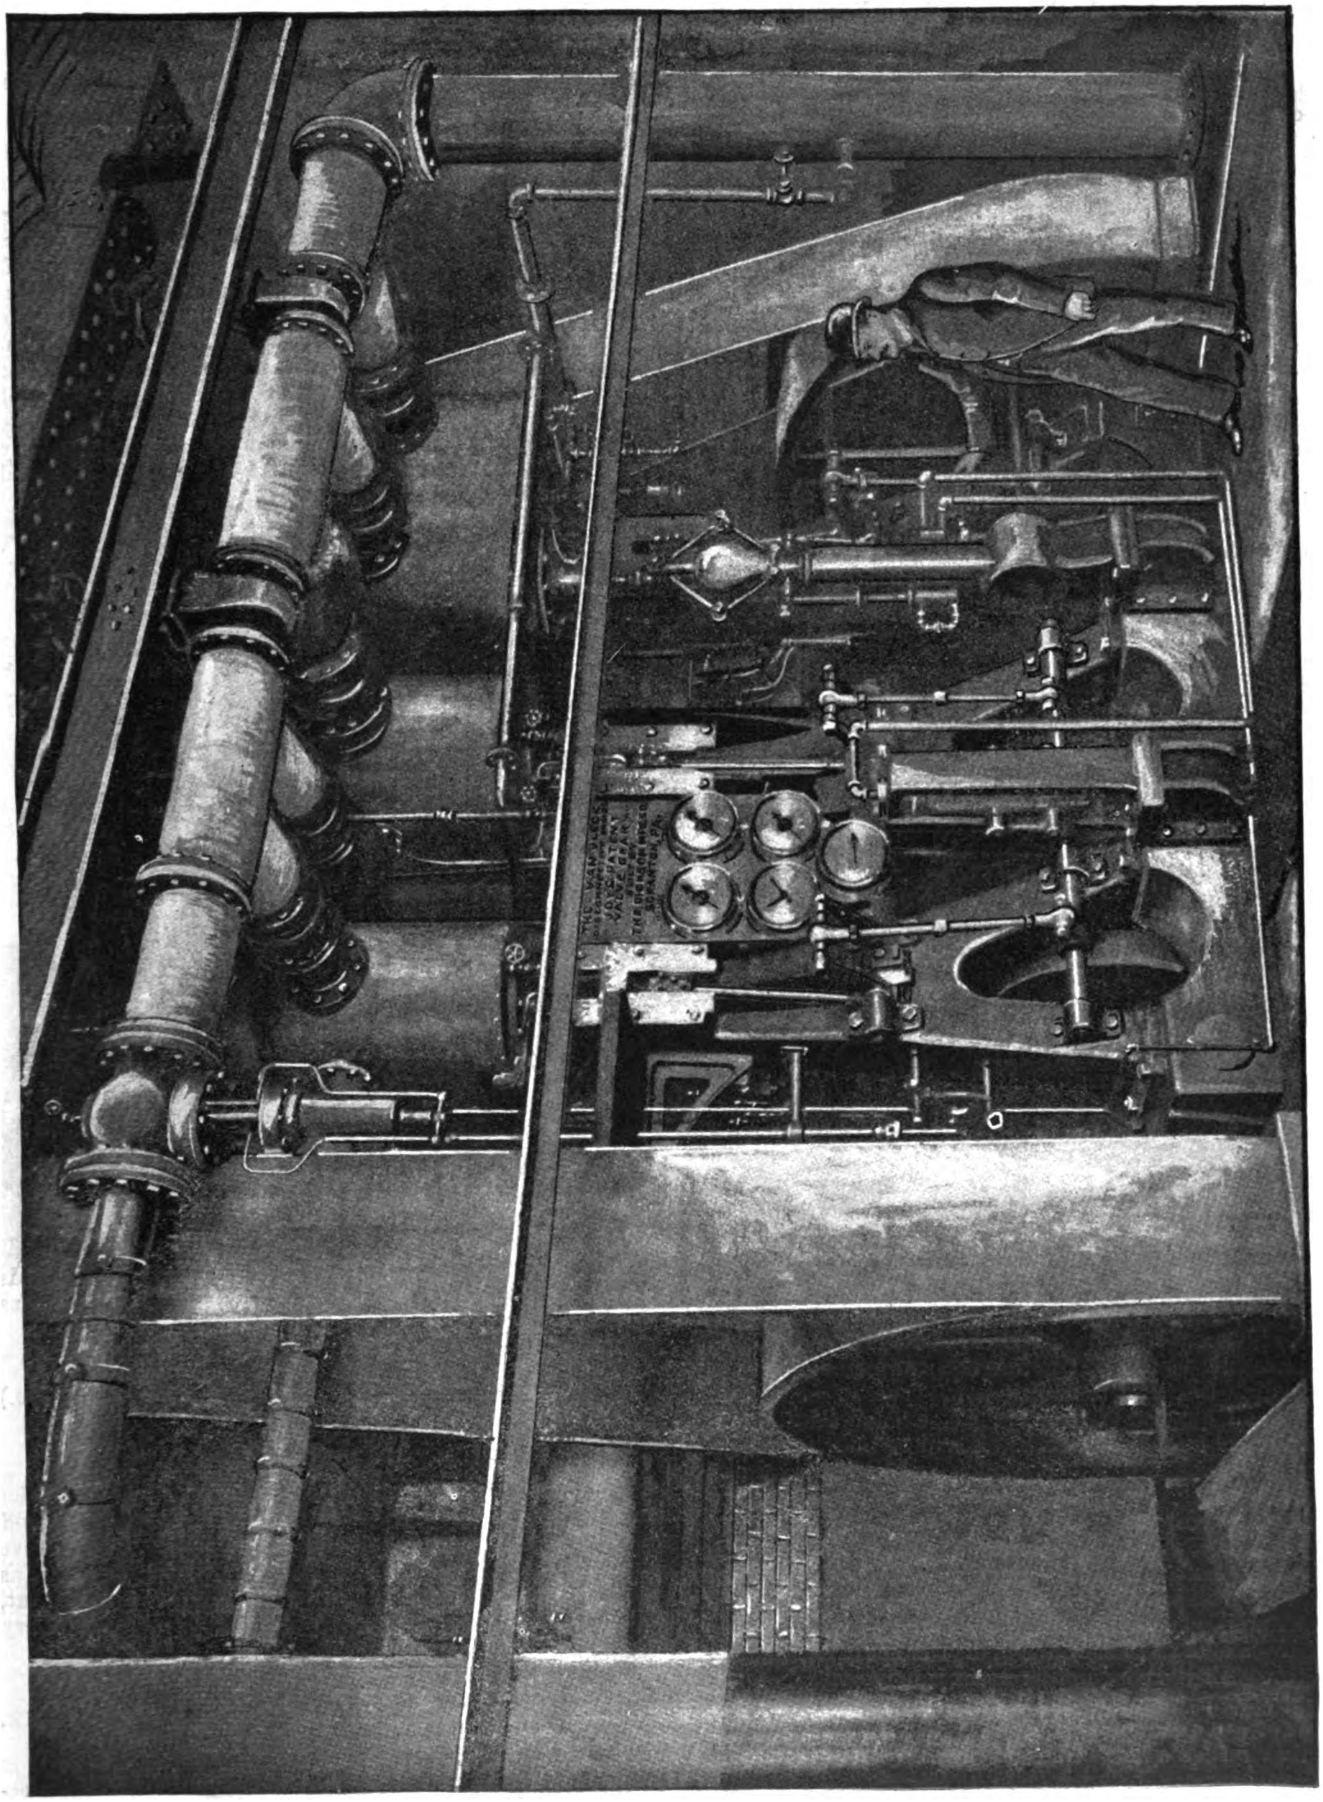

FIG. 1.—VAN VLECK DISCONNECTIVE TRIPLE EXPANSION NON-CONDENSING ENGINE FOR CENTRAL STATIONS.

the centre aisle through the station. The operating engineer need, therefore, but rarely go behind his engine or between the columns as in the case of the ordinary arrangement of triple engine with steam chests between the cylinders.

The point of cut-off is automatically controlled on all three cylinders, a feature, probably not possessed by any other triple engine. The exact point of cut-off in each cylinder is indicated on a dial attached to the "slipper guides," so that the engineer can always see just where his point of cut-off is. By means of a novel adjustment the point of cut-off on each cylinder can easily be altered while the engine is running, while the speed can also be changed without shutting down.

The general construction of the engine is thoroughly modern, and is on a par with the excellent work now being done on English and American war vessels. The engine has water-jacketed main bearings and slide surfaces, and its piston heads and piston covers are of the simple "coned" pattern and are made of cast steel.

The engine is the result of much study on the part of Mr. Van Vleck, who believes that he has developed in his new combination the best possible and most reliable land engine for this class of work. Much valuable assistance has been given him by such engineers as Messrs. S. F. Prest and David Joy, of London, while the designing of details has been mostly in the hands of Mr. W. J. Sargent, of Scranton, Pa.

The engine was built by the Dickson Mfg. Co., of Scranton, whose success in constructing this engine is greatly to their credit. We understand that this type of engine, in its triple and quadruple form, is to be energetically exploited for central station work. It will be built for steam pressures of from 200 to 300 pounds, and in its quadruple arrangement will, it is claimed, give a far greater economy than has heretofore been the attained practice.

In connection with this advanced type of engine it is gratifying to note that important steps have also been taken in the way of improving the ordinary American methods of steam piping and fittings. The entire system of piping furnishing steam to this engine is of the most substantial character. All the cast and wrought iron portions of the piping are much heavier than is usual, while the flexible copper parts of the pipe are banded with iron bands placed every five inches apart. This is probably the very first American copper pipe treated in this way, and we think that if such advanced practices as we have seen in this case could only become more common, then steam pressures of 200 pounds and over would be met with in every first-class stationary steam plant, where, with multiple-expansion engines, the high efficiencies now obtained at sea would be realized by the land engineer.

THE THEORY OF THE PERRET MAGNETIC FIELD.

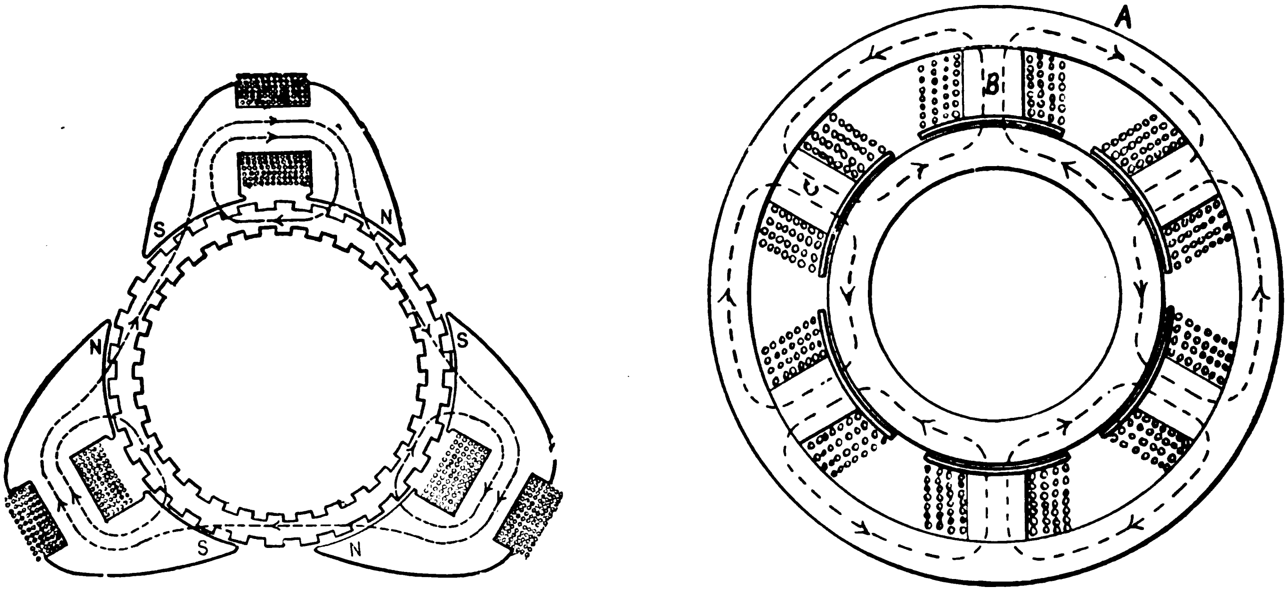
BY

H. R. Wellman

I CANNOT but think that there is a grave error in Mr. Perret's theory as to the advantage, in multipolar construction, of the magnetism entering and leaving the armature at several points in succession.

Taking the "Perret" type shown in Fig. 1, and assuming that the total flux *does* enter and leave the armature at six points successively, as shown by the continuous line of arrows, then, the three fields being in series, the whole number of lines is clearly the magnetic carrying capacity of each. Calling this M, the number of volts E generated per conductor for a given speed S, is

$$E = S\frac{M \times 10^{-8}}{60} \times 6 = S M 10^{-9} \qquad (1.)$$



FIGS. 1 AND 2.—THEORY OF THE PERRET MAGNETIC FIELD.

Taking the typical six-pole machine, Fig. 2, the fields being two in series, the magnetic capacity is 3 M, and as this is cut twice, we have,

$$E_1 = S\frac{3\ M \times 10^{-8}}{60} \times 2 = S\ M\ 10^{-9}, \qquad (2.)$$

which is identical with (1.)

Furthermore, if the poles are equidistant around the armature, surely not more than one-half of the lines would pass from the positive pole of one pair to the negative pole of the next, the remainder taking the other path, as shown by the short lines of arrows, which would prevent, to that extent, the machine operating upon the theory propounded.

ELECTRICAL UTILIZATION OF WATER POWER.

A PRIZE is offered by the Société des Eaux et de la Dranse, in Switzerland, for the best system for the electrical utilization of a fall of water. Particulars of the competition may be had from the Secretary of the Société des Ingénieurs Civils, of Paris.

VOL. XIII. NEW YORK, JANUARY 20, 1892. No. 194.

The end of the new philosophy is to subordinate the blind forces of nature to the uses of man; to mitigate the ills and multiply the joys of life.—Edward N. Dickerson.

HIGH-PRESSURE STEAM IN CENTRAL STATION WORK.

ELECTRICAL engineering has from the beginning been so intimately connected with steam engineering that it has in a certain sense come to be looked upon as part and parcel of it. Many of the failures which have been scored in electrical work have been due to lack of knowledge of the principles of steam engineering; while, on the other hand, the many successes scored have been the result, largely, of the application of correct steam engineering in connection with electrical work. Although the cardinal principles of central station practice are fairly well defined, the controversy which has been going on in our columns for some time past, as to the most economical size of power units, shows that on several details a considerable divergence of opinion may still be met with. While "Carleton" and Mr. William Lee Church agreed substantially on the size of this unit which they fixed at 500 h. p., they were not entirely agreed on the relative merits of the condensing and non-condensing engine. At the other extreme we find Mr. J. T. Henthorn, whose experience confirms him in the belief that the slow-speed Corliss compound engine, acting through counter-shafting, is capable of effecting the highest economy in central station work. To these varying practices may still be added another, a most striking example of which is that now described by us and which is illustrated in the Van Vleck disconnective triple-expansion non-condensing engine. Aside from the fact that this engine is probably the first of the triple-expansion type to go into an American central station, and intended ultimately for direct connection to multipolar machines, its most striking feature from the steam engineering standpoint consists in the fact that it is operated non-condensing. In adopting this method of operation, Mr. Van Vleck takes the same stand as that of a number of well-known European engineers who maintain that condensing is no longer economical when pressures as high as 160 or 180 pounds to the square inch are employed. It would take us too long to enter into a discussion of the many points, and to follow out in all its details the reasoning which leads to this conclusion, but it will be evident on but slight consideration that as the pressure is increased, the percentage of gain due to condensation becomes less and less, and finally a point is reached where the additional cost of the condensing apparatus, increase in size of engine and cost of maintenance, outbalance the gain due to the condensation. Mr. Van Vleck, being a thorough believer in the application of high-steam pressure, has designed his engine accordingly, and contemplates even the utilization of pressures as high as 200 or 300 pounds per square inch, at which pressures even quadruple expansion will become economical. The introduction of such high pressures, however, involves not only special design of engine parts, but necessarily entails a thorough considerations of the methods and apparatus for steam distribution. Among the latter, the subject of steam piping is one which much be considered as of the first importance. Experience has shown that the present style of steam fittings most generally employed in this country are totally inadequate and, in fact, unfit for use in connection with steam pressures as high as 200 pounds. This had been recognized by Mr. Van Vleck and is confirmed by experience abroad. Such pressures can be carried with perfect safety, but they require the most substantial work and a liberal use of metal to withstand the strain. The method of strengthening copper pipe, for instance, by the application of bands at short intervals is one among these improvements. Taken as a whole, the work inaugurated by Mr. Van Vleck adapting, as it were, the best marine engine practice to stationary land engines will not fail to arouse the interest of central station managers and will more than likely influence not a few in the adoption of high steam pressures for central station work. It is indeed strange that the employment of these pressures in locomotives and latterly in marine practice should be so tardily followed in stationary engine practice where all the conditions are most favorable to their successful use.

PORCELAIN INSULATORS FOR OVERHEAD LINES

THE appeal to porcelain manufacturers, made in our columns last week, by Mr. F. W. Jones, the electrician of the Postal Telegraph-Cable Co., touches a very important part of telegraph and telephone construction work. As Mr. Jones pointed out, although porcelain insulators are given the preference in Europe and are found to present three or four times the resistance to leakage that glass does, our companies continue to use glass, in spite of the great loss of efficiency in service. It would in fact be interesting to know just what becomes of the various classes of telegraph circuits under heavy conditions of rain and damp. Our own impression is that a seriously large proportion of them is "shut down" until fine weather comes around again, and that this is chiefly due to the poor character of the insulation at the poles. We doubt whether in this respect there is any material gain over the efficiency of twenty-five years ago.

Mr. Jones by his appeal to the porcelain manufacturers of America has assumed that with them rests the remedy, and that if they will give us porcelain insulators cheap enough and good enough, all will be well. On these points we have now been favored by Mr. C. H. L. Smith, of the Union Porcelain Works, of Brooklyn, with copies of a very interesting correspondence between himself and Mr. Jones, and the data thus submitted is important. Mr. Smith remarks in a letter to us, with great truth and pertinence, that the question of the most perfect insulation obtainable will before long be well recognized by those who use electric plants of any kind as one of the prime factors in reducing operating expenses, but he seems to fear that for the present the short-sighted policy will prevail of looking only at the first cost of the equipment. In one of his letters to Mr. Jones, he says but too truly: "The managers of European lines look at other points than the first cost of their insulators. Unfortunately in our country, in too many cases, quality is sacrificed to price, and the first, and sometimes the only, element that cuts any figure in transactions is, 'What is the price?' The glass telegraph insulator being much less costly than the porcelain, our electricians as a rule have very little option in the matter. They are compelled to work with such tools and equipment as the management provide for them." In other words, the tariff plays little part in the matter, and there is no need to consider importation, if the companies interested will only buy what they can already get. Has any determination been arrived at, we would ask, as to the exact point at which the loss of efficiency and business on our telegraph lines, from poor insulation, would be less or greater than the added outlay required for high-class insulators?

As to the porcelain itself, Mr. Smith is worth quoting:

> "The insulating properties of porcelain depend upon its quality. You are no doubt aware that there are many goods manufactured that have somewhat the general appearance of porcelain but in reality are not *true* porcelain. Such inferior goods do not make a good insulator but are quite deceptive in their appearance. True hard porcelain such as we manufacture is identical with the class of insulators used in Germany and France, and is a superior insulator to that used in England.
>
> "In regard to the glaze of true hard porcelain, it does not better the insulator one particle. The body of the true porcelain is as perfect an insulator as the glaze. The only objection to omitting the glaze is that the surface of the body becomes more quickly and readily soiled. We have thoroughly and carefully investigated this whole matter, and the only point that interferes with the general use of a porcelain telegraph insulator, which is an item only in first cost."

This last sentence is plainspoken, although it deserves to be borne in mind that the question of renewals comes in. We believe that about 6 per cent. of the Western Union insulators are renewed yearly. But here again, however, there might be an economy in a smaller percentage of renewals.

In another letter to Mr. Jones, objection is made by Mr. Smith that the former's requirements do not go quite far enough, and that

> "A high-grade porcelain insulator should be composed of simple earths only, both in body and glaze, and of the same material. No lead or other metallic oxides must enter the composition of either glaze or body. It must be absolutely vitreous and perfectly homogeneous. The body and glaze must be fused together at the highest porcelain heat, which is over 4,000 degrees Fah. It must be resistant to all influences of heat, cold, dampness, acid or alkali fluids or gases."

With the need so well recognized and with the ability to supply it so well manifested, there should be little delay on the part of porcelain manufacturers in this country in finding a new market in the telegraph field.

THE CENTRAL STATION AS A DISTRIBUTER OF ENERGY.

THE intelligent central station manager has long recognized that to obtain the greatest measure of success in his work, he must be prepared to furnish electrical energy in any form and practically for every purpose required. This has given rise to not a few composite stations in which side by side we find the low and the high tension, the direct and the alternating current employed for lighting and power purposes, and latterly for heating by the current. But there is still another method by which a central station may distribute energy in the form of heat. Probably more than nine-tenths of the present existing stations are so situated that the operation of condensing engines is impracticable, so that the steam as it leaves the cylinder is exhausted directly into the atmosphere. The latent heat contained in the steam thus thrown away forms by far the largest part of the energy originally imparted to it from the coal under the boilers, and if the central station manager can in the same way utilize this waste product, he is to that extent availing himself of his resources and as a result increasing his revenue. The utilization of this otherwise waste steam has recently been advocated in connection with electric central stations and appears to us to be one of the most promising fields open to electric light and power companies, provided, of course, the conditions, among which is the situation of the station, are such as to permit of the thing being done. As illustrating the facility with which such distribution can be carried out, we give in another column a description of the system designed for this purpose by the American District Steam Co., which embodies the experience obtained in the practice of a long period of time. As the system involves a distribution under a pressure of but a few pounds to the square inch, the question of danger and leakage involved in high steam pressure distribution does not here come into play, so that it remains merely a question of calculation as to the successful application of this system.

Another Object-Lesson in Car Heating.

ON the evening of January 8, the cars on a street railway at Scranton, Pa., were stalled. In expectancy of a long delay in reaching the car barn, five men, employees of the road, entered an empty car, stretched themselves on the seats, and slept. The heating device used upon the car kept them warm; and it also very nearly killed them. The fumes from the stove did the deadly work. Now it seems to us worth while to remark that the Burton Electric Company has worked incessantly the past season to correct the evil condition of things occasioned by the heating devices now used upon the street car lines in this country. It has placed its absolutely clean, safe and efficient electrical heaters upon 100 lines the past year.

THE VARLEY LOOP TEST.

BY

J. A. Jones

MR. FRANK L. POPE's 1891 edition of the "The Electric Telegraph," so admirably adapted to the wants of the electricians, managers and operators to whom it is addressed, in a few particulars has some shortcomings that detract from its value to the students less advanced. For the benefit of those interested I will call attention to "Varley's Loop Test," on page 203. The bridge, Fig. 1, is there shown with the $A\,B$ and $C\,B$ arms equal in resistance and the rule is given, on page 204, to subtract (2) (the resistance in $E\,A$ to balance) from (1) (the total resistance of loop) and divide the remainder by 2, which gives the resistance between the instruments and the fault.

This rule is correct only for measurements made with equal $A\,B$ and $C\,B$ arms. As there are a great number of submarine and underground wires in use at the present time it becomes necessary to employ methods of measurement that will give a closer approximation to the true position of the fault than by the foregoing method where it may not be arrived at closer than one unit of resistance, which, in the case of an underground cable, means about 400 feet of wire. It is obvious that such a test has but small value.

It is usual to make "Fault" tests with the arms of the bridge multipled. If an ordinary bridge is used, the range of which does not exceed 10,000 ohms then the arms $C\,B$ and $A\,B$, Fig. 2, are made 10, and 1,000, respectively; provided the loop does not exceed 100 ohms when the fault is near the point E. Having first ascertained the resistance of the loop, and of the wires between $C\,D$ and $A\,D$ when possible by test 346a on page 201, the Varley test is then made thus:

Assuming the figures in the diagram Fig. 2, between C and D, and A and D, to additively represent the resistances of the looped conductors it will be found that $R^3 = 7{,}475$ ohms, and R^1 the resistance from E to the fault = 25 ohms, — which is given by the following formula, where $a = 10$ ohms; $b = 1{,}000$ ohms; the loop $L = 100$ ohms; $R^3 = 7{,}475$ ohms; $R^1 = 25$ ohms.

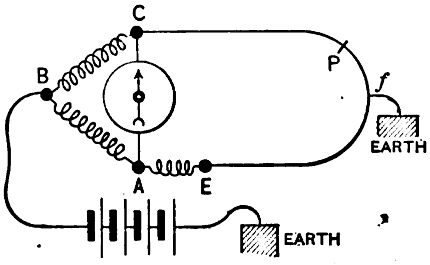

FIG. 1.

$$\frac{L\,b - a\,R^3}{a + b} = E \text{ to } x,$$

$$\textit{Example:}\ \frac{(100 \times 1000) - (7475 \times 10)}{10 + 1000} = 25 \text{ ohms.}$$

Should greater range of measurement be required a special bridge is necessary with higher resistance in the arm R^3, and the test made at the ends farthest from the fault. The above formula holds good with the arms $A\,B$ and $C\,B$ multiplied 10 to 100 or in any other ratio. With 10 to 100 the loop may be 1,000 ohms but the fault cannot be so closely located, as it may not be possible to bring the spot of light to zero by adjustment of the resistance R^3. In such a case Kempe's formula will be found valuable.

EXAMPLE: a and b being 10 and 1,000 ohms, respectively, $R^3 = 156$ ohms, gave a left-hand deflection of 15 degrees; $R^3 = 157$ ohms, gave a right-hand deflection of 20 degrees; then the correct resistance x will be given by this formula:

$$x = \frac{10}{1{,}000}\left(156 + \frac{15}{15 + 20}\right) = 1.5643 \text{ ohms, nearly.}$$

It is to be remembered that the earth to which the battery is attached must be the outside metallic sheath of the cable, or connected to an earth plate in which there is no difference of potential between it and the cable conductors. Should the cable conductors have low insulation (in addition to the fault) there will be a natural resultant fault which will tend to throw the true position of the fault to one side of the place located by the tests. In this case Kempe furnishes a correction, as follows: The difference in ohms between the apparent position of fault and the true position

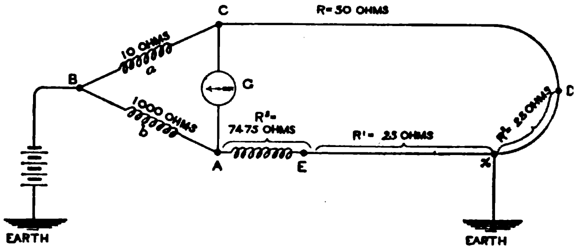

FIG. 2.

$$= \frac{I}{P - I}\left(R^1 - i\right) \text{ ohms.}$$

Where P = the absolute insulation resistance in ohms before the fault occurred;
I = the absolute insulation resistance in ohms with fault at time of test;
R^1 = apparent distance in ohms of fault by loop test;
i = apparent distance in ohms of natural resultant fault obtained before fault occurred.

Accuracy demands care, coupled with a correct bridge, and a good dead beat reflecting galvanometer with corrections properly applied for variations of temperature in the apparatus and wires.

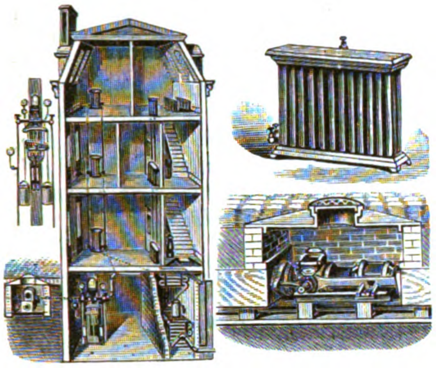
ELECTRICAL EXPOSITION IN MOSCOW.

THE Moscow Section of the "Imperial Russian Technical Society" will open an Electrical Exposition in that city on April 14th to the 26th, 1892.

The programme published by the board of management mentions eight groups, as follows: 1, electric light, transmission of power; 2, telegraphy and telephony; 3, electro-technology (electro-metallurgy, electrolysis, electro-plating, etc.); electricity as applied for railway use, military and marine purposes, medicine, and domestic economy, etc.; 4, electric piles, condensers, static apparatus, thermo-electric batteries, dynamos, motors, etc.; 5, motive power, boilers, motors used for electro-technical purposes; 6, scientific apparatus, measuring and precision instruments; 7, novelties; 8, literature, plans, designs, diagrams, etc., pertaining to electricity.

Exhibits will be admitted free of duty, provided they are returned within one month of the closing of the Exposition, or if given to the Imperial Russian Technical Society towards the formation of a museum or electro-technical laboratory. In the event of a sale, however, the duty will be exacted. Prizes, in the shape of gold, silver and bronze medals, etc., are to be awarded.

DISTRIBUTING EXHAUST STEAM FROM CENTRAL STATIONS.



ELECTRICITY as a commercial product for the lighting of cities and villages, or to furnish power for running stationary motors or street cars, or for other industrial uses, has necessitated the construction of many large steam plants for its development. Now it is well known that only about 10 per cent. of the heat in steam passing through the engine is converted into mechanical energy, and that nine-tenths remains available for the heating of houses, stores and public buildings, provided this exhaust steam can be distributed where it is wanted without too much expense, or too great loss by radiation in transmission. If this can be done, then the exhaust steam of central stations, which is usually thrown away, can be made an important source of revenue. As revenue is the incentive to the establishment of all industrial enterprises, it follows that the prudent manager will not long neglect to utilize the resources at his command. Sometimes the location of a station may not be favorable to the profitable distribution of its exhaust steam, but in most cases a short line of underground pipe laid in the streets, will reach districts of residences or business blocks, from which services can be taken off to buildings on either side. Many steam systems proper are now in operation so that this plan of steam distribution can no longer be called an experiment.

Some twelve or thirteen years ago Mr. Birdsill Holly, the inventor of direct pumping for water-works systems, conceived the idea of heating cities and villages, and supplying power therein with steam carried underground in protected iron pipes. There were serious obstacles to overcome, one of which was the buckling and breaking of the iron pipes on account of their expansion and contraction, caused by changes of temperature. This was accomplished at first by the device which he termed a "junction service box," placed at intervals in the mains. This was a steam-tight box into which sections of pipe could expand, the other end of the section being stationary. This box also served as a fixed point from which to take off service pipes to the buildings along the streets. The objections to this plan were that these packed joints required occasional repacking, and necessitated the construction of manholes in the streets in order to gain access to them. This device is shown in the vignette at the head of this article.

Later the device now in use in the "Holly system" was invented, known as the "Variator," a sectional view of which is shown in Fig. 1. This embodies a corrugated copper diaphragm, with cast-iron backing plates for strength; the yielding and reflex action of which provides for varying lengths in the sections of pipe. No stuffing-box is required in this, and the device is protected from

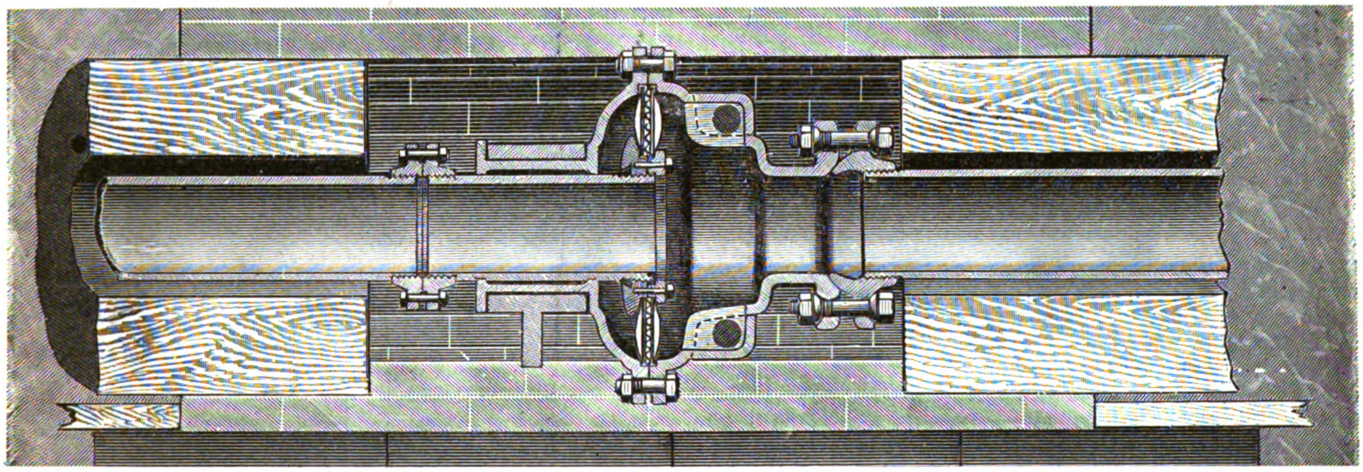


FIG. 1.—SERVICE VARIATOR, SECTIONAL VIEW.

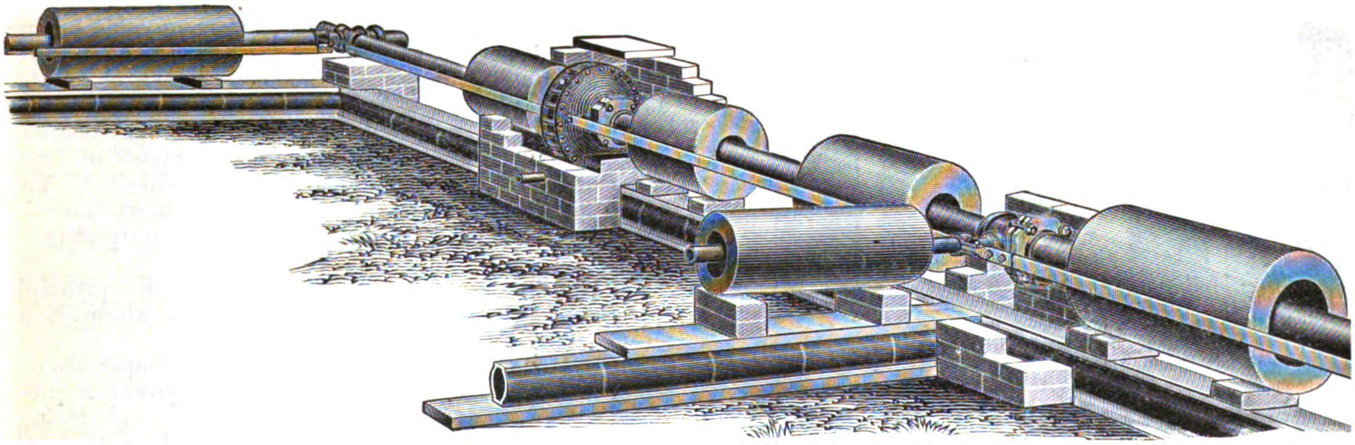

FIG. 2.—SECTIONAL VIEW OF A LINE OF STEAM MAINS, SHOWING IRON PIPE, WOOD LOG COVERING, ANCHORAGE, VARIATORS AND STREET ANGLES.

contact with the earth and covered the same as the pipe itself, no manholes being required.

Another point to consider was the prevention of undue radiation of heat from the pipes, which would be the case if they were laid in contact with the moist earth. Experiment showed that this could be accomplished by the use of pine logs, bored for the purpose with four-inch shell, the outer surface being coated with asphaltum. These were tenoned together and the iron pipe, which is first covered with asbestos, is inserted therein. Under this pipe is laid a line of tile, with proper outlet to convey away any surplus water in the surrounding earth. Service pipes to the buildings are laid in a like manner. A sectional view showing the method of construction is shown in Fig. 2.

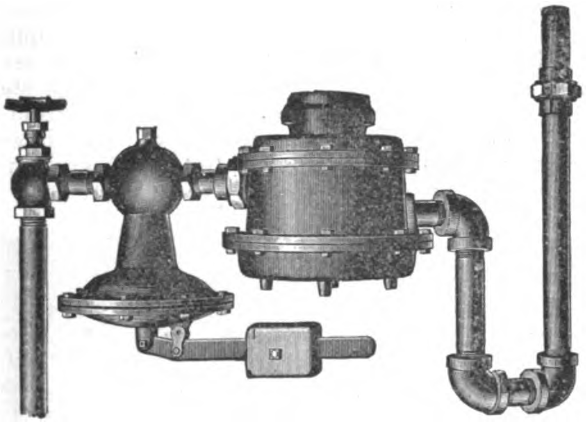

FIG. 3.—HOLLY'S REDUCING VALVE AND STEAM METER.

The steam is first conveyed into the basement of the building, passes through the "regulator," which reduces the steam pressure to a low and uniform pressure, and then through the steam meter, which records the amount of steam used by each consumer. The meter and regulator are shown in Fig. 3. The Holly system differs from the ordinary house system, in that it does not return the water of condensation. This water goes from the radiators to a trap shown in Fig. 4, and then to a cooling coil in the basement, where all the heat is abstracted and passes through a register in the floor above; the water then passes to the sewer; or, being chemically pure, may be used for any purpose desired.

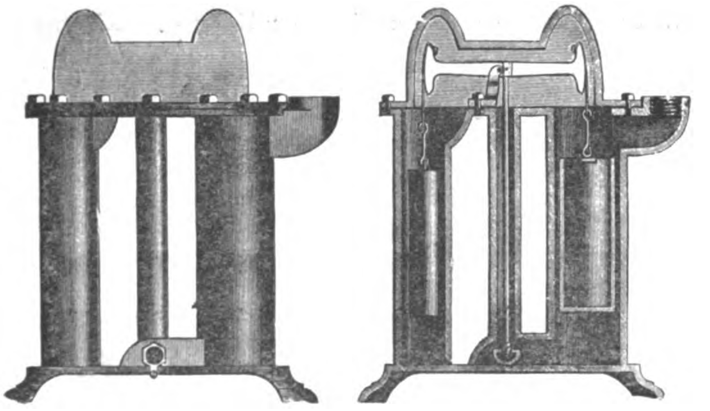

FIG. 4.—HOLLY'S STEAM TRAP.

It is calculated that 100 h. p. of steam will heat one million cubic feet of space; and a fair commercial rate to be charged for heating with steam in most localities is $4 per thousand cubic feet of space for the heating season. When large batteries of boilers are in use it will thus be seen that they are capable of bringing in a large income. In a village lighting plant where steam is supplied only during certain hours, the exhaust may be supplemented by live steam during the rest of the time, thus keeping boilers and men in continuous service. The same practice holds good in lighting plants in large cities, and the heating becomes an important feature of the business. In railway plants, or railway and lighting combined, where the engines run continuously, but little live steam may be required. One such plant, two years ago, constructed two miles of mains under the "Holly system," and has since extended its lines. The company is heating about two hundred customers, and doing nearly all this work with exhaust steam. In the coldest weather some live steam may be required, which is regulated by an automatic device. This branch of the business has proven very profitable and has made the whole enterprise an assured success. Several smaller exhaust steam plants are in operation and all are represented as being eminently successful.

This system is now being installed in many central stations by the American District Steam Co., of Lockport, N. Y. The success of these plants is attested by from 40 to 50 central stations already so equipped.

We have attempted to give but an outline of this plan, which is somewhat of an innovation, and for this reason, perhaps, the electric companies have been rather slow to put it in practice, or else have been but imperfectly informed in regard to it. But when we consider the fact that every electrical company has the machinery for a heating plant and a supply of steam to deliver into the mains practically free of cost, and that it lacks only the mains for distribution, this utilization of the waste steam ought to be seriously considered by station managers as a promising method for obtaining increased revenues from their stations.

WORKING ANNUNCIATORS AND BELLS FROM STREET CIRCUITS.

BY

W. M. Miner

MR. ARMSTRONG'S excellent article on "Improvements in Annunciator and Bell Work," in your issue of Dec. 23, is very much to the point, ~~as~~ such work is often merely thrown together in an anything-will-do-for-this fashion.

His method of supplying the necessary current for annunciator and bell work is good; but why not go further and use current from the light circuits direct, without the intervention of any *moving* parts? Current could be supplied for this purpose direct from the light mains, through two 50 or 100 c. p. lamps, and connecting each of the bell wire mains through a lamp to one of the light mains. This would give sufficient current to work any ordinary annunciator or bell. By different combinations of lamps one could get nearly any amount of current desired. Very heavy bells could be made of high enough resistance to work from the light circuit without any interposing resistance.

Burglar alarms can also be worked on this principle, throwing on all the lights in the house as an alarm, if desired.

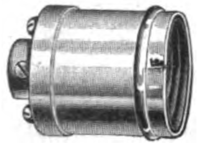
The motor-dynamo is, I think, of more importance to small telegraph offices, where the battery power required is not sufficient to warrant the installation of an isolated plant, and where current to run the motor-dynamo can be procured. It takes but a very small machine to take the place of 1,500 cells of battery, as I know from experience in Minneapolis during the past summer, on the lines of the North American Telegraph Co. with a Crocker-Wheeler $\frac{1}{6}$ h. p. motor, wound to be used as a dynamo. I worked four heavy wires between Minneapolis and Chicago, a distance of 500 miles, and two short ones, all from this small dynamo at the same time, and did it as well as, or better than, the 1,000 or more cells of gravity battery that the dynamo displaced.

RECENT EDISON LAMP SOCKETS.

INCANDESCENT lighting has developed not a few features of special interest, and prominent among these are the lamp sockets, of which there are to-day a great variety on the market, differing in shape, design and purpose, and covered, it is said, by at least 300 patents. We illustrate on this page three of the recent Edison sockets, the features of which are such as to command general interest.

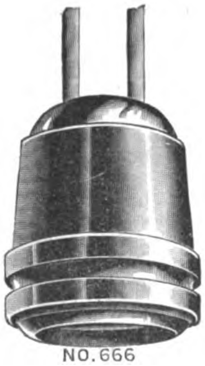
The Edison socket, born at almost the same time as the incandescent lamp, has followed with but slight deviation a straight evolutionary line. The key socket still retains the familar feature of the spring tongue brought down on the lamp tip by the pressure of the key, and making a sliding contact. It is an instantaneous switch of almost perfect type, and in its new brass casing is attractive among sockets. This key socket, however, did not fill all the requirements; to turn on the light or extinguish it demands in certain cases a pair of hands, and busy men are prone to consider the employment of two hands for so slight a task as one hand too many. Another socket has, therefore, lately been devised—the "pressure" or "push-button" socket. The circuit is made by pressure on a small button at the side of the socket, which brings a contact-piece between four phospor-bronze brushes set in a circle in the interior, but on the other side of the socket. The lamp tip makes an ordinary contact with the tip at the top of the socket screw shell. The button is retained in position by a little catch. On pressing this catch the button is released, thrown out by a spring, and the contact is broken. This socket is used mostly on flexible cords and other single light pendants, although it is also used instead of the key socket in other positions.

Recognizing the fact that their ordinary keyless socket was not always suitable for fixtures of an artistic character, the Edison Company have designed a smaller socket. It is about half the size of the well-known keyless socket, and is compact in structure and neat in style. It is claimed that there is not on the market any other socket for lamps of 16 c. p. and upwards as small as this, nor one that so well serves the purpose for which it was invented.



The other sockets and receptacles of Edison make are already well known to all who have had anything to do with the practical working of electricity in this country. But there is still another socket not yet mentioned, viz., the No. 666 Weatherproof Socket. The outside shell of this is of hard rubber, the interior parts being imbedded in insulating material capable of resisting the disintegrating effects of moisture and steam. This socket was designed for use in brew houses, dye houses and other such positions, and has even been used successfully in railway tunnel lighting and in mines.

The insulation in all these sockets, with the exception of that last named, has hitherto been of the best insulating material to be found, but now that a regular porcelain factory has been established at the Schenectady works of the company, the insulation will be of hard white vitreous porcelain there made and impervious to the influences which affect many forms of insulating material.



Letters to the Editor.

CATALOGUE AND PAMPHLETS WANTED.

I AM instructed by a foreign government to ask through your columns for catalogues and other illustrated matter describing the most modern instruments and machinery used in telegraphy, telephones; obtaining light and power from waterfalls, oil engines, etc.; and also applications of electricity to naval and military purposes, and to chemical industries such as tanning. Postage must be prepaid. Samples and photographs should be sent where possible. Samples and prices of subterranean telegraph line are particularly required.

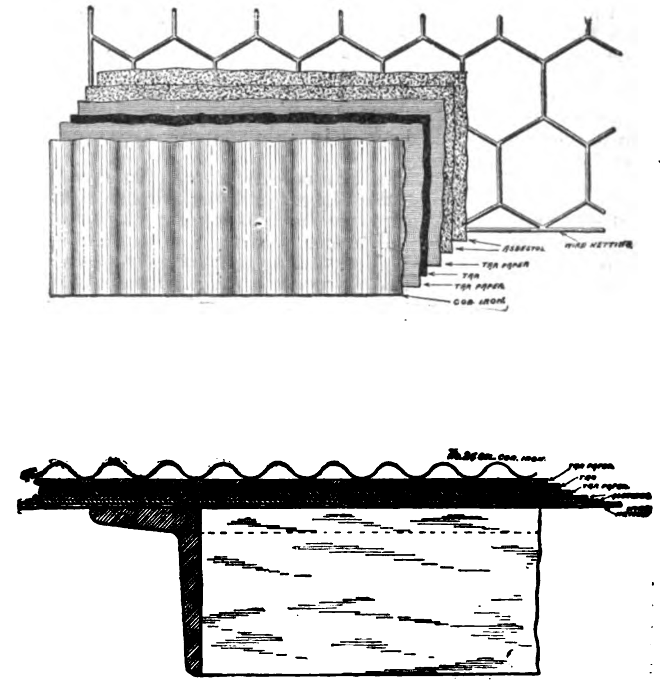
C. PURCELL TAYLOR, D. Sc.,
Patent Expert.

57 CHANCERY LANE, LONDON, ENGLAND,
Jan. 6th, 1892.

METHODS FOR OVERCOMING CONDENSATION INSIDE IRON ROOFS.

WE notice the communication of Mr. Alfred Braddell, electrical inspector, Underwriters' Association, Middle Department, Philadelphia, Pa., in your issue of Jan. 6th, and beg to say in reply to same that there are a number of ways to overcome the condensation he complains of on the underside of the corrugated iron.

This is caused more particularly in cold weather by the warmer air inside the building, condensing on the under side of the corrugated iron, which is of a lower temperature, and this can only be overcome by placing some non-conducting material between the corrugated iron and the inside of the building. The ordinary way to prevent this condensation is to place plank directly on the purlins, cover it with tar paper and then lay the corrugated iron directly on top of this, which is probably the most economical way, but it does not make the station absolutely fireproof. We have also used fireproof non-combustible boards about ⅞ in. in thickness, secured to purlins, and on top of this laying tar paper, and then our corrugated iron. Examples of this construction can be seen in the station of the Lynn Gas and Electric Light Company, at Lynn, Mass.; also on the foundry of the Pratt & Cady Co., of Hartford, Conn.; the power house of the Newport News Ship Building, Dry Dock and Construction Company, of Newport News, Va., and the machine shop for the Upson Nut Co., at Unionville, Conn., also several other buildings.



Patented.

FIREPROOF ROOF SHEATHING FOR PREVENTING CONDENSATION OF MOISTURE.

There is still another method which we have used with great success on three of the largest electric light stations in this country, namely, the United States Electric Lighting Co., of Washington, D. C.; the Narragansett Electric Lighting Company, of Providence, R. I.; the Pawtucket Gas and Electric Light Co., of Pawtucket, R. I., and also on our new shops at East Berlin, Conn., which although slightly more expensive than the other constructions described, still has the merit of being thoroughly fireproof and also preventing any condensation.

This method is described as follows: Galvanized iron wire netting with a small mesh is first tightly stretched and secured to the purlins of the roof. On this we place two thicknesses of asbestos paper board and on this two thicknesses of tar paper, being careful to make good laps and breaking joints. On top of this is placed the corrugated iron securely attached to the iron purlins. The accompanying cut will show the general idea, although in practice it varies somewhat from the method as there shown.

This makes a neat, substantial fireproof sheathing and has proved a success in practice. We would be pleased to enter into communication with any electric light company wishing further information in regard to this work.

The Berlin Iron Bridge Co.
Burr K. Field,
Vice-President.

East Berlin, Conn., Jan. 9, 1892.

LONG-DISTANCE TRANSMISSION OF POWER IN CHICAGO, WITH SPECIAL REFERENCE TO NIAGARA.

The distance that power can be electrically transmitted today is governed by the voltage that can be manipulated in the generators, motors, and on the line. With the alternating current the use of 20,000 volts is approaching a commercial stage, notwithstanding the induction in neighboring metallic bodies. There is no evidence, however, of a continuous current of this pressure being used, the nearest approach being the arc current, which years have demonstrated to be of very easy management. Is it not certain that owing to this ease of operation the high-pressure continuous current will be the future medium for electric power transmission? The limit to the pressure to be used is the sparking distance between the two conducting mains. The ordinary condenser or Leyden jar with naked conductors at 100,000 volts discharges within six inches; it is such a voltage or higher but with insulated conductors, that may be assumed a possibility. This leads into the region of the potentials of static electricity.

Suppose at Niagara there be a condenser of sufficient capacity to absorb the power of the Falls, then, if discharging wires be carried 500 miles to Chicago, we have the means of conveying the power of Niagara this distance. With the Leyden jar it should be noted, as mentioned before, that naked discharging wires are used, and one well-insulated wire only is required, the earth being used as a return, but for absolute safety two mains are preferable.

Five hundred miles of No. 0000 wire would cost about $528,000 and would transmit 3,000 h. p. at a loss of 4 per cent.; that is, 3,125 h. p. furnished at Niagara would deliver 3,000 in Chicago; this at a potential of 100,000 volts.

By using a highly insulated transmission wire, the voltage might be raised to 1,000,000 volts, and along a No. 0000 wire, at this potential 31,000 h. p. would be transmitted with a loss of less than ½ per cent.; 1 ampere at 1,000,000 volts would transmit 1,250 h. p. The generating and motor machinery for these high potentials is of the simplest character, and details will be published as early as possible.

The crux of the whole question lies in the production of a cable that will carry a high potential Leyden jar discharge. The current would be a veritable flash of lightning. Michael Faraday remarked that the current required to decompose a drop of water, was sufficient to make a thunderstorm; this is about to be realized.

The Leyden jar has already been used for exploding fuses in mines, one terminal being connected with the earth, the other with a gutta-percha-covered wire; it has also been used for telegraphing across the Thames. These instances are not referred to with the idea of actually using condensers, but, as showing an actual employment of high potentials in a limited way. The generators and motors contemplated are continuous-current machines of ordinary type, but specially wound and arranged.

George Edensor Dorman.

THE LIMITS OF FAST LOCOMOTION.

I observe that one of your estimable contemporaries devoted to railway matters has been collecting the opinions of a number of prominent experts as to whether a speed of 100 miles per hour is ever likely to be reached by passenger trains in this country. Bridge Engineer Thompson of the New York Central thinks that such a result is bound to come in the natural order of things, if the doctrine of evolution holds true in railway progress as in other things. General Manager Layng of the West Shore, too, seems to regard it as a possibility. Another G. M., whose name, out of consideration for the future feelings of his family and friends, I forbear to mention here, replied to the effect that no one with common-sense would ever run a train 100 miles per hour.

Now it won't do to be too sure about these things. I have in my library a valuable work on "The Internal Navigation of the United States," printed in Philadelphia in 1830, by Lydia H. Bailey, which contains, among other matters of interest, a report by "State Chief Engineer" C. Crozet, of Virginia, dated July 1, 1826, in which the comparative advantages of railways and canals receive an able and exhaustive discussion. In summing up the conclusions arrived at, "it will be sufficient to observe," says the State chief engineer, "that railways are advantageous only when *great speed* is a desirable object," and on this head he further remarks: "By increasing, therefore, the velocity of the rim of the wheels *by any means whatever*, the speed of transportation might be increased *without limits*, by a propelling steam engine. Prudence alone fixes a limit to the velocity; a great swiftness on a straight road might occasion very serious accidents, but on curves it would be particularly dangerous. It seems admitted that a rate of speed of more than 6 miles an hour would exceed the bounds set by prudence, though some of the sanguine advocates of railways extend this speed to 9 miles an hour." But the State chief engineer is evidently somewhat distrustful of the notions of these ultra-progressive persons, for he remarks in another part of his report that "the railroad cause itself has suffered injury throughout the last year or two by a premature zeal in its partisans," and he thinks that "it may with confidence be affirmed that the canal system in this country is not likely to be superseded by that of railroads, as by some advocates of this latter was at one period not long since contended must be the case." Three years later George Stephenson's "Rocket," the prototype of the modern locomotive, astonished the engineering world by a speed of 29 miles per hour.

The developments of the past few years have conclusively established the correctness of one of the State chief engineer's conclusions, viz., "prudence alone fixes a limit to the velocity," for at least it is no longer limited by the capabilities of a "propelling steam engine" which has to be carried upon the train.

New York, Jan. 11, 1892.

A NEW ARGUMENT FOR IRON ROOFS.

In regard to iron roofs for electric light stations, they are valuable for fire protection from outside sources. In my experience with the dampness during cold weather, I found it necessary to put in a wooden ceiling with an air space between the ceiling and the roof; it also became necessary to wainscot the side stone walls for the same reason, an air space of two inches being left between the walls and the wainscoting.

Brush Electric Light Co.,
Rochester, N. Y., Jan. 11, 1892.

Geo. A. Redman,
Supt.

IRON ROOFS FOR LIGHT AND POWER STATIONS.

My attention has been called to a request for information in your recent issue from Mr. Braddell, of Philadelphia, as to "the best means of obviating this trouble (rapid condensation from iron roofs in cold weather in electric light and power stations) as it appears to be one of no little importance." I would suggest that the remedy is so simple that I am surprised that one who lives in Philadelphia, near Cramp's ship yard, should not be aware of it.

Two years ago I had the privilege of thoroughly examining some of our new United States cruisers, and was struck with the roughness of the paint on the inside of the steel shells or bottoms of the ships. On inquiry, I was informed that this roughness was purposely contrived by the mixture of ground cork and lead paint to prevent condensation and moisture. In accepting the courteous invitation of the admiral for a short voyage of 20 hours along the coast, we were blessed with a dense wet fog, during which I observed that there was no more moisture inside the ship than in an ordinary vessel, and that there was no condensation on the inside of the iron hull even down below the water line, as I several times discovered by passing my hand over the painted iron work.

In planning a new electric light station for the Brookline Gas Light Company I was extremely anxious to avoid the risks of fire, and concluded to have the plan embrace an iron roof covered with slate. In carrying out this plan I borrowed the above-named experience and have just completed the painting with a coat of cork the under side of the iron and slate roof. We had difficulty, owing to inexperience in getting a sufficient amount of cork to adhere to the roof, the surface of which measures nearly 80 squares (10 feet x 10 feet is this square measurement).

It required four coats of lead paint and about 10 bushels of ground cork, but the result is fairly good in getting a roughened surface. I presume the theory of absence of condensation is explicable by the fact that the cork contains so much air between the cold iron and the warm air that there is no direct contact between the two, and a consequent avoidance of condensing surface. In any event during the cold weather of the past 10 days, the inside surface of the slate and iron is dry, though the large building, 120 feet x 90 feet, has been kept well warmed by steam pipes running along the inside of the three outer brick walls. In the attached boiler room, not by any means kept warm, the condensation from the under surface of the slate and iron roof is strongly marked.

AN INDICATOR FOR CALCULATING HORSE-POWERS.

I HAVE just had brought under my notice an article in your issue of Nov. 18, 1891, by Mr. Francis R. Hart, on "The Determination of the Available Energy of Water Powers," with a diagram assuming 75 per cent. of the total energy of such water powers as the efficiency.

I have brought out and supplied a good many indicators for obtaining the horse-power of water wheels or turbines, but with the advantage that they carry the falls from 2 to 200 feet, and give the horse-power from 1 to 1,000, and that, with *any percentage* of the total energy from 50 to 100 per cent. The results are also much easier to read than with a diagram, being given by discs with graduated scales ; the former are always more or less tedious to read off.

A description of a similar indicator for obtaining the horse-power of a steam engine was published in the November number of *The Compass*, which may perhaps interest your readers. I have also made these indicators to give the horse-power of a waterfall issuing from a *jet*, from $\frac{1}{10}$ inch to 6 inches diameter, with any rate of useful effect.

WM. COX.

New York, Jan. 13, 1892.

Reports of Companies.

THE CROCKER-WHEELER ELECTRIC CO.

ON December 1, 1891, all the interests owned by the Crocker-Wheeler Motor Company were bought by the Crocker-Wheeler Electric Co. and the capital stock was increased from $100,000 to $200,000. At the annual meeting held Jan. 13th the following officers were elected :

President, S. S. Wheeler; vice-president and treasurer, F. B. Crocker; secretary, D. H. Jeffery; directors : R. M. Peterson, David Crocker, W. B. Baldwin, A. Foster Higgins, F. M. Jeffery.

The company was awarded a gold medal at the electrical exposition recently held at Augusta, Ga., and attractive exhibits are now being made at the Crystal Palace, London, Exhibition, and at New Haven.

Among the new articles recently put on the market by them is an automatic switch of very substantial character. Their new fan-motor, which at the same time revolves a fan and rotates on a pedestal, is proving a decided success. Extensive additions are now being made to their factory, and the business of the company bids fair to be very largely increased the coming year.

Literature.

The Galvanic Circuit Investigated Mathematically. By Dr. G. S. Ohm, Berlin, 1827. Translated by William Francis, with a preface by the editor, Thomas D. Lockwood. *New York, D. Van Nostrand Company*, 1891. Science Series. Price, 50 cents.

ALTHOUGH Ohm's law forms the basis for most of our theory and calculations in electrical work, there are comparatively few who take the trouble to go back to the original source of information and to study the memoir which Ohm has left as an enduring monument to his fame. We use the word "trouble" advisedly, because the only previous translation of Ohm's great work is to be found in *Taylor's Scientific Memoirs*, to which but comparatively few have access, and, as the original work itself has become a much-prized rarity, few have undertaken the task. Its publication in this handy form will, we are sure, be welcomed by a large number of students and lovers of electrical science. We notice that the illustrations which in the original are given at the end of the work as an inset are wisely printed in the text, thus facilitating reference to them. While the work before us is not entirely free from error, the translator's task will be conceded to be no easy one. The work of the editor must, however, be commended. Mr. Lockwood's preface is an exceedingly concise statement of the work which led up to the formulation of the law by Ohm and the various annotations throughout the work aid considerably in elucidating passages by the light of more modern investigations. We can heartily recommend the little book.

A First Book of Electricity and Magnetism. By W. Perren Maycock, M. I. E. E. *London, Whittaker & Co.; New York, Macmillan & Co.* 5 x 7 inches, pp. 133. 84 illustrations. Price, $0.60.

THIS, as its name implies, is a book for beginners, treating of the kindred sciences of electricity and magnetism in their simplest and most elementary forms. Appended to each part, of which there are three, is a list of questions for the purpose of testing the proficiency of the student. The book will be quite useful.

Society and Club Notes.

BOSTON ELECTRIC CLUB.

THE Boston Electric Club held its inaugural dinner on Monday evening, the 11th inst., under its new auspices, in the Parker House. The dinner was well attended, and proved a very enjoyable affair. Before the dinner there was a short business meeting, at which it was resolved to have monthly dinners. Mr. Henry B. Cram was elected president, Mr. R. F. Ross, secretary and treasurer, and a board of seven directors was appointed. The club had for its guests on this occasion Prof. Elihu Thomson, Prof. Cross of the Massachusetts Institute of Technology, and Prof. Dolbear of Tufts College. After the dinner, which was quite a success, and was attended by about 40 members, Prof. Thomson gave a very interesting address on the recent development and progress of electricity, touching more particularly on electric railways, electric drilling and electric mining.

In the course of his remarks he said that electric engineering for large light and power stations was undoubtedly turning towards large engines directly coupled to the generator, and tending to do away with the intervening countershafting and belting. He gave also an interesting explanation of the development of the three-phase generator, referring in particular to the transmission of power at Frankfort, and the great possibilities for its development in this country with its numerous water-powers.

Prof. Cross then gave an interesting description of how electrical knowledge was carefully instilled into the student of electrical engineering at the Institute of Technology, after which Prof. Dolbear described some interesting experiments which he had recently made, to discover if there were any torsional effect in a wire when a current was passing through it. Mr. W. J. Denver and Mr. C. J. H. Woodbury then followed, and lastly Mr. George Cutter, of Chicago, gave some of the most recent news relating to the development of the electrical department at the World's Fair. Mr. Cram presided in his usual graceful manner, and a most enjoyable evening was spent. It is to be hoped that this series of dinners will be kept up and be well attended, and it is the intention of the directors to have some interesting speakers or some discussion on a live topic on each occasion, so as to make the occasions not only social, but interesting and instructive.

COMPILING THE ELEVENTH CENSUS BY ELECTRICITY.

ONE of the most beautiful and ingenious of the recent applications of electricity has been its use in the Eleventh United States Census for the purpose of counting and tabulating the returns. The apparatus used is the invention and design of Dr. Herman Hollerith, of Washington, under whose supervision it has summed up the totals of a population of 62,000,000, and has now begun to furnish a variety of interesting data as to age, occupation, resources, education, health, etc. The apparatus has also been adopted for census purposes by Canada and Austria. Dr. Hollerith is a member of the New York Electric Club, and he has now kindly consented to make an exhibit of the whole system at the club house on January 28, when the members will be able to see how electricity has been applied with wonderful ingenuity and not less extraordinary success to the intricate and complex work of counting and classifying a whole nation. This is the first time that the apparatus has ever been exhibited in public, and the great interest that has been taken in New York in census matters gives special timeliness to this meeting at the Electric Club.

NATIONAL ELECTRIC LIGHT ASSOCIATION.

MR. GEO. F. PORTER, the secretary of the association, has issued a letter canvassing the desire of the electrical trade to make a feature of an electrical exhibition at the Buffalo Convention, Feb. 23, 24 and 25. Should enough members signify a desire to exhibit to justify the management in taking such action, space and power will be provided gratis. It is believed that while the miscellaneous exhibit of supplies will be good, no attempt will be made to repeat the effort put forth at Montreal last September.

Personal.

HON. JAMES D. REID.

THE personal friends of the Hon. James D. Reid, U. S. Consul at Dunfermline, Scotland, have been gratified at receiving from him and Mrs. Reid a beautiful new year souvenir in white and gold, printed in his own striking penmanship. On the cover in gold are three circles with the words "Fifty years" and the dates 1842–1892. Inside are several stanzas of a touching poem by Mr. Reid, who always had a weakness for elegiac and ballad verse. There is also a little steel plate of the old Scotch town, and the whole is tied with gold braid. The period named 1842–1892 covers practically Mr. Reid's active work in the telegraph field, dating from his association with Morse; and his thousands of juniors in that department of electrical industry may well hope to be as blithe and serene and active as he when they in turn have tried to emulate his career.

MR. L. W. COLLINS.

THE above-named gentleman, who is too well known in electrical circles East and West to need any formal introduction, has moved from Chicago to New York, and has become the trade editor and advertising representative of THE ELECTRICAL ENGINEER in this city. Mr. Collins will contribute the New York Notes and other items of a business and industrial nature to these columns, and the publishers ask for him from its friends, readers and patrons whatever help they can give that will go towards rendering the paper useful in furthering the interests of electrical industry.

MR. NIKOLA TESLA left for Europe on the "Umbria" on January 16, to be gone several weeks. He has been invited to lecture before the various electrical and scientific societies of the Old World, and will appear before the English Institution of Electrical Engineers at the end of this month or early in February. While abroad he will seize the opportunity to visit his mother and relatives in Smiljan Lika.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JANUARY 5, 1892.

Alarms and Signals:—

Electric Annunciator, C. Molitor, 466,357. Filed Sept. 14, 1891.

Relates to that class of annunciators having a pointer moved by operating devices controlled by an electric current.

Combined Electrical Protective and Time-Detecting System, J. S. Morse, 466,505. Filed June 5, 1891.

Consists of one or more thermostatic circuits containing alarm-bell, battery, circuit-controlling mechanism, time-detector, etc.

Electrical Signal-Box, T. F. Gaynor, 466,604. Filed Jan. 23, 1888.

A signal-box for use on fire-alarm circuits.

Multiple-Signal Transmitter, C. E Nash, 466,620. Filed May 2, 1891.

A transmitter for police-telegraph systems in which it is desired to record any desired one of a number of distinct messages from each signal-box.

Clocks:—

Apparatus for Synchronizing Clocks, L. Von Orth, 466,518. Filed Jan. 23, 1891.

Conductors, Conduits and Insulators:—

Insulator, W. S. Andrews, 466,391. Filed May 27, 1891.

A trolley hanger or pull-off for electric railways.

Extensible Electrical Conductor, B. C. Rowell, 466,427. Filed April 18, 1891.

An arrangement for bridging brakes in a trolley system as, for instance, where the line crosses a steam railway track or a drawbridge.

Insulator, G. B. Norgrave, 466,726. Filed April 9, 1891.

Consists of a pair of insulating blocks having corresponding grooves cut in their faces to hold the wire; said blocks being held together by a clamp forming part of the insulator's support.

Dynamos and Motors:—

Commutator Brush and Holder for Dynamo-Electric Machines and Motors, F. J. Sprague, 466,448. Filed Dec. 10, 1886.

Has for its object to so arrange the brushes that the armature may run readily in either direction, and also to produce a simple and efficient construction of the brushes and brush-holders.

Regulation of Dynamo-Electric Machines, R. Thury, 466,760. Filed Aug. 4, 1891.

Relates to the automatic regulation of the lead of collecting brushes on electric generators.

Galvanic and Thermo-Electric Batteries:—

Electric Battery, P. B. Delany, 466,664. Filed Nov. 13, 1890.

An improvement in the ordinary battery cell whereby the wire leading from the copper element is held in a fixed relation to the jar, and also means whereby the zinc "crowfoot" may be cleared of the ordinary formations on its lower side without in any way disturbing it.

Lamps and Appurtenances:—

Cut-Out for Incandescent Lamps, T. A. Edison and J. F. Ott, 466,400. Filed Oct. 27, 1886.

Consists of a fusible cut-out included in the base of the lamp.

Electric Switch, G. E. Painter, 466,508. Filed Mar. 17, 1891.

Consists in so constructing a switch that it shall grasp the pipe which supports a collection of lamps and be easily removable therefrom.

Electric Drop-Light, G. E. Painter, 466,509. Filed Apr. 29, 1891.

Comprises a reel by means of which an incandescent lamp may be raised or lowered at will, the flexible cord being wound upon said reel.

Electric Lamp Socket-Switch, G. E. Painter. 466,510. Filed Mar. 17, 1891.

A device for turning on or off an individual lamp from any distance within the length of the circuit.

Electric Lamp Socket-Switch, G. E. Painter, 466,511. Filed Mar. 17, 1891.

Similar in its object to 466,510.

Incandescent Lamp, P. Grant, 466,562. Filed July 7, 1891.

A lamp that may be taken apart at any time for insertion of a new filament or for other repairs without destroying any portion thereof.

Globe-Guard for Electric Lights, C. P. Robbins, 466,576. Filed May 11, 1891.

Metallurgical:—

Ore-Separator, C. J. Reed, 466,513. Filed Oct. 13, 1890.

Ore-Separating Machinery, C. J. Reed, 466,514. Filed Dec. 1, 1890.

Ore-Separator, C. J. Reed, 466 515. Filed Apr. 6, 1891.

Miscellaneous:—

Device for Electric Elevators. R. C. Smith, 466,447. Filed Mar. 17, 1891.

A safety switch for electric elevators.

Damper Controller, J. V. Stout, 466,450. Filed Mar. 23, 1891.

An automatic controlling device for heating apparatus in buildings.

Art of Electrolytic Decomposition, T. A. Edison, 466,460. Filed May 26, 1882.

Process of decomposing substances consisting in subjecting them to the action of an electric current while under great pressure and high temperature.

Electric Reciprocating Tool, H. N. Marvin, 466,541. Filed June 6, 1888.

An electric drill of similar device actuated by pulsating currents.

Electric Push, J. F. Wollensak, 466,644. Filed Oct. 23, 1891.

Electric Meter, C. K. Huguet, 466,686. Filed Dec. 3, 1890.

Safety Fuse for Electric Conductors, J. A. Wotton, 466,761. Filed Oct. 12, 1891.

A safety fuse employing an explosive sufficiently violent to blow out any arc that might form between terminals on the fusing of an ordinary safety plug.

Multiple Switchboard Busy-Test Circuit and Apparatus, F. A. Pickernell, 466,702. Filed Aug. 17, 1891.

A completely localized test arrangement, *i. e.*, one that shall be entirely insulated from the line circuit.

Railways and Appliances:—

Electric Railway Crossing, W. Osner, 466,262. Filed Oct. 16, 1890.

Provides means for the crossing of electric railway conductors and for maintaining the line uninterruptedly across drawbridges, etc.. without loss of current by induction or danger of breaking the circuit.

System of Electric Distribution for Railways, N. W. Perry, 466,367. Filed Mar. 2, 1891.

Relates to the distribution of electricity by a current which remains constant in quantity, while the translating devices are arranged in series with one another and with the generator or dynamo.

System of Electric Distribution for Moving Translating Devices, N. W. Perry, 466,368. Filed April 2, 1891.

Similar to No. 466,367.

Underground Conduit for Electric Railways, C. P. Tatro, 466,471. Filed Nov. 14, 1891.

Provides means for obtaining continuous electric communication between an insulated line wire and the cars, and also means for perfectly insulating said line wire and temporarily communicating with segments thereof without exposing any portion of said line wire.

Circuit Controller, H. P. White, 466,519. Filed April 29, 1891.

Has for its object a construction whereby the natural yielding of a rail in a railway track operates a circuit controller of an electric circuit.

Car Truck for Electric Railway Cars, P. M. Kling, 466,539. Filed Dec. 26, 1890.

A car truck especially adapted to the convenient mounting of railway motors and mechanism.

Lubricator for Trolleys, E. M. Doig, 466,737. Filed Aug. 17, 1891.

A self-oiling journal for trolleys.

Telegraphs:—

Cable Telegraph, W. E Facer, 466,492. Filed Dec. 22, 1890.

Has for its object to overcome difficulties experienced in long-distance ocean cable lines arising from induced currents, etc.

Telephones and Apparatus:—

Magneto-Telephone for Personal Wear, A. E. Miltimore, 466,725. Filed Feb. 24, 1891.

Legal Notes.

DISSOLUTION OF A TEMPORARY INJUNCTION AS TO EDISON STOCK.

JUDGE BARRETT of the New York Supreme Court has dissolved a temporary injunction obtained by Martin A. Frank against the Edison Electric Light Company restraining it from declaring a dividend of 80 per cent., payable in bonds of the company. This decision is rendered upon the point raised by the defendant that Frank should should seek relief in a separate action, and not in his present suit against the company. The injunction is dissolved without prejudice to an action to secure the relief prayed for.

Judge Barrett says in regard to his recent decision upholding the dissolution: "I did not mean to be understood as asserting that a corporation could not under any circumstances distribute its surplus earnings through the instrumentality in part of bonds issued to represent such earnings. There may undoubtedly be circumstances which would justify such an expedient for temporary purposes. And indeed it might be made to appear that such bonds simply represented surplus earnings, and could not possibly impair the actual capital of the company. But I have not changed my opinion as to the scheme here sought to be begun. In my judgment the affidavit of defendant does not justify the issuing of these debenture bonds upon the collateral security of stocks and bonds of the subsidiary companies for the purpose of raising money to declare a dividend upon the stock of this defendant."

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

The man who steadily advertises never misses business because his " wires are down."

THE G. S. A. LINE WIRE HOLDER.

"SIMPLE and cheap" are the qualities aimed at in this new device. Keeping the same insulators as are now in use both for telegraph and electric light and power transmission, this invention consists of a neck-band sprung into an annular groove of the insulator, a U-shaped lever pivoted to the neck-band and provided with eyes and a fastening bail or link that is pivoted to the eyes and provided with a bent or hook shaped portion for engaging the line wire. The bent portion presses the wire, when the lever is swung in a downward direction, into the annular groove of the insulator, so that the rounded end of the bail forms a continuation of the neck-band, in which position the line wire is firmly locked to the insulator. The wire members of the fastening device can thus be readily opened or closed so as to permit the insertion or removal of the line wire to or from the hook-shaped bail and the attaching and detaching of the same to the insulator, thus facilitating by a great deal the stringing or repairing of telegraph and electric light and power lines.

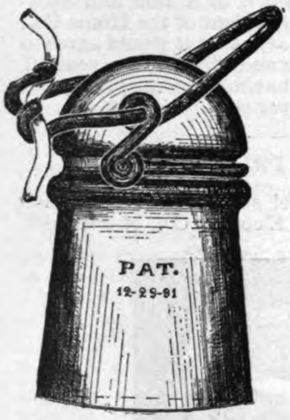

FIG. 1.—TELEGRAPH OR TELEPHONE WIRE.

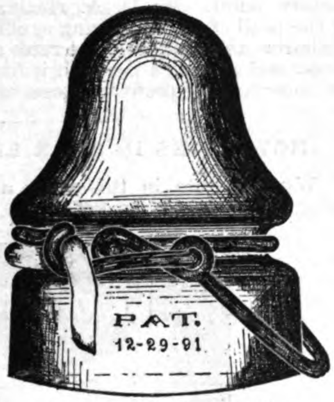

FIG. 2.—LIGHT AND RAILWAY FEEDER WIRE.

The practical lineman needs this device which was invented and patented by G. Sacco Albanese, formerly of Orange, N. J., now of Lynn, Mass.

PERRET MOTORS IN NEWSPAPER OFFICES.

In our issue of January 6 we gave an illustration of the Perret motor in the printing office of the New York *Commercial Advertiser*. We now publish an interesting letter from the *Lancaster Era*, of Lancaster, Pa., with regard to the plant that it has had in operation for over a year:

OFFICE OF THE "NEW ERA"
(Daily and Weekly),
WARFEL & GEIST, 41 No. Queen Street,
LANCASTER, PA., Jan. 1, 1892.

MR. E. H. CUTLER,
Manager the Elektron M'f'g Co.

DEAR SIR—One year ago we substituted electrical for steam power in the *New Era* printing house. A 20 h. p. Perret motor furnishes power for the machinery in the main press-room, driving a Goss perfecting newspaper press, with double folder, an Adams and three cylinder book presses, freight elevator, and the machinery in stereotype foundry.

A ten-horse Perret furnishes power for the half dozen presses and other machinery in the jobbing department, with ample reserve power for increase of both plants. The performance of these motors has been satisfactory in all respects. They run free from sparking, maintain a uniform speed under all variations of load, and cost nothing for engineering. We would not exchange for steam power upon any consideration. They are always ready for duty at any hour of the day or night without waiting to "get up steam." Steam for drying matrices is furnished by Murray's generator and steam table combined, which is both economical and convenient. As you are aware, we selected the Perret motor from a number of competitors because, while equal to the best in points in common, it was the only one which developed its maximum power at such slow speed as enabled us to run our line shafts without the intervention of counter-shafting.

The experience of a year fully confirms our judgment in the selection of these machines.

Yours truly,
(Copy). WARFEL & GEIST.

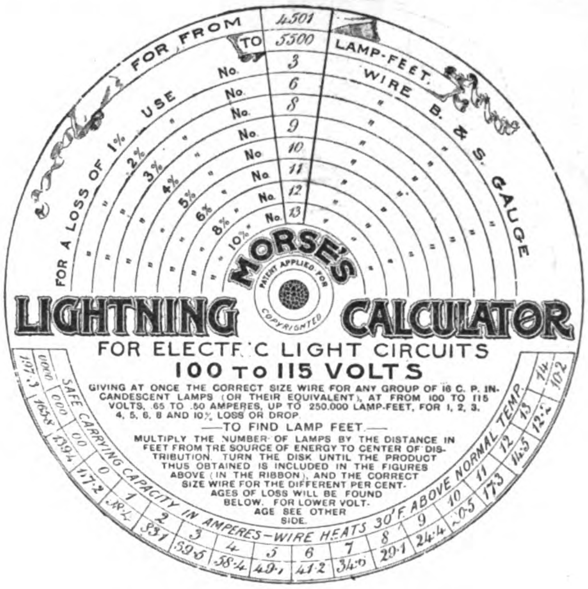
WAGNER-QUEEN VOLTMETER.

A FEW weeks ago we described the new portable voltmeter bearing this name, and which has been placed on the market by Queen & Co., of Philadelphia. The prominent features of this instrument are such as to render it of great value to electricians for measuring both alternating and direct current. It is very portable, weighing only 22 ounces, and the dimensions of the case are 7¾ by 4 by 2 inches, so that it can be carried in a good-sized pocket. The pointer is dead beat and direct reading, and the indications are accurate within one per cent. The price is also very low, which is of importance to those purchasers who may not feel warranted in buying the more elaborate and standard Cardew type. We are informed by the makers that up to date the demand has far exceeded the supply of these voltmeters. A large quantity is being pushed through their factory and they hope soon to keep up with the orders as received, so that delays in shipment will not occur. It will be well for those in need of a good portable voltmeter for both alternating and direct currents to obtain a copy of circular No. 265 from Queen & Co.

MORSE'S LIGHTNING CALCULATOR FOR ELECTRIC LIGHT CIRCUITS.

ONE of the most useful as well as unique devices to which we have called the attention of our readers is "Morse's Lightning Calculator" for electric light circuits, an illustration of which accompanies this article. This invention will readily commend itself to all those interested in electricity on account of its extreme simplicity and the readiness with which all ordinary problems of house wiring may be solved. It is quicker and more easily consulted than a chart or table as there are no intersecting lines to follow or columns to confuse. The readings are direct, plain and absolutely correct. It is sometimes desirable to ascertain the proper size wire to use for certain circuits in places where it is inconvenient to spread out a chart or consult a table, but this calculator may be consulted anywhere during the progress of work as well as in the office. It can be carried in the pocket and gives instantly the information desired. The calculations are for 50 to 60 volts, 1 ampere on one side, and for 100 to 115 volts, .65 to .50 amperes on the other, and range from 0 to 250,000 lamp feet, with from 1 to 10 per cent. drop or loss. This meets the requirements of all ordinary installations.

By consulting the cut below it will be readily understood how if "You turn the disc, it does the rest." Suppose the problem is to install 50 16 c. p. 110-volt lamps with a loss of 5 per cent., at a distance of 100 feet from the generator or source of energy. Multiply the number of lamps (50) by the distance in feet (100) (see rule on calculator) and we have 5,000 lamp feet. The calculator as it stands in our illustration reads "For from 4,501 to 5,000 lamp feet, etc." Five thousand is therefore included in these figures, and by noting the figures opposite the 5 per cent. mark, it will be seen that No. 10 wire B. & S. gauge is the proper size wire to use.



FOR FROM 4501 TO 5500 LAMP-FEET.
FOR A LOSS OF 1% 2% 3% 4% 5% 6% 8% 10% USE No. 3 6 8 9 10 11 12 13 WIRE B. & S. GAUGE
MORSE'S
PATENT APPLIED FOR
COPYRIGHTED
LIGHTNING CALCULATOR
FOR ELECTRIC LIGHT CIRCUITS
100 TO 115 VOLTS
GIVING AT ONCE THE CORRECT SIZE WIRE FOR ANY GROUP OF 16 C. P. INCANDESCENT LAMPS (OR THEIR EQUIVALENT), AT FROM 100 TO 115 VOLTS, .65 TO .50 AMPERES, UP TO 250.000 LAMP-FEET, FOR 1, 2, 3, 4, 5, 6, 8 AND 10% LOSS OR DROP.
—TO FIND LAMP FEET.—
MULTIPLY THE NUMBER OF LAMPS BY THE DISTANCE IN FEET FROM THE SOURCE OF ENERGY TO CENTER OF DISTRIBUTION. TURN THE DISK UNTIL THE PRODUCT THUS OBTAINED IS INCLUDED IN THE FIGURES ABOVE (IN THE RIBBON), AND THE CORRECT SIZE WIRE FOR THE DIFFERENT PER CENTAGES OF LOSS WILL BE FOUND BELOW. FOR LOWER VOLTAGE SEE OTHER SIDE.

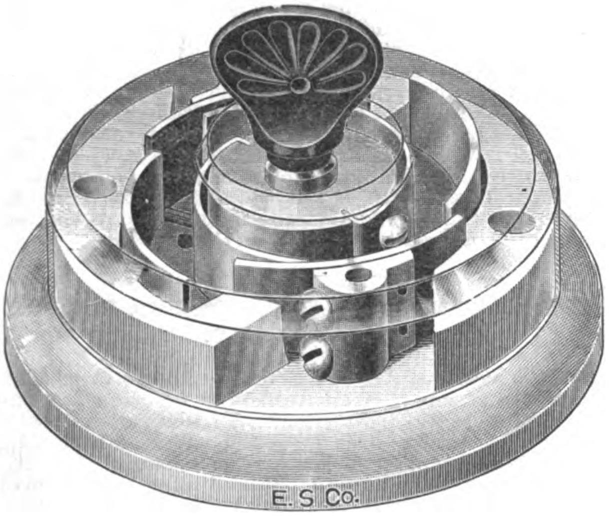
MORSE LIGHTNING CALCULATOR.

The time-saving qualities, together with the accuracy insured by the use of this device, makes the price of 50 cents at which it is sold appear very low. It has been placed on the market by Edward Lasell, N. Y. Life Building, Kansas City, Mo.

A NEW WIRT SNAP SWITCH.

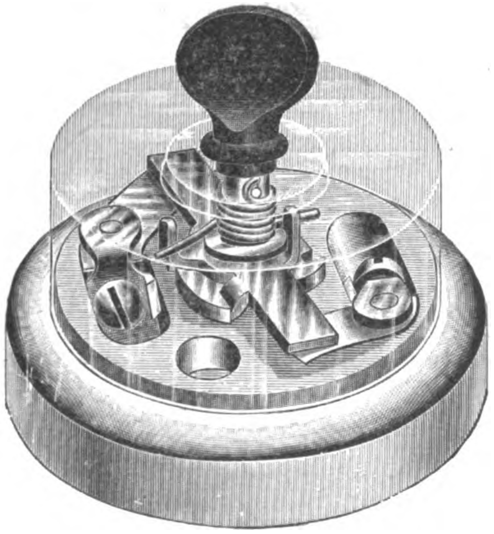
It would seem that the field was pretty well covered in the way of switches and other devices for interrupting or controlling electric currents. But about the time we have settled down to the conviction that the thing is done, and well done, we discover that there are other and probably better ways of doing it. The snap switch shown in the illustration is the design of Mr. Charles Wirt and embodies some distinctively new ideas while it accomplishes the purpose simply and satisfactorily. This is clearly seen by reference to the cut. It is of small size but has a large carrying capacity as it will break the full current of 220 volts without injurious sparking. It is very neat in finish and appearance and is made by the Electrical Supply Co., Chicago.



New Wirt Snap Switch.

THE ACME SINGLE POLE DOUBLE-BREAK SWITCH.

The Electric Appliance Company, of Chicago, are placing upon the market a new double-break switch, which it is claimed combines all the desirable points which can be suggested for an incandescent snap switch, at the same time doing away with the many bad features commonly found in others. The Acme 10-ampere switch measures less than three inches over all and has but two working parts. It is operated by a thumb-piece which unscrews when turned backwards and its action is easy and positive. The wide double break which, combined, measures more than 1¾ inch, will break several times the voltage in ordinary use, thus insuring long life to the switch. The motion of the bar passing over the flexible bronze brushes always keeps the contact surfaces clean and bright. There is embodied in this switch a unique device which is very simple and absolutely mechanical. This releases the bar at the proper time and also prevents it from being turned backwards. The Acme does not depend in the least upon friction between any of its parts to retain the bar until the handle is given the required turn to release it.



The Acme Single Pole Double-Break Switch.

Several new features have been introduced in the construction of the Acme switch which are strongly recommended by first-class line men, including among them being the manner of making connection by means of which the wires entering the switch are always open to inspection and require no extra perforations in the base for their admission to the terminals.

THE ELECTRIC MUTUAL INSURANCE CO.

The announcement is made that the directors of the above company have executed a contract whereby the entire liability under all of its outstanding policies is assumed by the Home Insurance Co., of this city, a strong organization with ten million dollars of assets. The Home Co. will have the benefit of the expert services of Mr. S. E. Barton and Capt. W. M. Brophy, whose work for the Electric Mutual has been so effective in bringing insurance rates on electric plants down to a fair and satisfactory point. Mr. D. A. Heald, the president of the Home Co., at the head of the reinsuring syndicate says that it would agree to authorize a reduction in the rates at the end of, say, two years if at the end of such a period it is found that the existing rates yield an underwriting profit in excess of ten per cent.

NOVELTIES IN STAR ELECTRIX SWITCHES.

We illustrate in this issue a novel switch, Fig. 1, which is being put upon the market by the Star Electrix Co., of Philadelphia. This switch is intended to go into a panel or wall, and, as will be seen, instead of protruding, as is the case with ordinary switches, the handle or button is set in a recess so that the end comes flush with the wall.

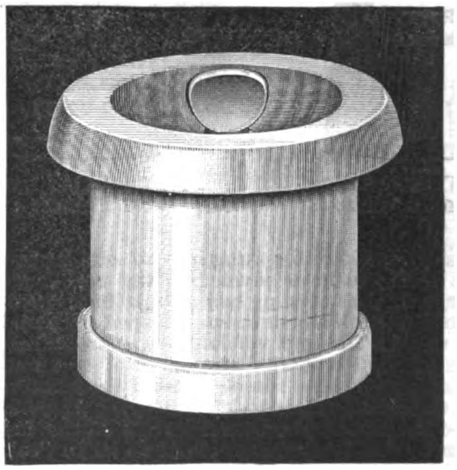


Fig. 1.—The Star Electrix Wall Switch.

We also show, Fig. 2, an interior view of the improved construction of the well-known 10 amp. S. P. Electrix switch. The handles have a large flattened metal nut in their interior, making it impossible to break or twist them off, while the wire connections are provided with a very convenient set-screw.

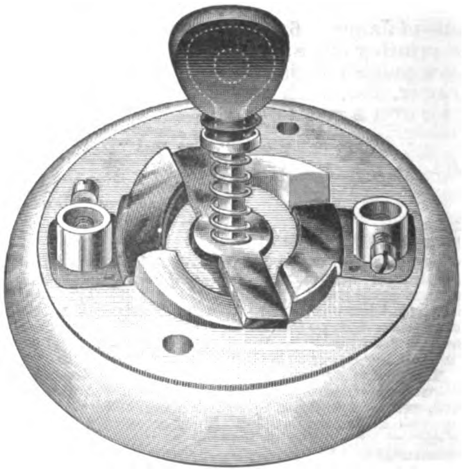

Fig. 2.—The Star Electrix 10-Ampere Switch.

LIGHTING CHICAGO'S ALLEYS.

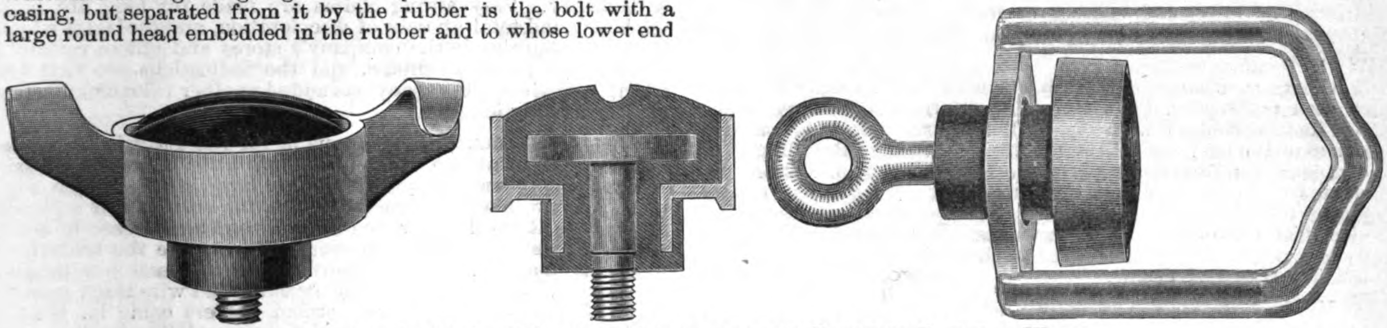
Major McClaughry, Chief of Police of Chicago, in an address at the banquet of the Methodist Social Union, recently made this statement: "Vice flourishes in darkness, and if a 20,000 c. p. arc light was placed in every alley on the South Side of Chicago, more good would be done than if the police force was trebled."

OLD RAILS AS TELEGRAPH POLES.

Old rails are used for telegraph poles in India. Two short pieces of rail are bolted to the foot of a long rail and the ends are buried in the ground. The bracket is of wrought iron, with the ends turned up for the insulators. The cost is less than half of that of wooden posts.

THE "ELLIOTT" INSULATORS FOR ELECTRIC RAILWAY WORK.

The rapid development of electric railway work, with its overspreading network of overhead wires, has induced many manufacturing companies to produce electric insulating devices specially adapted for railway work. Among the most recent to be put on the market are the "Elliott" insulators, manufactured by the Revere Rubber Company, of 63 Franklin street, Boston. Fig. 1 represents the "Elliott" trolley line insulator as applied to the span wire, and Fig. 2 shows the insulating part of it in section. The insulation is composed of a special hard rubber which possesses great strength, and is at the same time tough, and not at all brittle. The outside of the insulator is made of brass, in which are the lugs for going over the span wire. Inside this brass casing, but separated from it by the rubber is the bolt with a large round head embedded in the rubber and to whose lower end is screwed the clip for supporting the trolley wire. It will be seen also that the insulation is turned up round the bottom flange of the outside casing, so that any short-circuiting by moisture is effectively prevented. Fig. 3 shows the "Elliott" pull-off, or strain insulator, the insulation of which is also made of rubber, and is in many respects similar in design to the hanger. It is extremely simple, strong, has high insulating properties, and is at the same time small and light, considering that it will stand a strain of upwards of 8,000 pounds. The Revere Rubber Company are making many other electric specialties, and their large factory at Revere, Mass., is well equipped to turn out the highest class of work in this line.



Figs. 1, 2 and 3.—"Elliott" Insulators for Electric Railway Work.

BROOKLYN NOTES.

The Citizens' Electric Illuminating Co. are making enlargements of their entire plant as rapidly as the work can be pushed. They have nearly completed an addition of 500 h. p., of the Cowles Engineering Co.'s boilers and in the spring will erect a 150-foot chimney. Drawings have been made for a very elaborate arc switchboard which is to control their 74 circuits and 60 dynamos. The circuits are completely interchangeable, and operated without the use of cables. A large alternating switchboard is also to be built.

President Huntley, of the National Electric Light Association, with several other gentlemen, looked over the electric interests of the city with Superintendent Peck, of the Citizens' Co., on January 7th.

A very cheerful and unique display is made over the station of the Edison Electric Illuminating Co. Between the two massive chimneys is suspended a large sign with these words spelled out in vari-colored lamps:

"A Happy New Year,
1892."

From Fulton street at night the effect is beautiful. This was lighted by the fire-alarm for the first time at exactly midnight on the beginning of the new year. The Edison Company will immediately install two triple-expansion, non-condensing engines of 750 h. p. each. They will be coupled direct to two Edison 300 K. W. dynamos Since January 1, forty h. p. of motors have been installed and contracts for isolated plants of 2,700 lights have been closed.

The Water Famine.—During the recent water famine caused by the breaking of a conduit in Brooklyn practically all business requiring power was suspended. The Edison Electric Illuminating Co., however, kept their entire plant running without a stop, in the following enterprising manner: Temporary leases were at once secured on all the available artesian wells. With the aid of a score of carts and an extemporized electric pump just enough water could be secured. Their own well unfortunately became clogged by sand at the outset. In this manner the company was enabled to stand the 36-hour famine, while all others were nearly shut down. The company was offered $100 for a single cartful of water by the *Brooklyn Citizen*, whose edition had got partly through the press when the famine occurred. The water was at once gratuitously given.

Street Railway Matters.—The Mayor's veto still withholds the permission granted by the common council last December to the street railways of this city, giving them the right to operate by electricity. Private consent has cheerfully been given, as well as the sanction of the State Board of Railroad Commissioners, and it is hoped that the mayor will soon withdraw his veto. In this event work will be immediately begun by several roads. The telephone company expect no serious trouble from the trolley system. They have now a large number of metallic circuits. To show the magnitude of telephone work about New York, it may be said that the exchanges within a twenty-mile radius of the city show a list of over 20,000 subscribers.

PHILADELPHIA NOTES.

Electric Club.—The question of organizing an Electric Club in Philadelphia has been agitated for a long time and ought to be accomplished. Such a club properly conducted and supported by the electrical fraternity would be a credit to the city. In order to learn what interest is manifested in such an organization the writer would ask all those who would like to participate in the forwarding of this scheme to send their names to the Electric Club, City Trust Building. If one hundred names are received, each party will be notified to attend a meeting of the whole at some hotel or other designated place.

Mr. G. H. Fisher, Philadelphia agent for Chas. A. Schieren & Co., reports an unusually large demand for the Schieren famous perforated belting. Among the electric light plants which have been recently equipped with this belting are the following: The Diamond Electric Light Co., Columbia Electric Light Co., Southern Electric Light & Power Co., West End Electric Light Co., Powelton Electric Light Co., and the plant at the Gladstone Apartment House.

The Jenkintown (Pa.) Light Co. has just placed an order with the Penna. Electric Engineering Co. for two 1,000-light National alternating current dynamos. The Jenkintown Co. already have a plant of 4,000 lights covering an area of 25 miles, and are lighting 10 stations on the Reading Railroad.

The Pennsylvania Electric Engineering Co. report large sales for their lamp, "The Pennsylvania," from all parts of the country, and from all reports they undoubtedly have one of the most efficient lamps upon the market.

F. A. La Roche, general manager of the La Roche Electric Works, was the recipient, on Christmas eve, of a very handsome solid silver service from the employees of the concern.

NEW YORK NOTES.

THE ALEXANDER-CHAMBERLAIN CO.—The system of entire plant station inspection which the Alexander-Chamberlain Co. are introducing is meeting with flattering success. The adoption of this scheme means to the company the entire supervision of the plant and the attempt to run the same in the most economical manner. Companies which have adopted the A. & C. Co.'s system of inspection have found a material decrease in the cost of running. The plants under the company's care are inspected some once and some twice each week, thus preventing the long standing of the slightest trouble. The Alexander-Chamberlain Co. have just closed a contract with the City Button Works for an arc lamp installation; also a 300 light incandescent plant with an auxiliary storage battery installation.

MR. A. J. BARON, general manager at Wellington, New Zealand, for the Gulcher Electric Light Co., of London, who is making a flying trip through this country, spent a few days in this city recently. So far as possible Mr. Baron has made at least a passing inspection of all electrical devices coming to his notice. He called at the offices of the Ongley Electric Company recently and was very much interested in their system of electric watchman's clocks and recorders, and especially in their new electric alarm for automatic sprinklers, which has been favorably spoken of by the board of fire underwriters in this city. Mr. Baron sails from here to London, thence to New Zealand.

MR. T. J. MURPHY has secured a handsome office in the Electrical Exchange Building. Mr. Murphy has been in the Exchange Building for some time, but has now been compelled to occupy an entire office to accommodate his increasing trade as well as to make room for some handsome sample slate and marble switchboards, etc., of which he makes a specialty. A feature Mr. Murphy is introducing in his business is the making of drawings of switchboards, etc., and sending them direct to the quarries, where all drilling of holes and cutting is done. This saves time and trouble, making it necessary only to assemble the instruments thereon.

COBB, DANBY & KNOTT.—The firm of Cobb, Danby & Knott, general contracting and supervising electrical engineers, which had its inception a few weeks ago has secured a desirable suite of offices on the first floor of the Electrical Exchange Building. The company is now prepared to make bids in open market on contracts for all classes of electrical equipment. The gentlemen composing the firm have all held responsible positions with the larger electrical companies. They are Eastern agents for the Riker dynamos and motors and Hart switches and specialties manufactured at Hartford, Conn.

MR. E. F. KELLEY AND M. R. RODRIGUES have joined forces and hereafter will be known in a business way as the Premier Electric Co. They are located at 11 Whipple street, Brooklyn, and have facilities for handling everything in light repair work. They are also manufacturing a special type of carbon battery, and the Premier dry battery and fan motors of the same name. The shop will be in charge of Mr. Rodrigues, whose work gives evidence of his being a thorough craftsman. Mr. Kelly will look after the sales and business generally.

MR. JAMES H. MASON, inventor of the well-known Mason battery, has been ill at his home in Brooklyn, N. Y., for something over three weeks, his ailment being pneumonia. His many friends will be glad to know that he will soon be on his feet again, although he is not able to do any work at the present time.

THE C. & C. MOTOR CO. report an unusual demand for motors of large capacity. Several orders for 100 horse-power motors have been received. Their present plant is far too small to cope with their increasing business. Early in the spring a much larger factory will be built just outside New York.

THE NEW YORK INSULATED WIRE CO. are about settled in their new offices. The location is a desirable one, and it is needless to say that at 15 Cortlandt street they are within easy reach of all the electrical interests in the city. They have taken the whole suite across the front of the building on the fourth floor.

THE BLAKENEY ELECTRIC CO., 435 Broadway, Brooklyn, N. Y., is introducing a special, neatly constructed and remarkably efficient induction coil for experimental use. Catalogues giving particulars and prices will be mailed. This company manufactures and deals exclusively in experimental apparatus.

MR. C. W. PRICE, a former resident of this city, and until recently a representative of the Northwest Thomson-Houston Co., of St. Paul, Minn., has resigned his position there and returned to New York, where he intends locating.

MR. E. P. THOMPSON, of Temple Court, reports a large sale of his admirable book: "How to Make Inventions." It is a perfect gold mine for inventors and will probably reach several editions.

GEN. O. E. MADDEN has secured in the Electrical Exchange Building a desirable suite of offices which he is fitting up in handsome shape.

AMSTERDAM, N. Y.—The Amsterdam Street Railway Company, Amsterdam, N. Y., since January 1st have combined the offices of secretary and treasurer with that of general manager. This leaves their able manager, Mr. H. K. McCay, open for position at that time.

MR. W. H. WISSING, who has represented the interests of L. J. Wing & Co. in the West for several years, is spending a few days in this city. The Western office of the firm is located at 96 Lake street, Chicago.

WESTERN NOTES.

THE GREAT WESTERN ELECTRIC SUPPLY COMPANY, Nos. 201 to 207 S. Canal street, report a most gratifying increase in the demand for their electrical goods, especially their Sun arc lamp, which is giving universal satisfaction. It can be used singly or in series and gives a most beautiful, steady, white light. They are also receiving large orders for a new focusing arc lamp, several of which are in use in various parts of the city. There is also an ever-increasing demand for their celebratad K. K. wire. They are doing a large business in housegoods supplies, and the sales are increasing daily. The fixture department reports very large sales in Missouri, Louisiana and Illinois. The business of this year compared with last, shows a big gain, while the outlook for 1892 is better than it was this time last year.

THE ELECTRIC APPLIANCE COMPANY report having closed arrangements for the general selling agency for the Standard lamp. The Standard lamp is a new competiter for favor among lamp users, and from results already secured after prolonged and careful tests it promises fair to be a very strong lamp in the field. The Electric Appliance Company have taken hold of this lamp only after a series of most severe tests, which have proven more than satisfactory. Very strong claims are made for long life, high efficiency and total absence of discoloration, and the lamps which have been burning in the company's stores and offices certainly show up to good advantage, and the indications are that the Electric Appliance Company has added another valuable specialty to their already long list.

"**OLD RELIABLE**" is a fitting name for the Electric Merchandise Company, Chicago. Giving its whole attention to the electric railway supply business and carrying a large stock of such supplies, it has won an enviable reputation for prompt and accurate shipment. Recently improved facilities and an increase in stock make the company more than ever ready to serve the trade in a handsome manner. The company reports this season unusually prosperous. Frequent orders for Brand's steel wire track brooms with Wardwell's patent track broom holders come in, besides large orders for motor parts, station, car and line repairs. An encouraging order just received by this company was for 3,000 pounds of the well known "E. M. Co." tape.

MR. WM. HOOD, 239 La Salle street, has just made up a model private lighting plant consisting of gas engine, dynamo and storage batteries. Everything is exceedingly handsome and complete, and he will no doubt sell a large number of small plants for private lighting as there are many advantages clearly shown in this plant that will be appreciated by those who desire a cleaner and more beautiful light than gas, at a reasonable expense.

THE CENTRAL ELECTRIC CO. have just taken the agency for Illinois, Missouri, Nebraska and Indiana for the Interior Conduit & Insulation Company, and will carry in stock at Chicago, St. Louis, Kansas City and Omaha a sufficient supply to meet the demands of the business. This is a very important agency, and the Central Electric Company can be congratulated in securing it.

THE ELECTRIC MERCHANDISE CO. report numerous orders coming in all the time during the cold weather for extra supplies for Burton electric heaters by those who have used them, and are also placing on their books names of many new customers who are adopting this highly desirable method of heating their cars.

NEW PROCESS WELDING AND SPINNING CO.—The annual meeting of the above company was held at its offices, 21 Rialto Building, Chicago, January 5, when the following officers were elected for the ensuing year: Geo. D. Cook, president; Mortimer McRoberts, vice-president, and W. L. Trowbridge, secretary.

THE CENTRAL ELECTRIC CO. report a very flattering increase in their lamp orders, and the immense stock of various voltages and sizes which they carry enables them to make exceedingly prompt shipments, which are being thoroughly appreciated by users of incandescent lamps.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.

VOL. XIII. JANUARY 27, 1892. No. 195.

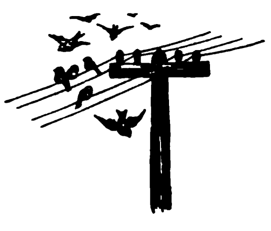
THE NEW EQUIPMENT OF THE WESTERN UNION TELEGRAPH COMPANY'S OFFICE IN NEW YORK.

BY

Alfred S. Brown

Electrical Engineer, Western Union Telegraph Company.

I.



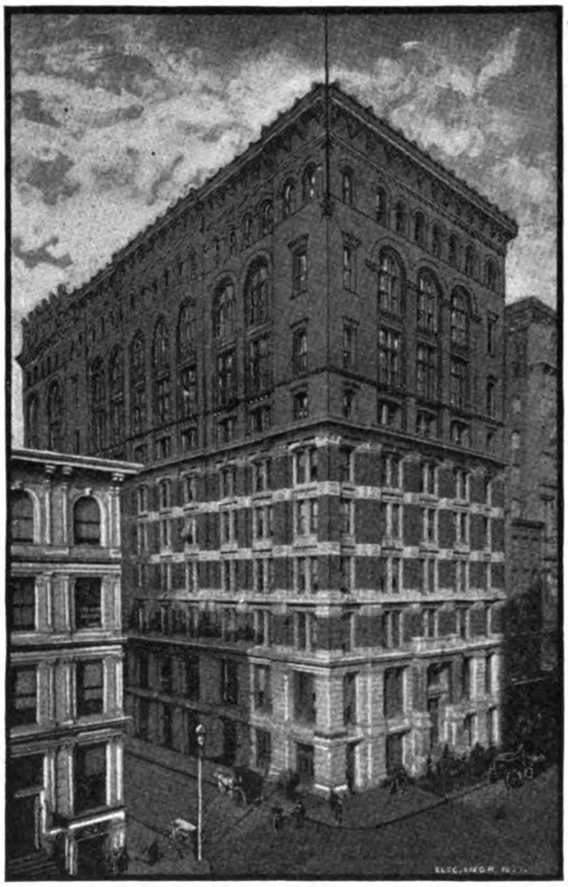
THE new general office of the Western Union Telegraph Company, in New York, is, with one exception, the largest telegraph office in the world. In respect of volume of business handled, it is second only to the London office and a very good second at that. In completeness of equipment and adaptation to all possible requirements of the modern telegraph service it easily takes first rank. It is intended to point out, in the following, some of the characteristics which distinguish this from all other telegraph offices and which are relied upon to establish the claim that it is the best-equipped telegraph office in the world.

The building in which the office is situated was designed and built to meet the peculiar requirements of the telegraph service. It is thoroughly fireproof in construction and every precaution has been taken in fitting it for use to prevent the possibility of a recurrence of such a disaster as destroyed the old office on July 18, 1890.

Two thousand one hundred and fifty wires enter the building from underground conduits. These wires are led in cables of one hundred conductors through iron ducts to a terminal board enclosed in a fireproof vault under the Dey street front. This terminal board is of slate supported in an iron frame and is fitted to receive 3,200 wires. Leaving this vault the cables enter wrought-iron pipes three inches in diameter, a separate pipe being provided for each cable, and are led through two widely separated fireproof shafts, indicated in Fig. 1, to the operating department on the seventh and eighth floors. On reaching these floors the cables, leave the pipes and enter ducts formed in the floors through which they are distributed to the various switches.

The construction of the floors and floor-ducts needs a brief description. The iron floor beams and brick arches are of the usual kind. On these was placed a network of wooden forms or moulds to shape channels from four to six inches deep and twelve inches wide. The spaces intervening between the forms were filled in with concrete, after which the forms were removed and a coating of rock asphalt an inch in thickness was laid on the bottoms and sides of the channels. Over the channels were then laid slabs of slate, thirteen inches wide and one inch thick. The floor between these slabs was then covered with one inch of rock asphalt, which makes the surface of the finished floor. The slate slabs are in short lengths and may be readily lifted out of place, giving convenient access to the wires in the channels.

The finished ducts are three to five inches deep and ten inches wide. They run in parallel lines, crossing each other at right angles at a distance of about eight feet apart, and are so planned as to bring the intersections under the centres of the operators' tables. At each intersection an iron plate 13 inches square takes the place of the slate slab for convenience in reaching the wires without removing the slate. Wires from the floor to the tables lead up up through iron ring frames set in the floor directly under the centre of each "quartet" table and split cast-iron pipes protect the wires between the tables and the floor. The floor channels are filled at intervals of a few feet with sea beach sand as a security against the spread of fire in them.



THE WESTERN UNION TELEGRAPH BUILDING, NEW YORK.

The cables and all of the insulated wire used in the building are covered with fireproof braid outside of the insulating Kerite or "Safety Insulated" compound.

The wire used is of Nos. 16 and 18 B. W. G., insulated to $\frac{6}{32}$ and $\frac{5}{32}$ inches, respectively, exclusive of the braid. Every joint in the office is thoroughly soldered and insulated with as much care as is given to cable jointing. In fact this part of the work was done by a detail from the company's cable crew.

II.

It has been the common practice in telegraph offices to lead all wires to one central point where the switch is located, the point selected being usually, for convenience, directly over the flues or wire-ways leading from above or below. Such an arrangement is plainly objectionable as exposing the most vulnerable point in the office to the greatest danger from fire. In this case, instead of the usual central switch there are five main line switches separated as widely as possible from each other and placed as far as possible from elevator shafts and stairways. The location of these main line switches is shown in the floor plan, Fig. 1.

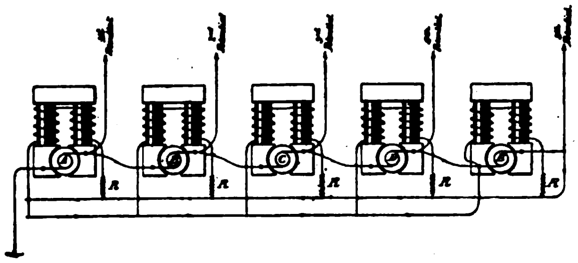


FIG. 5A.—ARRANGEMENT OF TELEGRAPH DYNAMO PLANT.

This method, besides affording greater security from fire, permits each section of the switch to be located in that division of the office where its wires are operated, a feature which becomes of great importance in large offices. For convenience of commumication between the chief operators of the different switches, an office wire is provided connecting all switches and furnished with keys and sounders at convenient intervals on the switch tables.

The five main line switches are of the usual double-jack pattern with a total of ten hundred and twenty-five straps and thirty horizontal rows of discs. They are supported in iron frames with clear glass panels at the ends and front, and are surmounted by frames containing banks of lamps used as resistances, as illustrated in Fig. 2, which shows the "City Lines" switch. About twenty-one hundred of these lamps are in use over the switches, as will be explained later. Behind each main line switch is placed a set of knife switches which, when opened, cut off all dynamo leads and ground connections from the switch. This is only useful as a precaution against fire.

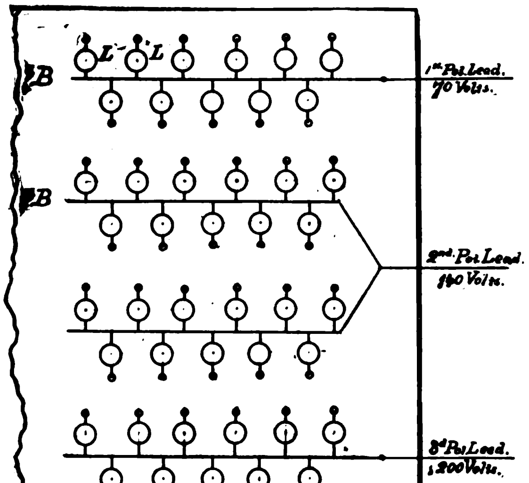

FIG 6.—ARRANGEMENT OF RESISTANCE LAMPS ON SWITCHBOARDS.

The main lines from the street are connected to the switch through "W. B. G" protectors. These protectors consist of a short piece of fuse wire (No. 20) around one end of which is wound a number of turns of No. 30 silk-covered German silver wire. The heating effect of any abnormal current is relied upon to melt the fuse wire. This device is capable of accurate adjustment so as to open the circuit on any desired current with great certainty. In this case the maximum current that the protectors will carry is ¾ ampere. They are placed directly back of the switches. Loops and instrument wires with their cords

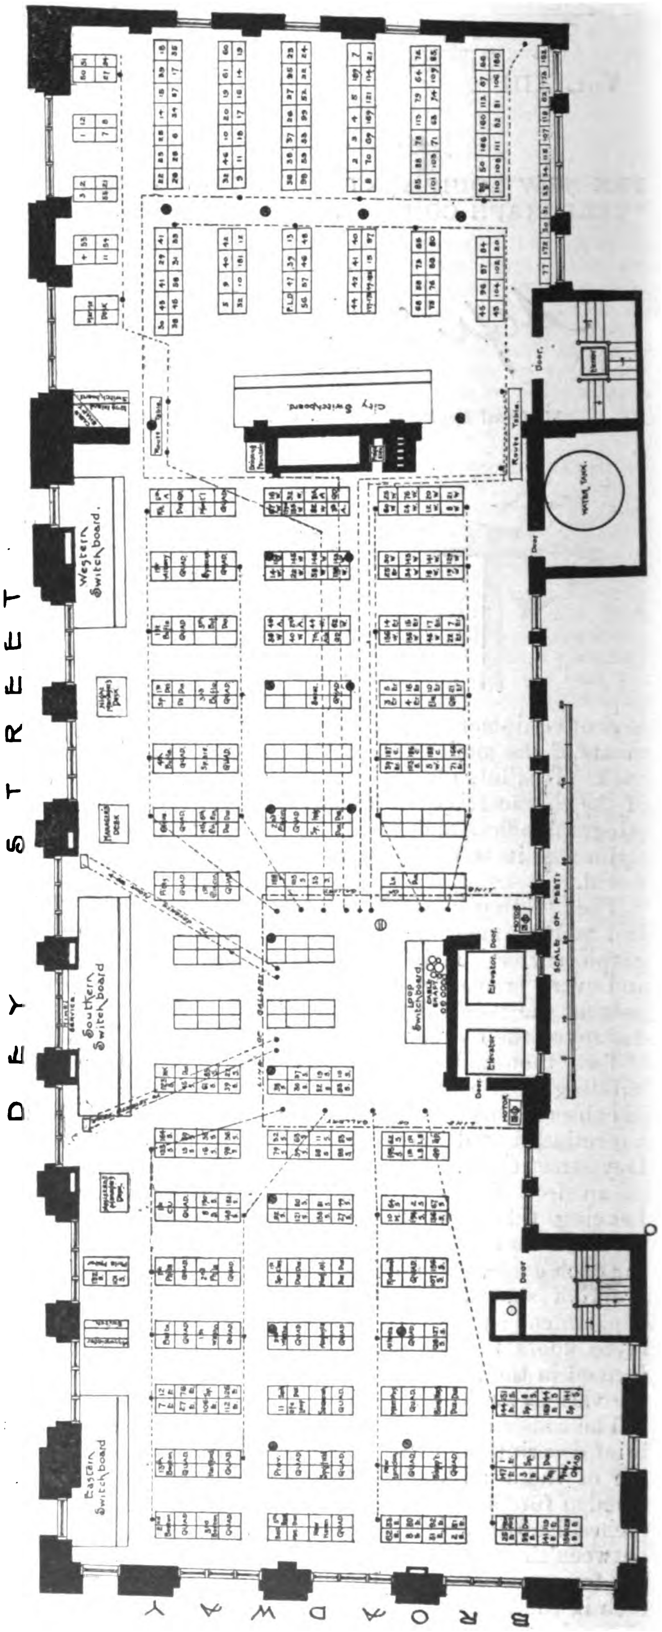

FIG. 1.—PLAN OF GENERAL OPERATING ROOM, 8TH FLOOR.

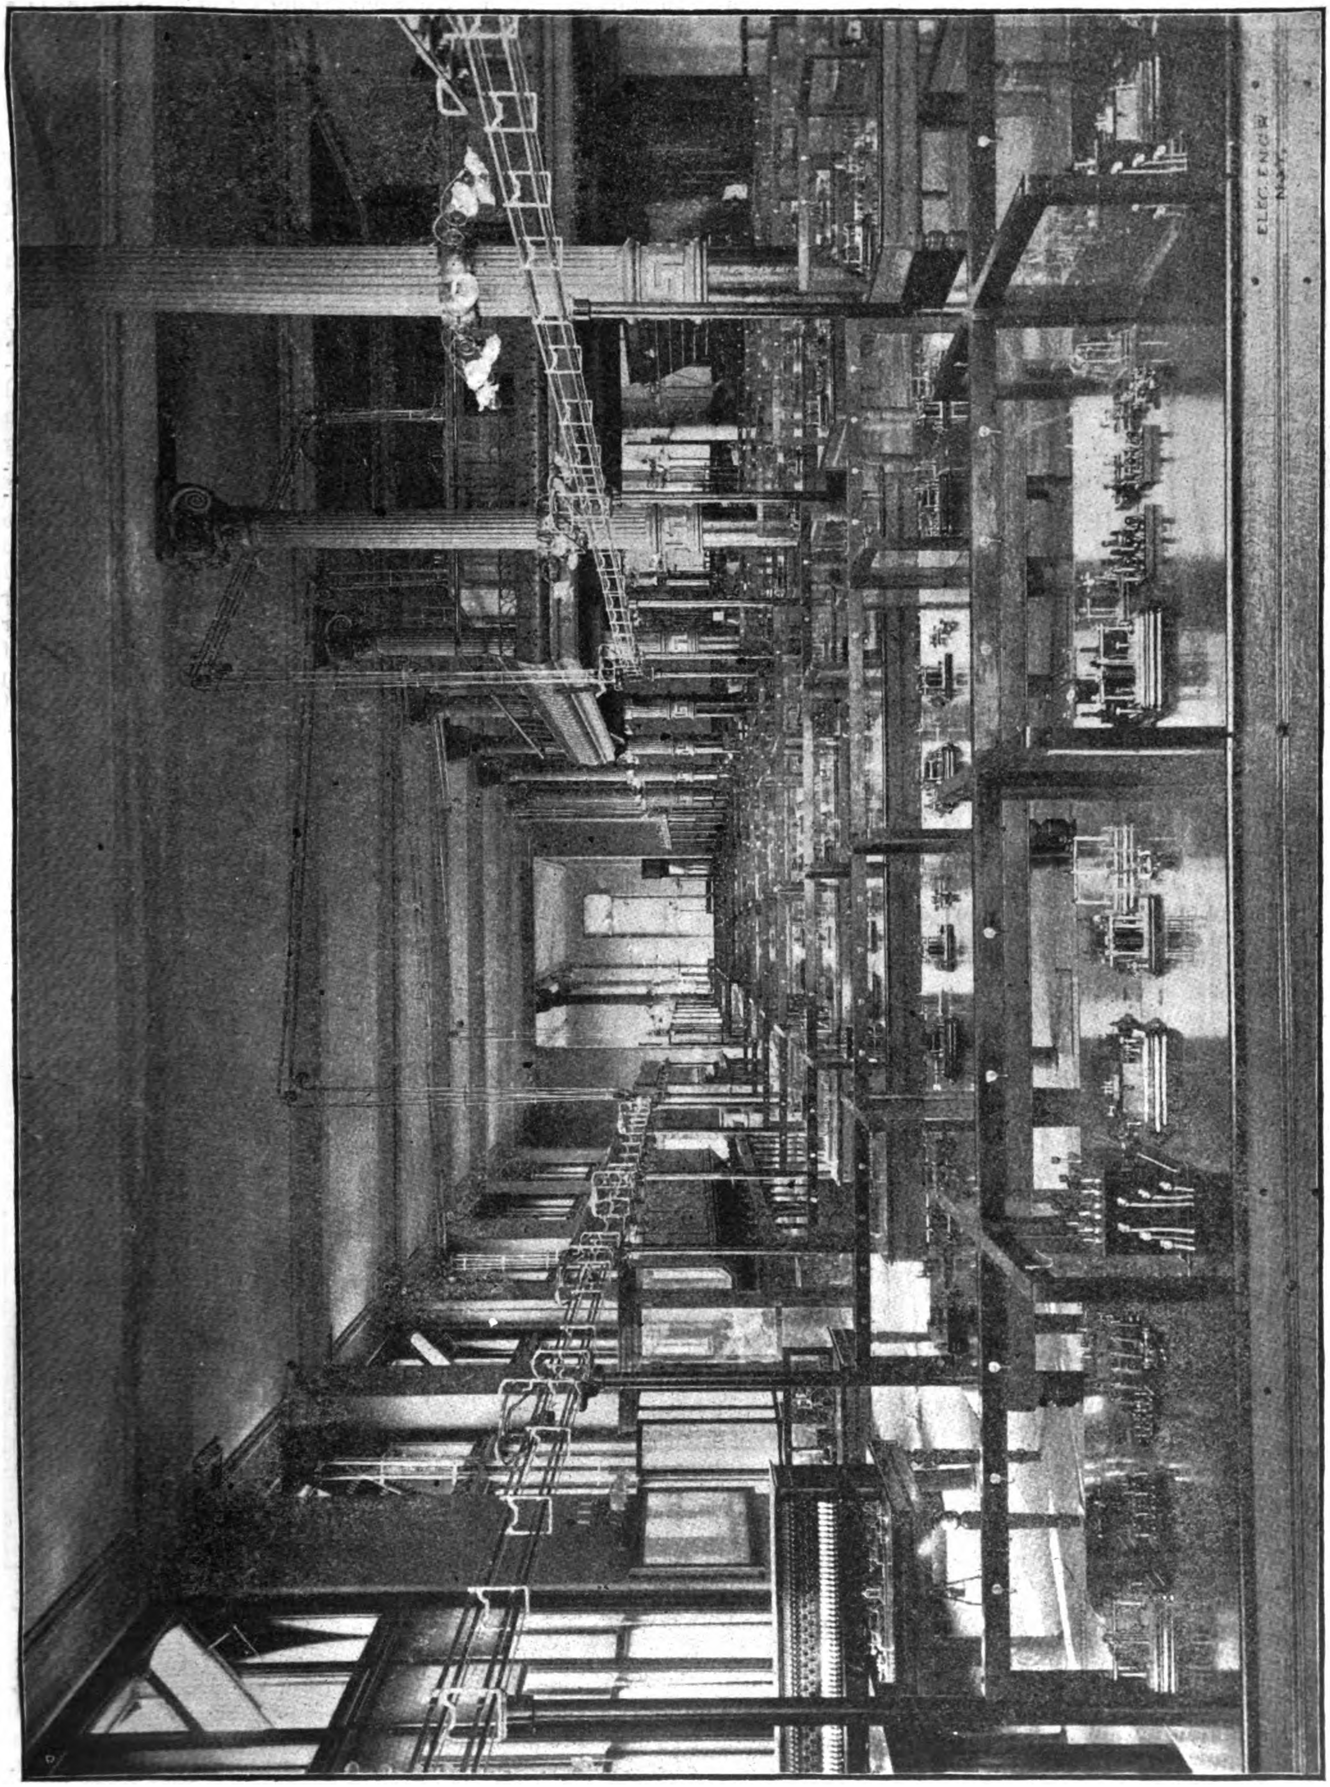

FIG. 10.—THE NEW EQUIPMENT OF THE WESTERN UNION TELEGRAPH CO., NEW YORK.—GENERAL OPERATING ROOM, 8TH FLOOR.

connect with terminal boards, also back of the switches, in the usual way.

In addition to the five main line switches above mentioned there are a number of others used for special purposes. The most important of these is the "Loop Switch," Fig. 3, which is a collection of 375 spring jacks with 450 cords and wedges. The frame supporting this switch carries in the lower part a board with 900 lamp sockets fitted to receive resistance lamps, two for each loop. Every quad and duplex loop entering the office is led directly to this board and connected through a pair of lamps to a double conductor cord terminating in a wedge. The jacks connect with the quad and duplex sets of repeaters, etc., in different parts of the office. Thus any loop may be connected to any multiplex set by inserting the wedge in the proper jack. The lamps have resistances ranging from 20 to 80 ohms and serve to equalize the resistances of the loops, bringing all to a standard of 92 ohms in each "leg" or as nearly as practicable thereto. Nine hundred lamps are required to equip this switch.

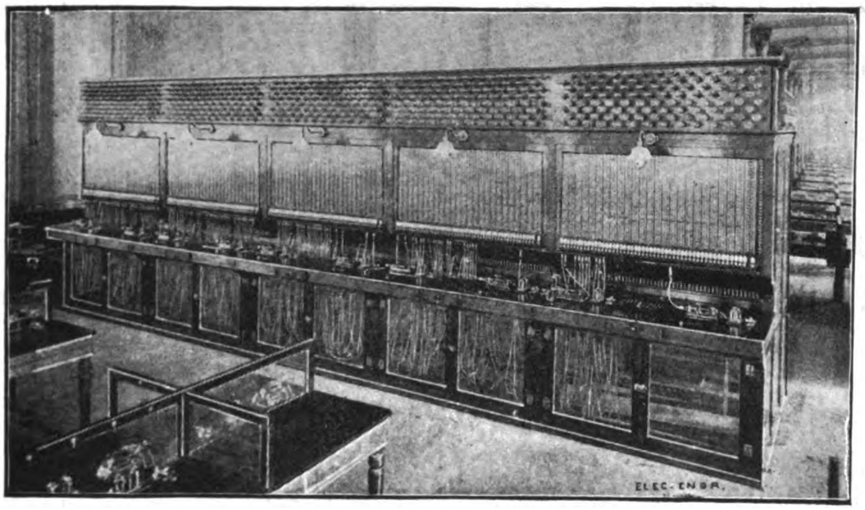

Fig. 2.—The "City Lines" Switchboard.

There are 125 "flying loops," so called, connecting this switch with all other switches, by means of which any wire from any of the other switches may be brought to this switch and thence to any part of the operating rooms. A number of special dynamos used as intermediate batteries are brought in here and may be thrown by means of these "flying loops" into any of the main line switches, as required. The functions of this switch are not unlike those of the central office in a telephone exchange system. This loop switch and the system of operating the multiplex loops connecting with it is due to the skill and ingenuity of Mr. George W. Gardanier, who has succeeded in providing for about every conceivable requirement, or emergency.

Another valuable device is the annunciator switch, Fig. 4, page 82. This consists of 100 annunciator drops set in a frame with an equal number of spring-jacks connected with an automatic alarm in the usual way. The magnets operating the drops are of low resistance, that is, about two ohms. Each magnet is assigned to, and kept in circuit in, one of the leased wires and is between the loop running to the lessee's office and the dynamo. Its purpose is to enable the lessee's operator, without any delay, to call the attention of the chief operator in the general office to any interruption on the wire. To do this the lessee's operator "grounds" for an instant the wire in his office by touching a button. This, of course, throws through the annunciator magnet a current strong enough to operate the drop and ring a signal bell. The operator in charge at once connects into the circuit through the spring-jack and without loss of time is in communication with the lessee's office. This device is the invention of Mr. James B. Hurd and is a valuable addition to the office equipment.

Another piece of apparatus which has an important function to perform is the "time repeater." At noon every week day a signal is received from the U. S. Naval Observatory, at Washington, which indicates the exact hour. This signal is sent out from New York in all directions, at the present time on sixty different lines. The "time repeater" consists of ninety-two repeating magnets operated by local current through the points of a relay in the Washington circuit. The repeating points of the ninety-two magnets connect by as many loops to the five main-line switches where they are connected to the lines over which the time signal is to be sent. This apparatus can also be used as a repeater for sending dispatches over a number of wires at one operation. For example, election returns, bulletins of which have to be sent out on election night in every direction, may now be sent on nearly a hundred lines by one operator.

A good idea of the general arrangement of the operating room on the eighth floor will be gained from the engraving, Fig. 10, page 80.

The seventh floor contains the Wheatstone instruments, the automatic repeaters (Milliken-Hicks pattern), the quadruplex apparatus instruments used on such lines as are operated by branch offices direct and not requiring operators at the central office, the Gold and Stock quotation service, the commercial news department, etc. The latter have switchboards devoted specially to this service. About thirty perforating machines are required for preparing messages for transmission by the Wheatstone instruments, and as many typewriters copy the received slips for delivery. Four Wheatstone circuits are in operation, two to Chicago, one each to St. Louis and New Orleans. On the Chicago circuits a speed of 175 words per minute is easily attained with one repeater in circuit at Buffalo.

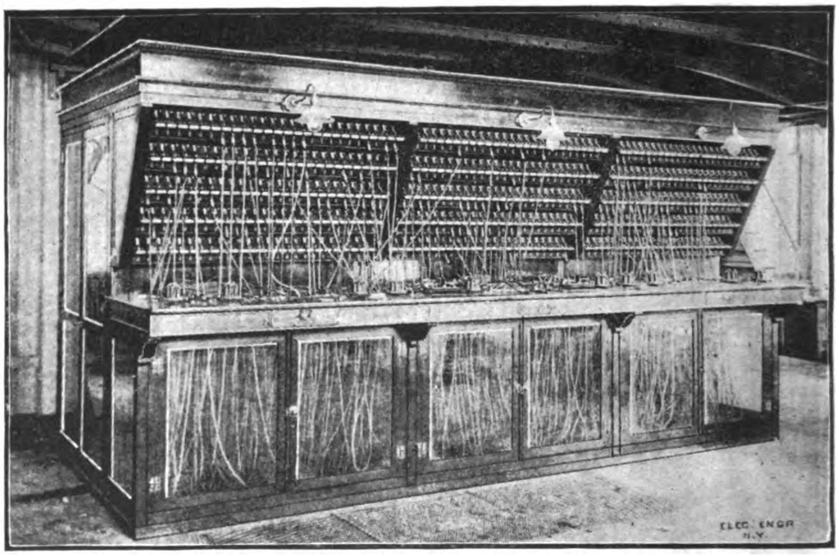

Fig. 3.—The Loop Switch Under Distributing Gallery.

Of the automatic repeaters there are fourteen in readiness for use. New York being the natural terminus of all circuit, a large number of repeaters is not required. They are all connected with the loop switch through which they can be connected with any lines entering the office.

The quadruplex sets on this floor are thirty in number and as they are operated by branch offices only, are compactly placed, a complete set (four "sides") on one desk.

There are five transmitting machines on the seventh floor for sending out quotations to as many classes of tickers, viz., produce, cotton, petroleum, coffee and financial news. The transmitters are each operated by small electric motors.

III.

In the cellar under the Broadway end of the building are the dynamos which supply the currents for telegraph work. The first dynamos ever used as substitutes for chemical batteries to furnish currents for telegraph purposes were placed in the New York office by Mr. Stephen D. Field, in 1880. Previous to their introduction, about 20,000 cells of "gravity" battery were used in the office.

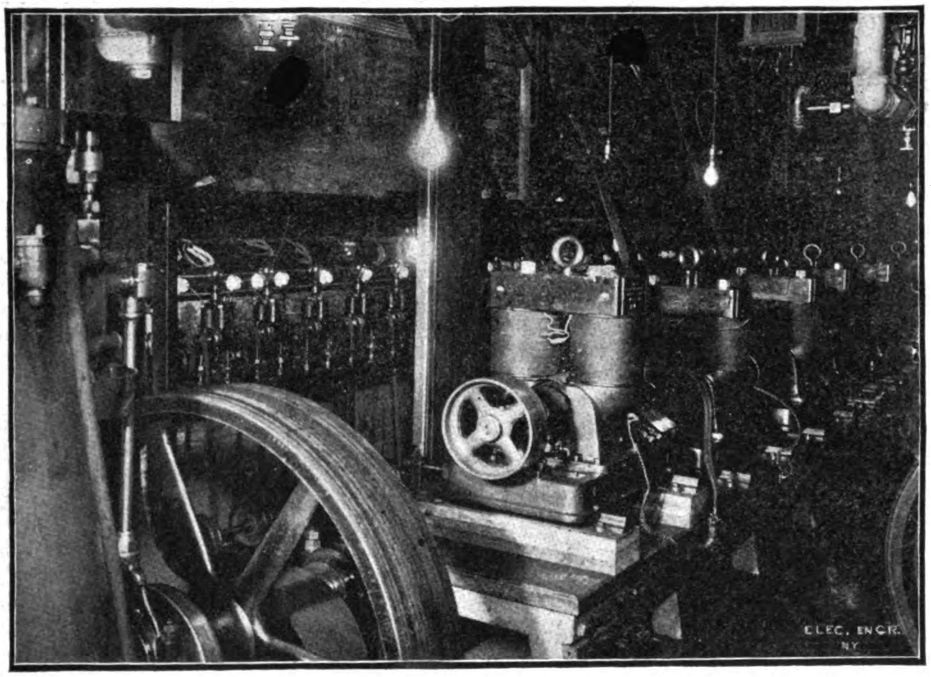

FIG. 5.—ONE SECTION OF DYNAMO TELEGRAPH PLANT, WESTERN UNION BUILDING, N. Y.
(*Taken by flash light.*)

The original dynamos replaced all but about eight thousand cells, that number being retained for locals, intermediate mains, etc. At the date of the fire in 1890 the office contained about 10,000 cells, nearly the whole of the sixth floor of the old building being occupied by the cells The great superiority of the dynamos over the batteries in efficiency of service, low cost of maintenance and saving of room had been abundantly demonstrated, and it was determined that in the reconstructed office dynamo currents should replace all others. So thoroughly has this plan been carried out that not a single cell of battery now remains in the building.

There are three gangs of dynamos supplying main-line currents, each gang consisting of five Edison 40-ampere machines connected in series and a view of which is given in Fig. 5. The first and second of each series have a potential difference of 70 volts each, and the third, fourth and fifth, 60 volts each. Leads from each machine carry currents of 70, 140, 200, 260 and 320 volts to resistance lamps in the operating department. The three lower potentials, only, are carried to the switches, the 260 and 320 volt leads being used exclusively for duplex and quadruplex circuits which take their currents through a separate bank of lamps. One gang of dynamos furnishes positive, and one negative currents. The third is a spare or relief gang and is so connected through a reversing switch in the dynamo-room that it may supply currents of either polarity, as required, to relieve either of the others. There are also two 80-ampere machines supplying currents at 23 volts for loops; two 300-ampere machines supplying currents at 7 volts for locals, and two 40-ampere machines supplying currents at 45 volts for city and short-line service. Of these lower-voltage machines only one of each pair is in use at one time, the other being held in reserve. Each gang is driven by a separate vertical engine of 16 h. p., running at 160 revolutions. The dynamos all run at 1,250 revolutions, belting from overhead shafting. The fields of all the machines in each gang are in multiple and are excited by a 60-volt current from the fifth machine of the series, as shown in Fig. 5A, page 78, this machine having less work to do than either of the others.

The dynamo switchboard contains indicators connected with the 4th potential, positive and negative leads, also for the three 5th potential machines and for the low-voltage machines, as well as regulators for each of the three 5th potential and for the six local loop and city dynamos. Regulators for all the others are placed directly over their respective machines.

There are in this room, in addition, 30 small dynamos ranged along the wall, as seen in Fig. 5, and used as intermediate main-line batteries. These deliver currents at from 50 to 125 volts, each machine having attached to it a one-half ampere lamp connected permanently in the circuit. As each feeds one wire only, they normally supply currents of .03 or .04 ampere.

The 1st, 2nd and 3d potential leads from the dynamos terminate in the operating-room in bus-bars placed directly over the switches, Fig. 6, page 78, in which B B are bus-bars and L L lamps. The lamps are held in sockets, one terminal of each connecting with its bus-bar and the other (through a short wire on the back of the board, not shown in the figure), with a disc in the switch directly beneath. Each lamp connects with one disc only. One horizontal row of discs is assigned to the first potential lamps, two rows to the second and one to the third. As comparatively few wires are worked on the 1st and 3d potentials and many on the 2nd, the latter has two rows of discs assigned to it, so as to avoid having to feed two wires through one lamp, which is objectionable for the same reasons that make it objectionable to work two wires from one battery.

The lamps used are specially designed for the purpose. The 1st potential lamps have one filament measuring (cold) 140 ohms; the 2nd have two in series measuring 280 ohms, and the 3d three in series measuring 400 ohms. On short circuit, with the currents supplied from the dynamos, these lamps all carry six-tenths ampere, showing with that current a dull red glow. This serves a valuable purpose as a signal calling attention to ground connections on the lines. Whenever a lamp is seen to glow, the chief operator knows at once that the line connected to the disc and strap directly below is grounded, without waiting for a report from the operator.

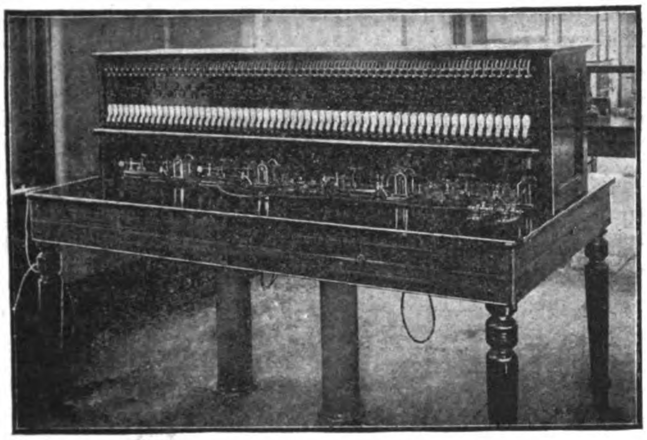

FIG. 4.—THE ANNUNCIATOR SWITCH FOR LEASED LINES.

It is to be noted that dynamo leads of only one polarity are connected with any one switch. The Eastern switch 200 lines, Long Island switch 75 lines, and the City switch 250 lines, are supplied with positive currents only, and the Southern switch 300 lines, and Western switch 200 lines, with negative currents only.

The local (7 volt) dynamos supply currents for operating all Morse and repeater sounders, the former being wound to 100 ohms. The repeater sounders, requiring extremely prompt action, are wound to 20 ohms and a non-inductive resistance of 20 ohms is placed in circuit with each. The multiplex loops are operated with the current of 23 volts, the resistance of each leg of each loop being adjusted to about 92 ohms. The loop magnets are wound to four ohms and the transmitter magnets each to six ohms. A considerable number of branch offices, as many in some cases as ten, are connected on one loop.

IV.

In a large telegraph office one of the first essentials to the proper handling of business is a means of rapid and continuous communication between all its parts. The London office depends upon pneumatic tubes for this purpose. In the New York office the requirements have been very successfully met by means of a cable carrier system. On the 8th floor, a plan of which is shown in Fig. 1, in the centre of the room, is a gallery 35 by 20 feet from which radiate 16 lines of message carrier railways each being a double-track line wtih four to six stations. The engraving Fig. 7, will give a good idea of the arrangement for the delivery and distribution of messages.

The system employed is an adaptation of the "Martin cash carrier" system and consists essentially of a number of double-track miniature cable railways radiating from the central station on the gallery. The carriers are so constructed that they drop the driving cable and are automatically "side tracked" at the particular station on the floor for which they are intended. There are at present 57 stations on the two floors, the location of those on the 8th floor being shown in Fig. 1. Two 5 h. p. Crocker-Wheeler motors furnish the power for running this system, one only being in use, while the other is held in reserve. Fig. 8 shows one of these motors driving a shaft under the gallery. The speed of the carriers is about 750 feet per minute and as the longest line is not more than 125 feet in length the most distant station is reached in ten seconds.

The gallery also contains the terminal valves of 24 pneumatic house tubes communicating with the receiving and delivery departments, the executive floor and other departments. Four pneumatic tubes to Twenty-third street and intermediate offices and four to the exchanges below Wall street are also operated from this gallery. Thus all messages coming into, and going out of, the general operating department must pass through this central distributing point.

V.

The pneumatic system is quite extensive. Four tubes of 3 inches internal diameter extend from Dey street through Broadway, Fourteenth street and Fifth avenue to the company's building at the corner of Twenty-third street. Two of these tubes, one for up and one for down business, have way-stations at Nos. 407, 549 and 854 Broadway; the other two run through to Twenty-third street direct. The tubes are of brass, weighing three pounds per foot. They are in 20-foot lengths with accurately fitted flanged couplings at each joint. They are laid in boxes of creosoted 2-inch spruce plank about three feet below the surface and near the middle of the street. Manholes three feet square are placed at intervals of 400 to 450 feet and in every alternate manhole expansion joints are provided. Two 2¼ inch tubes of similar construction extend from Dey street through Broadway, Maiden Lane and Pearl street to the company's office 134 Pearl and the Cotton Exchange, and two others through Broadway, Wall and Broad streets to the company's building, No. 16 Broad street and the Stock Exchange, with a way station in the Equitable Building. Six other single lines of tube 1⅝ inch in diameter extend through Broadway and Park Row to the offices of the daily morning papers. There is altogether a total length of 70,320 feet (over 13 miles) of underground tube in operation.

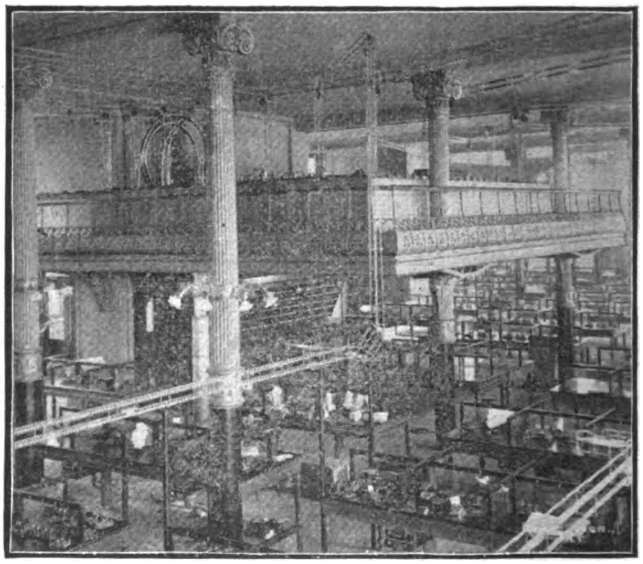

FIG. 7.—THE "MARTIN" CABLE CARRIER DISTRIBUTING SYSTEM.

The tubes running to Twenty-third street are operated by vacuum alone, power being provided at both ends of the line. The speed attained on these tubes is about 24 miles an hour with the gauge showing 22 inches, which is the usual working vacuum. With both pressure and vacuum, carriers have made the distance between the general office and Twenty-third street (13,454 feet) in 2 min. 38 secs.; but a pressure of 22 pounds in addition to 20 in. of vacuum was required to accomplish this. The shorter tubes are operated by pressure for outgoing and vacuum for incoming carriers, 7 pounds pressure and 15 inches vacuum being the usual standard. All lines are double, that is, one tube for up and one tube for down business, except those to the newspaper offices. The latter are therefore provided with signal wires. But in all cases the double-line tubes are operated without signals, carriers following each other as fast as occasion may require. The capacity of the tubes is therefore far greater than where a block signal system is used, as is always done in Europe, and no inconvenience has been found to arise from the practice followed here.

The cellar under the Western Union Building contains the engines and air pumps which operate the tubes. These consist of two horizontal direct-acting adjustable cut-off duplex engines and air pumps, shown in Fig. 9. The steam cylinders are 20 in. and the air cylinders 32 in. in diameter and 36 in. stroke. With 80 pounds steam pressure the engines are capable of developing 125 h. p. for each cylinder, that is, a total of 500 h. p., but nothing like this amount of power is required for ordinary operations. As now working they develop about 40 h. p. Each engine has a fly-wheel 14 feet in diameter, weighing seven tons. Pressure and vacuum tanks are provided of suitable capacity to secure easy and regular working. The whole plant is duplicated at the Twenty-third street building.

At times there is more or less water in the tubes due to condensation; this makes necessary the use of carriers which will protect their contents from dampness. The carriers are of a rubber compound in the form of a tube slightly smaller in diameter than the pneumatic tube and about seven inches long, the bottom being closed with a flange fitting easily the tube and the top covered by a flanged cap screwed on the carrier. These carriers are a trifle heavy but are strong and durable as well as waterproof.

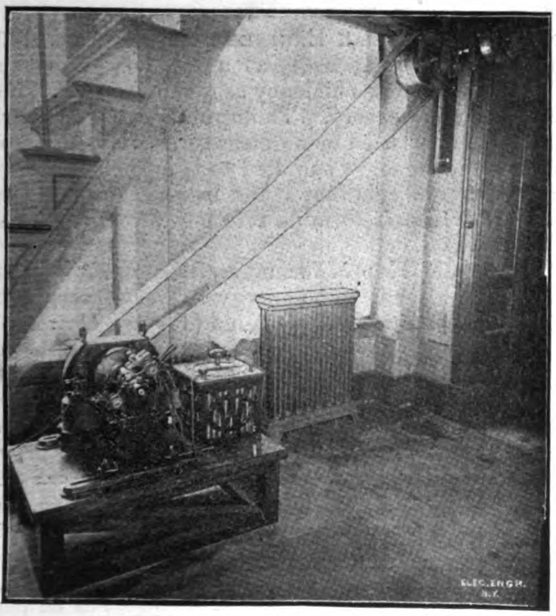

FIG. 8.—CROCKER-WHEELER MOTOR FOR DRIVING CABLE CARRIER SYSTEM.

VI.

The building is lighted throughout by electricity, the current for the purpose being supplied by three Edison No. 16 (45 K. W.) machines, driven by three 75 h. p. "Straight-Line" engines. These are situated in a room adjoining the telegraph dynamo-room. Steam is supplied from the street mains, but for security against accidental interruptions to this supply there are in the building six boilers always kept ready to fire up at a moment's notice.

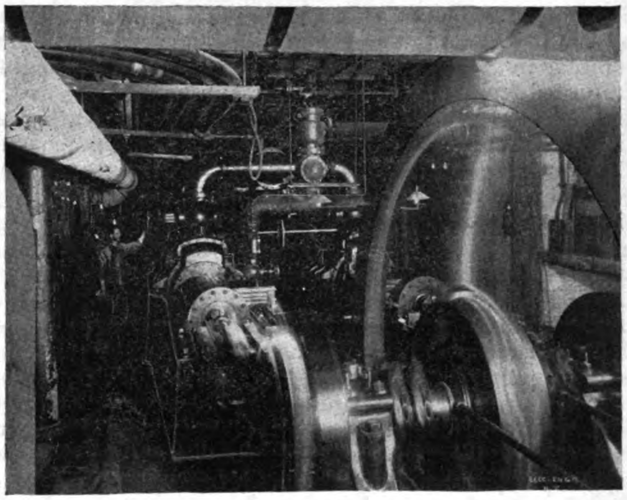

FIG. 9.—ENGINES AND AIR PUMPS OF THE PNEUMATIC TUBE SYSTEM.—(*Taken by flash light.*)

The building as a whole, or at least the reconstructed part, which comprises all above the fifth story, is in marked contrast to the old building, which was regarded at the time of its completion, just seventeen years ago, as a model telegraph building. But the enormous growth of the telegraph business had made the old quarters quite inadequate long before the fire occurred which necessitated the reconstruction, and the company acted wisely in placing in the hands of General Eckert, its vice-president and general manager, full power to construct such a building as would meet the wants of the present and as much of the future as it is possible to foresee. Under his supervision, not only the requirements of the operating department, but also of all the executive departments of the company have been carefully and amply provided for.

Some statistics of interest as showing the magnitude of the business here transacted may be of interest. About 750 lines radiate from the building, by far the larger number being operated by the familiar Morse system. There are four lines operated by Wheatstone, forty-two duplex and sixty-two quadruplex lines. Two lines are operated by "combination" printing instruments. The office is provided with fourteen automatic repeaters, and has accommodations altogether for about eight hundred operators. The longest circuit is from New York to San Francisco, about 3,400 miles. The volume of business varies slightly at different seasons, but the daily average for the year is over 100,000 messages, exclusive of press reports.

WORKS ON THE TELEPHONE.

MESSRS. WHITTAKER & Co., of London, have made arrangements with the editor of *El Telegrafista Espanol* for the translation into Spanish of Mr. Preece's work upon "The Telephone." The book already has been translated into both French and German. The same firm will publish shortly, in a cheap form, Mr. A. R. Bennett's papers on the "Telephoning of Great Cities" and the "Electrical Parcel Exchange System," which attracted considerable attention at last year's British Association meeting.

THE WESTERN UNION'S NEW OFFICES.

The contribution of Mr. Alfred S. Brown, the electrical engineer of the Western Union Telegraph Co., which will be found elsewhere in this issue will give an excellent idea of the electrical and mechanical equipment of the new offices of the Western Union Co. in New York ; but our readers may also be interested in a few details relating to the general equipment.

On the seventh and eighth floors is the general operating department. The dimensions of each of these floors are 75 by 200 feet, having windows on all sides, 36 on each floor, ranging in width from 5 to 14 feet. At night light is furnished from 600 incandescent lamps. At the east, or Broadway end of the seventh floor is the Superintendent's Office ; at the west end is the book-keeping department. Between them is the Commercial News department, which collects and distributes the quotation service. These consist of stock, grain, oil, cotton, coffee, financial and general news tickers, besides Morse wires connecting with all the exchanges and all the principal cities of the country. On this floor, also, enter the wires leased to brokers, newspapers, etc., and the Wheatstone automatic system. Thirty or more "punchers," as the demands of the service require, prepare the messages for transmission by this system and as many typewriters copy the messages from the slips as they roll out from the receiving instruments. Next to the Wheatstone service and near to the book-keeping department where the files of messages are kept are the assorters, inspectors and service clerks, the first keeping the business of the office arranged in alphabetical order of place of destination, the second noting that every message bears proper indication of transmission and the service clerks making, or attending to, any necessary inquiries.

On the eighth floor are the wires to the Southern, Eastern and Western points, also the City, Long Island, and Suburban wires. On this floor there are accommodations for upwards of 1,000 operators and other employees. Here are the simplex, Morse, duplex, quadruplex Phelps, motor-printer, and marine circuits,—the latter to Quarantine, Highlands, Sandy Hook, City Island, Fire Island ; also the special circuits for the transmission and reception of United States Government weather signals. Over the Marine Circuits are received the reports of all incoming steamers and other vessels.

On the gallery in the centre and on the north side of the room the entire business of the two floors is handled by an efficient corps of assorters and distributing clerks. The pneumatic tubes are on this gallery in connection with the receiving and delivery department on the basement floor, and with the several offices and floors of the building ; also with down-town exchanges, and with the 23d Street Western Union Building, and intermediate uptown offices. The pneumatic tubes to the newspaper offices are worked from the delivery department on the basement floor. There are also on this gallery two revolving belts to facilitate the passage of business to and from the pneumatic tubes and carriers.

Thirty-six cables, containing conductors, enter the building underground to the test board in the cellar. On the seventh floor there are four switchboards and on the eighth six, manufactured by the Western Electric Co., who also furnished the complete equipment of sounders, relays, repeaters and accessory apparatus for the new offices throughout. The total number of flexible switchcords in connection with the various switchboards is about 2,000. Current for the wires is generated by 41 dynamos in the cellar, the larger machines of the Edison type and the smaller made by the C. & C. Electric Company.

Of the 200 miles of insulated wire employed in effecting the various office connections, part consists of Kerite, furnished by A. G. Day, and part of wire of the Safety Insulated Wire Co., of New York.

Wardrobe facilities and the lunch room are on the ninth floor. Here lunch is served to employees between 11.30 A. M. and 3 P. M., and again from 7 to 9 P. M. The kitchen is on the tenth floor and is supplied with all the latest improvements in the culinary art. About one-third of the 1,200 employees of the operating department are women.

On the other general circuits are transmitted and received business to and from all points in the United States and Canada land-line circuits in connection with the European, Bermuda, Nassau, Cuba, West Indies and South America cable stations; all being worked from this floor jointly, or separately, with the service at the Central Cable Office, No. 16 Broad street, from which latter office there are also worked by the recorder system the two ocean cables to Europe. These cables and land lines are also connected into the office at the Stock Exchange, and in addition thereto direct wires from all cable centres of the country are connected at and worked from the "Central Cable" and "Stock Exchange" offices. In connection with the cable service it is interesting to note that the direct wire from the central cable office to San Francisco—the longest in the world—is 3,348 miles in length, and that the next longest is that to Galveston, 1,820 miles. These circuits are worked duplex.

Messages between the seventh and eighth floors and from any section of one floor to another section of the same floor and the same with regard to any section on the other floor are handled by the Martin cable carrier system, there being 57 stations. This system is a modification of the Martin cash carrier system and was installed by the Martin Cash Carrier Co., of Springfield, Mass. The architect of the new building was Henry J. Hardenbergh, of New York.

THE EXPRESSION FOR THE WORK DONE BY MOTORS.

BY

Samuel Sheldon

In The Electrical Engineer for Jan. 20, 1892, Mr. Arner indicates that he is at a loss how to reconcile the formulæ for motor efficiency as given by S. P. Thompson and Kapp, respectively. Thompson's formula refers to a motor, which, if used as a generator, would transform all the mechanical energy supplied to it into electrical energy. Thompson states this fact at the beginning of his chapter on motors. Kapp's formula refers to a real motor, such as we buy.

To reconcile Kapp's formula with Joule's law, take the first case tabulated. The energy fed each second to the motor $= E\,C = 4{,}500$. Of this $(E - e)\,C = 405$ watts is dissipated in heat. There is a further loss because of friction, etc. Its amount can be determined from the results of the experiment cited, where four amperes were required to run the motor when unloaded. In this experiment the energy given each second to the motor was 400 watts. The loss from heat $C^2\,R = 16 \times 0.2 = 3.2$. The difference, 396.8, is required to overcome friction, etc.

We have, therefore, in (1) : Loss from heat, 405 ; loss from friction, etc., 396.8.

$$\text{Efficiency} = \frac{\text{Useful energy,}}{\text{Energy supplied,}} = \frac{3698.2}{4500} = 82 \text{ per cent.}$$

For (2) : Loss from heat, 80 ; loss from friction, 396.8.

$$\text{Efficiency} = \frac{\text{Useful energy,}}{\text{Energy supplied,}} = \frac{1523.2}{2000.0} = 76 \text{ per cent.}$$

For (3) : Loss from heat, 1125; loss from friction, 396.8.

$$\text{Efficiency} = \frac{\text{Useful energy,}}{\text{Energy supplied,}} = \frac{5978.2}{7500.0} = 80 \text{ per cent.}$$

THE CARE OF RAILWAY MOTORS.

BY

Lucius E. Marple.

Queerly managed roads are sometimes to be found in out-of-the-way towns. The dynamo tender at the light and power plant dispenses all the electrical knowledge to be had, while the superintendent is perhaps busy performing the additional office of treasurer. All the electrical instructions that were given on the founding of the road have been handed along in tradition by the motor-men, undergoing curious modifications meantime.

In many larger towns as well, it is likewise the fact that the men are ill-instructed how to handle their cars. Scarcely any piece of machinery is more simple and economical than an electric motor, yet even it has its limits of endurance—it is costly apparatus and should be treated with care. Skilled men are not needed to operate it, but the rules of its makers should be observed to some extent. An eminent engineer recently remarked that the success of any electric road was in the hands of the armature-winders and motor-men.

The managers of several enterprising roads keep a reading-room of electrical books and papers for their men, and in addition to this it is found profitable to give them talks on the management of their cars.

Of course the first requirement of a motor-man is caution added to common sense. He should be required to examine his motors near the end of every trip, and if a little informed, he may save his company many dollars in the course of the year by fixing on the spot, either temporarily or otherwise, any small trouble that may occur, such for instance, as loose connections, broken brush-springs, and the like.

Almost every system has its own way of controlling the current, but a few points may be mentioned in general which are common to all systems. How to hurry a car is an art that but few motor-men attain properly. The current should not be thrown half on instantly. Let the car start very easily, and when a little motion has been gained it can be applied much faster. On the other hand, if time is to spare, do not drag the car along on the first points of the switch. It requires much less power and is easier on the armatures to run at a higher speed, and then to coast when opportunities are given. Get all the power on as soon as practicable in going up a hill (excepting some systems where the last point on the switch or the "loop" is only to be used for speed on nearly level ground).

It is not economy to ascend a steep hill or to run any length of time with only half the power on.

The delight of a new motor-man is to try the reversing effect on his car, and this of course is of no material benefit to it either. When for some reason the car does not start as soon as the current is applied, do not throw it all on immediately. If half of the current will not start the car, stop and investigate the cause. It is harmless even to caution motor-men not to leave the switch partly on in such an event. I remember to have seen such a case, where the motor-man found at length the trolley was off, and on replacing it was rather startled to see his car sail off and leave him.

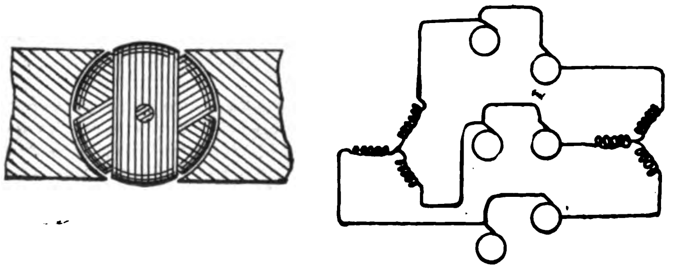
The vital parts of the motor are the commutator and its fittings. It should be constantly examined for surface irregularities, which work ruin to both it and the brushes, and consequently the motor. This in many cases is the primary cause of burnt-up brush springs.

It should be the chief feature of the work of night cleaners to see that every part of the commutator and its fittings is thoroughly clean and firm, and the insulation about the edges of the commutator in perfect condition. Loose pinions also should be renewed at once. It is a particular case where a stitch in time saves nine.

Perhaps some of these rules may seem scarcely worthy of mention, but electricians will agree with me that there are plenty of instances where they may all be used to advantage.

THE INVENTOR OF THE THREE-PHASE ALTERNATING MOTOR SYSTEM.

In a communication which appeared in one of our contemporaries a short while ago, Mr. C. E. L. Brown, the well known Swiss electrical engineer, in referring to the transmission of power between Lauffen and Frankfort, sought to correct the erroneous impression that the three-phase system was the salient feature of this installation, and pointed out that the principal object of the experiment was to prove the possibility of producing and transmitting high-tension currents over long distances by naked wires suspended from poles, and with such a degree of security against danger and such a small amount by leakage as to demonstrate that this method has a right to commercial existence. The adoption of the three-phase current, according to Mr. Brown, only increased the difficulties to be met since nearly all the apparatus thereby became more complicated, and the only reason justifying the adoption of the three-phase current was to demonstrate its advantages when applied to several small motors at the same time. The only novelty in the system shown at Frankfort were important constructive improvements in its application which Mr. Brown, almost without exception, claimed as his own. Mr. Brown concluded by asserting that the three-phase current as applied at Frankfort was "due to the labors of Mr. Tesla, and will be found clearly specified in his patents."



Drawings in Tesla's Patents.

In reply to the above, Mr. Carl Hering thought that Mr. Brown had not done proper justice to the real inventor of this modification of the Ferraris-Tesla system, namely, Dobrowolsky. Without the *invention* of a new principle or a new modification, the ablest constructor would hardly be able to make any very great departures from well-known systems. Due credit should therefore be given to the inventors as well as the constructors.

In support of the claims made in the concluding paragraph of Mr. Brown's communication, quoted above, that gentleman has asked us to publish the following letter which explains itself :

> I should like to make a few remarks on Mr. Carl Hering's comments on my letter of the 12th October last.
>
> I would first draw his attention to the concluding paragraph of that letter; and secondly refer him to Mr. Tesla's patents for the three-phase current filed October 12, 1887, Nos. 381,968 and 382,280, and his further patent No. 390,414, filed April 23 of the following year, of the existence of which patents Mr. Hering seems to be ignorant. For his further edification I enclose sketches which are fac-simile copies of drawings in the patents above referred to.
>
> I think that he should then see that I have done full justice to the true inventor of the three-phase current system.
>
> C. E. L. Brown

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JANUARY 27, 1892. No. 195.

The meaning of pure scientific discovery is very frequently misunderstood; one of the most common mistakes is to confound it with invention. The former, however, consists in finding new truths of nature, whilst the latter consists in applying those truths to some desired purpose.—George Gore.

THE LAW OF HYSTERESIS.

THE American Institute of Electrical Engineers has been the medium for bringing out not a few papers of scientific interest and practical importance, but we believe that none of more absorbing interest and practical utility has been presented to the Institute than that of Mr. Charles P. Steinmetz last week on the Law of Hysteresis. There was a time when the loss in the iron of dynamo electric machines, though recognized, was overshadowed by the importance attached to the losses encountered in the copper employed in the construction of such machines, but with the advent of the alternating current and the later developments of continuous current apparatus, the phenomenon of hysteresis and loss due to it at once rose to the highest practical importance as a factor largely influencing their efficiency. It is now generally recognized that in alternate current transformers the loss in the iron represents by far the larger part of the whole loss of energy. This iron loss, which, heretofore, may be said to have been practically unknown, and could be determined by experiment only, is now first expressed by Mr. Steinmetz in analytical formulæ of very simple form, so that we are enabled to calculate the loss in iron with the same exactitude as we have been able, for a long time, to calculate electric resistances. Thus we can now determine what change in the efficiency of the apparatus will be effected by a change in the magnetization, and hence also we can choose the kind of iron most economical to employ. But aside from alternating apparatus, hysteresis and eddy currents play an important part, for instance, in the armature cores of continuous current dynamos, and it is of great interest to see these important, but as yet little known, phenomena here yield to mathematical formulation. We are sure that electrical engineers will feel a sense of relief in having finally gotten rid of another factor of uncertainty in the designing of such machines.

It is interesting to note that the loss of hysteresis per unit of time is directly proportional to the number of periods and changes with the magnetization, so that doubling the intensity of magnetization very nearly trebles the loss; while the energy of consumption by eddy or Foucault currents is proved to be proportional per unit of time to the square of the frequency and of the magnetization, so that doubling the magnetization quadruples the loss by eddy currents. Mr. Steinmetz thus proves that eddy currents will be specially marked when high frequencies and high magnetizations are employed, and will practically disappear for low frequencies and low magnetization; while, on the contrary the hysteretic loss is still quite considerable even for low frequencies and low magnetization, indeed even for such extraordinarily low magnetization as 85 lines of magnetic force per square centimetre.

But from another point of view also this law of hysteresis is of the highest scientific interest, as was pointed out by Mr. Steinmetz in the discussion of his paper. While the law of conservation of energy teaches us that energy is indestructible and convertible into other forms of energy, Clausius' Law of Entropy proves that none of these conversions of energy are completely reversible, so that in any cyclic process, such as that met with in the alternating current transformers, etc., between electro-dynamic energy and magnetic potential energy, there is also a part of the energy lost, being dissipated as heat. This is the reason why a moving pendulum or an oscillating spring comes to rest, and why an electrically oscillating condenser discharges. But in none of these cyclic processes has it been possible heretofore to calculate exactly, and to formulate analytically, this law of nature, which determines the law of energy by conversion into heat; hence the electro-magnetic cycle is the first cyclic process in which the law has been determined, and in this case shown to involve the 1.6th power.

Besides this chief result, Mr. Steinmetz' paper contains a large amount of data of great value. Thus, for the telegraph engineer the cyclic curves will afford useful information on that most troublesome property of electro-magnets, namely, remanent magnetism. Of considerable interest also are the tests made on magnetic iron ore as they are, so far as we know, the first exact determinations of its magnetic properties. Though the first known magnetic body, magnetic iron ore, has not received its due consideration, and its magnetic behavior may be said to be as little known as it was 2,000 years ago, all that we knew being, that it was permanently magnetizable,—the tests on this material show at once the fallacy of the usual assumption as to the high remanent magnetism of magnetic oxide, and prove that its remanent magnetism is even lower than that of any other of the materials given in Mr.

Steinmetz' paper. It is also shown conclusively that the magnetic properties of iron and steel are influenced far more by their physical than by their chemical nature. The paper also deals with a number of what may be characterized as magnetic superstitions, such, for instance, as the lower hysteresis of the open magnetic circuit and of loaded [transformers, which must now be considered as definitely disproved. Mr. Steinmetz' paper also contains the first scientific researches made by means of the Eickemeyer differential magnetometer, first described in our columns some time ago; and the results obtained are such as to place this instrument among the most useful for scientific research.

"ELECTRIC POWER TRANSMISSION" AT THE CHICAGO ELECTRIC CLUB.

The last meeting of the Chicago Electric Club was made the occasion of what might be called a joint debate by the adherents of the alternating and direct currents as methods of effecting electric power transmission. The argument for the alternating current was made by Mr. William Stanley, Jr., who, after describing the new alternating motors designed by him in connection with Mr. John F. Kelly, took up the question of distribution and showed that the greatest difficulty in this direction lay in the cost and maintenance of working feeders from large stations. Mr. Stanley claimed that with a potential of 5,000 volts, the cost of copper mains for distances not exceeding 2,000 yards from a station was comparatively insignificant. As regards the method of employing this voltage, he advocated the installation of sub-transformer stations which would convert the pressure of 5,000 volts to one of 1,000, which could be distributed locally from that point. Admitting a loss of one per cent. in the iron and one per cent. in the copper, Mr. Stanley claimed that these sub-transformer stations could be operated at an efficiency of 98 at full load, or 93 or 94 at quarter load, and that the efficiency of the entire system from station to consumer might readily be 90 per cent. for very considerable distances, with proper designing.

Mr. Alexander Dow, who took up the subject as the advocate of the continuous current, argued that the saving in copper advocated by the employment of high-tension alternating current was not so great as that generally claimed for it, and that, in fact, the outlay for copper even for low-tension work constituted but a small fraction of the total cost of the distribution system, and this was especially the case when underground conductors were employed. He considered the question of the commutator as not so serious a matter as it is usually deemed to be, and the results of inquiries which he made on the subject would seem to show that up to 5,000 volts there is no serious difficulty in operating them, at least with a 10 ampere current, and even with 40 amperes. Prof. D. C. Jackson, who took part in the discussion, believed that the economical limiting distance for 1,000 volts at the motors is shown by practical experience to be about four miles, which, however, might be considerably exceeded under special conditions, particularly in small plants. Referring to the three-phase motor exhibited in Frankfort, Prof. Jackson gave it as his opinion that before such motors could be satisfactorily employed in this country, the rate of alternations now used in commercial work would doubtless have to be reduced, at least for circuits intended for power transmission. Indeed he thought that this was the reason of the failure of American companies to supply an alternating motor up to the present time.

THE MORSE TELEGRAPH SYSTEM IN AMERICA.

The admirable description of the new office equipment of the Western Union Telegraph Company in this city from the authoritative pen of Mr. Alfred S. Brown, the electrical engineer of the company, will give a good idea of the latest improvements which have been introduced with a view of reducing the business of telegraphing to its most effective point, considered from the standpoint of a telegraph central station. Perhaps the most noteworthy detail, and one which will appeal most strikingly to the telegraphist, is the fact that at this, the greatest telegraph centre in America—and the largest in the world, with perhaps one exception—the last voltaic cell has been finally discarded, even locals being operated from dynamo machines. There was, of course, no good reason why this should not have been done some time ago, but it is nevertheless gratifying to note that the opportunity afforded in the present instance was availed of. But looking further into the possibilities which the new equipment offered for the introduction of what are considered improved methods of telegraphic transmission, such as are embodied in the numerous multiplex and high speed systems now available, it is not unnatural to suppose that many might inquire why these systems did not find a place after their demonstrated success in other countries, abroad. Without attempting to answer this question here, the present equipment of the Western Union office is, we think, a tolerably sure indication that the Morse system, as such, will continue for a long time to be the standard system employed in this country. It certainly has stood the test of time wonderfully well, and in that respect probably stands unparalleled as an instance of a method which has, by the sheer weight of its practicability and simplicity, remained without a rival for over 50 years.

While we believe that the Morse, as a system, will long retain its hold in this country, we are not, however, quite so sanguine that the details of the apparatus employed in carrying it out will remain so firmly fixed. Indeed we believe that a change may be looked for at no distant date, the influence of which we are certain will be far-reaching and will serve to overcome many of the difficulties which are still met with in telegraphy, and which are due largely to the present type of instruments employed in carrying out the Morse system.

From the fact that Mayor Boody has wisely decided not to offer a second veto to the resolutions permitting the street railways in Brooklyn to introduce the trolley system, it is now safe to assume that the work will go ahead vigorously. This is an eminently satisfactory result, and we now expect to see other cities, such as Philadelphia, follow Brooklyn's example, and fall in line as users of electricity for heavy passenger traction.

THE BURTON SYSTEM OF ELECTRICAL FORGING.

IT must be clear to any one who is conversant with the details of the Patent Office, and who has followed during the past few years the numerous electrical patents granted, that the heating of metals by electricity has taken a distinct place in the inventions of the day. That electricity is peculiarly adapted for this purpose can easily be understood, as it necessarily eliminates many of the disadvantages which accrue from the old familiar mode of heating in furnaces of various kinds. At the same time there have been so many difficulties to overcome and so few practical results have been obtained with the exception of one or two notable cases, that the public are slow to believe that electric heating can be commercially successful. Electric welding, for instance, is well understood and has taken a distinct place in the manufacturing processes of the day. Electric heaters for ordinary work, such as heating houses, cars, cooking, etc., are also becoming well and successfully used, and can be procured as readily as a cooking stove. We propose in the following article, however, to describe more particularly a process by which metals can be speedily and accurately raised to any desired heat for forging purposes, and to give in detail a description of the Burton system of electrical forging, or more correctly the system of heating metals to such a heat that they can be readily forged by the special mechanical forging machines which are situated in the vicinity of the electrical apparatus. This system is controlled by the Electrical Forging Company of 163–167 Oliver street, Boston, which has a capital of $2,000,000, and it embraces numerous inventions of Mr. George D. Burton, the well-known inventor of the Burton stock car, and of many other well-known and useful mechanical and electrical appliances. The patents owned by this company also cover the mechanical application of the process to machines, enabling the automatic electrical heating and working of metals into any desired shape. These machines, one of which is shown in Fig. 5, page 90, are of special construction, and can be adapted to the production of any desired form or bulk of metal. Before describing further the nature of the work which may be carried out by this process, and the advantages which it possesses over other methods, we will describe in detail the plant which has been erected in Boston, and which has attracted a vast amount of attention in the scientific and engineering world. Fig. 1 is a general view of the generating-room on the first floor of building, and shows also one of the converters and a number of special machines for shaping the metal after heating. It should be stated here that from the first, alternating currents have been used in conjunction with large converters capable of developing enormous ampereage. The generating plant, proper, is contained within the portion of the building surrounded by a railing, as shown in the drawing, and consists, first, of a 60 h. p. Thomson-Houston motor, which receives its current from the regular street circuits of the Edison Illuminating Company of Boston. This motor is belted to a line of shafting carrying one Emerson power scale with meter attachments for accurate measurement of horse-power consumed. From this line of shafting is driven the 60 h. p. alternating generator, specially manufactured by the Eddy Electric Manufacturing Company, of Windsor, Conn., for the Electric Forging Company, and also a small exciting machine for the fields of the generator as shown in Fig. 1, but more clearly shown in Fig. 2. This main shaft also drives the line of shafting shown at the top of Fig. 1 which operates all the tools and forging machines both on this floor and in the basement below. The generator is specially wound to develop 24 amperes at 1,500 volts, and the current is controlled by a two-way switch, which throws it either into the converter shown in upper right-hand corner of Fig. 1 shown in detail in Fig. 3, or into the converter in the basement as shown in Fig. 4. Following the path of the current in Fig. 1, it is then brought to a switch and rheostat underneath the converter, and then passed up into the converter, an outside view of which is shown, suspended on beams from the girders above. This converter is of special design, different from anything before manufactured, and was also made by the Eddy Company. It consists of 14 coils in the primary circuit, through which flows the primary current, and 14 large secondary coils,

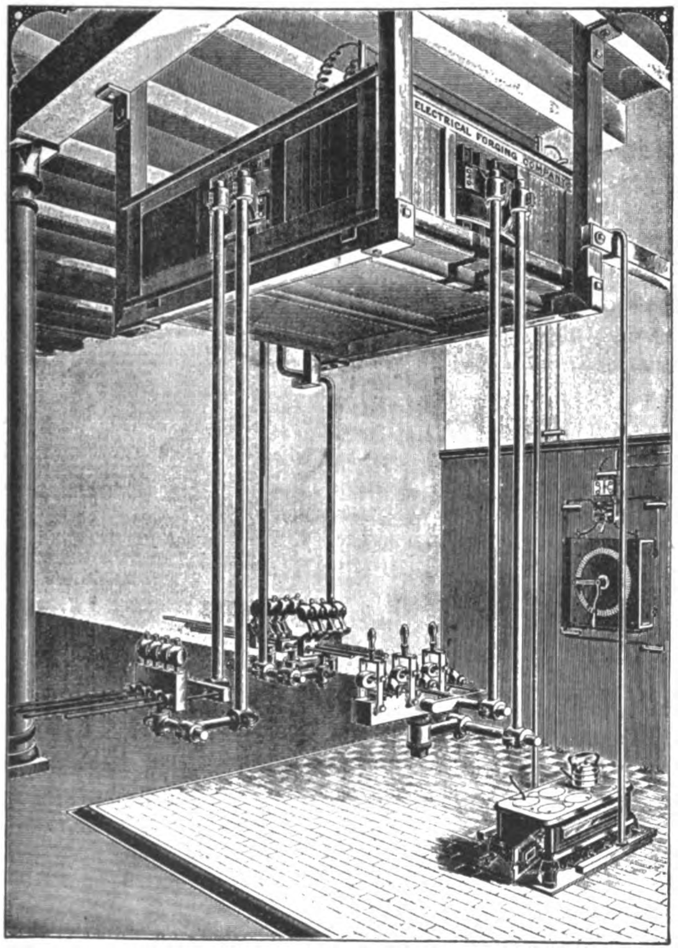

Fig. 3.—Large Forging Converter and Adjustable Clamps.

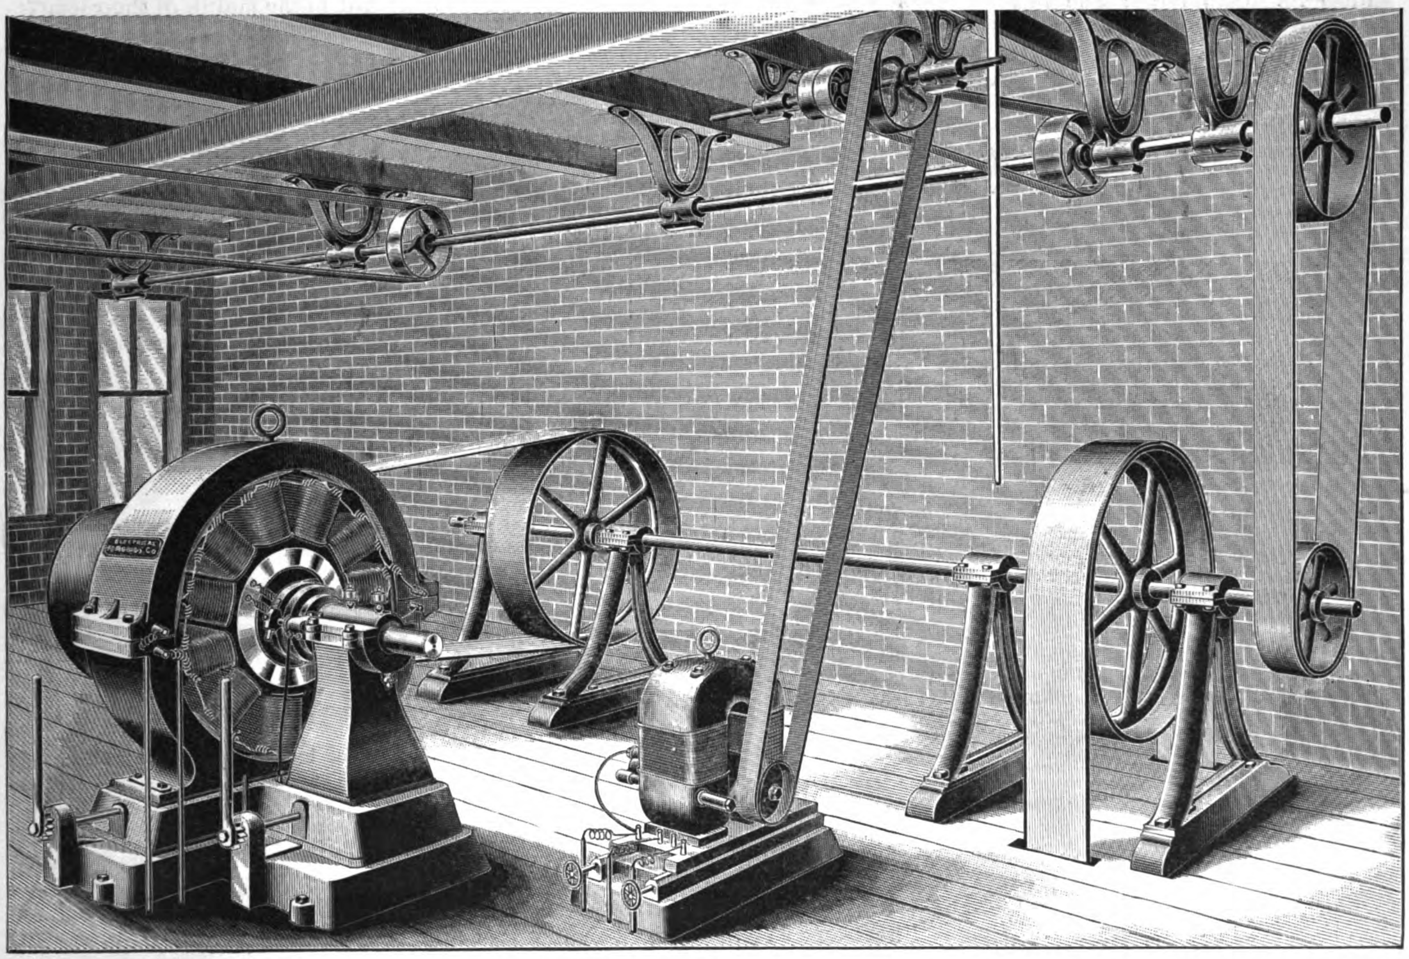

FIG. 2.—EDDY ALTERNATING GENERATOR AND EXCITER, BURTON ELECTRIC FORGING WORKS.

all of which are connected by special arrangement to the massive positive and negative conductors, which are composed of heavy copper rings, encircling the whole structure.

The converter has a capacity of about 60 h. p., and is designed to deliver current at 5 volts and from 5,000 to 8,000 amperes. From the rings above described, this enormous current is conducted by three sets of heavy copper bars, (as shown in detail in Fig. 3) to special electrodes provided with automatic adjustable clamps, in which the heating of the metals takes place. These electrodes are, as shown in Fig. 1, conveniently situated amongst machines for rolling balls, rivets and other kinds of regular and irregular shapes, the metal being heated and then passed into the machine. The electrodes shown in Fig. 3 are of special design, and vary according to the kind of work to be done. In certain cases where end heat is required, the clamps on the electrodes of one polarity are provided with a number of holes, through which a number of metal rods can be inserted, as shown in the figure. When these rods come into contact with the electrode or clamp of the other polarity, they are heated in a few seconds to a forging heat and while one heated rod is being worked by the rolling machines, the other rods are in the process of being heated, the machines being thus fed with a constant supply of heated metal. The capacity of this converter is about 1¼ inch steel, round or square, and four bars of this size can easily be heated at the same time. A complete outfit, however, has recently been shipped to England, and another to Canada, which will heat bars up to 5 inches square, and three feet long, throughout its entire length in about five minutes, with an expenditure of from 75 to 100 horse-power.

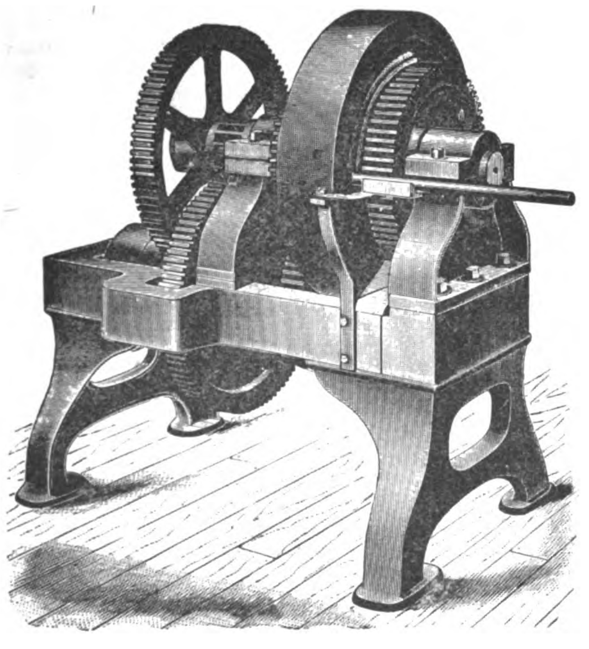

Fig 5.—Burton Electric Rolling Machine.

Passing down stairs into the basement, there is another 60 h. p. converter as seen in Fig. 4, showing different sides of the same type of converter, with a series of forging machines for doing larger and heavier work than those on the floor above and with a varied arrangement of clamps for special work. This converter has four sets of electrodes with clamps suitable for a varied class of work, and is designed for 2½ volts and from 8,000 to 12,000 amperes, having a capacity of heating to a forging heat a bar 1½ inches square, 20 inches long, in 5½ minutes with an expenditure of 42 h. p. In one case the set of electrodes has been specially designed to get an end heat on a bar of given size, and is also suitable for heating a bar throughout its entire length up to 24 inches. In Fig. 4 the electrodes shown on the left-hand side of the converter are designed for making coil springs, and for heating a moving bar 16 feet long its entire length as it passes through, into any form of mechanical forging machine. The electrodes shown in the middle of the converter in Fig. 4, are for heating rods for the manufacture of horseshoe nails, and also for general heating work. The electrodes on the right-hand side of the converter in Fig. 4, are of extra heavy copper 3 inches in diameter, and are for heating large stock for heavy forgings. This set of electrodes is placed between two heavy drop hammers, one of them capable of giving a blow equal to 60,000 pounds, so that with the proper dies any kind of forging can be readily made. There are also special sets of clamps for transverse currents, so that bars of metal can readily be heated in the middle of their length or at any desired place in their length. A glance at the figure will show a number of different machines for varied kinds of rolling and forging, including Bradley hammers, various punches, presses, rolling machines, machines for making balls for ball bearings, for rough and fine grinding, and a 10-ton machine for heavy forgings such as railway coupling pins, king-bolts, etc.

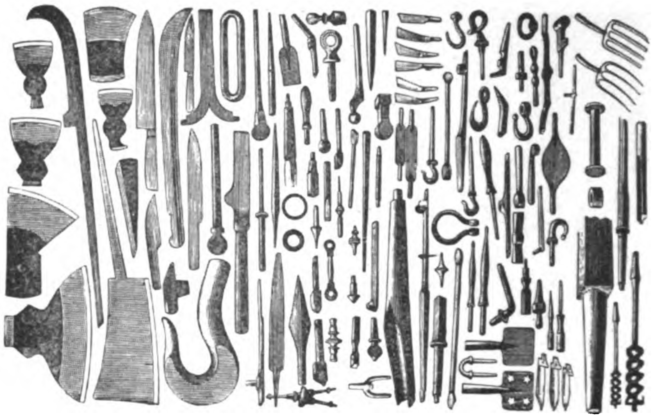

Fig. 6.—Hammered Pieces Made by The Burton Forging Process.

The shop is also well equipped with fine tools for the manufacture of all kinds of dies and the manufacture of the heavy copper clamps and conductors used on the converters. On the main floor is situated conveniently a draughting-room, where the drawings for the special machinery are made, and designs for applications to special purposes are carefully elaborated.

In order to give a better appreciation of what can be done by this process, a few cases may be cited:

(1) A round bar of tool steel, ⅞ inch diameter and 11 inches long between the clamps, is raised to the proper forging heat in one minute by 32 h. p.

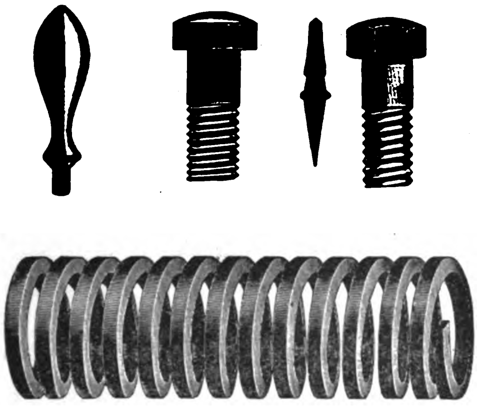
(2) A flat bar of machinery steel, ¼ inch thick, 1 inch wide, and 17 inches long, is heated in one minute by 34 h. p.

(3) Balling stock for balls, tool steel ½ inch diameter and 5 inches distance between the clamps, is heated in half a minute by 27½ h. p. This heat can be maintained for any length of time, by means of a perfect controlling apparatus, the heat on the metal during that time remaining perfectly constant.

(4) A bar of machinery steel 1 inch square and 12 inches long, is brought to a white heat in two and a half minutes by 36 h. p.

Taking the last case for an example, and two pounds of coal as a fair average per hour per horse-power, we have 72 pounds of coal used per hour for the 36 h. p., which is equal to a consumption of about three pounds of coal for the two and a half minutes.

One of the great advantages of the electric system of heating, lies in the evenness with which the metal is heated, the interior of the metal being heated first, and then extending uniformly and gradually over the whole mass. By this means objects can be forged by the electric process in one heat, which before required two or three heatings in furnaces. Owing also to the even heating, the metal forgings are much more reliable, the metal being subjected to no unequal strain either in heating or cooling. The quickness with which any piece of metal is heated by the electric current is also advantageous in many cases, as a few inches back from the part under treatment the metal is quite cool and can be conveniently handled. Probably one of the greatest advantages, however, lies in the fact that during the process of heating there are no gases developed, nor is there any foreign substance present to enter into the metal. So that whether the metal be iron, steel, brass or composition, after being heated electrically it is entirely without scale, which is impossible by any other method.



Figs. 7 and 8.—Products of the Electric Rolling and Coiling Machines.

The economy of electric forging is a subject well worth studying, and a few of the claims urged for this process may be here enumerated. First, there is the economy of space, no provision having to be made for large furnaces, and consequently more room can be allotted to the metal-working machines. Then there is great economy in the fuel, as the fuel, instead of being scattered in a number of different forges, is concentrated in one boiler furnace. There are also no ashes to be withdrawn from forges, nor fuel to be brought to them, thereby effecting a large saving in time and labor. The simplicity of the machine is another factor in its favor, it being extremely easy to operate and under perfect control, and after a few pieces of metal of certain size have been heated, the machines can be set to act perfectly automatically and without any skilled assistance.

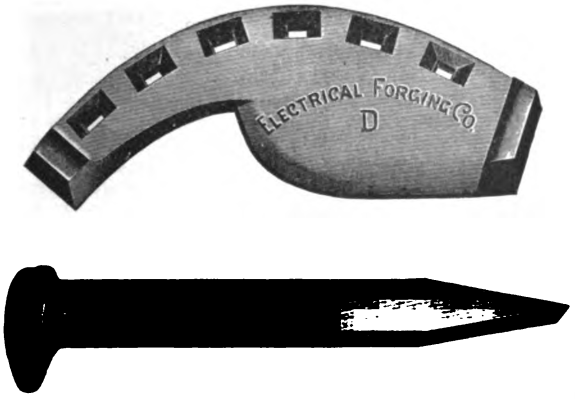


Fig. 9.—Electric Drop Forged Ox Shoe and Railway Spike.

We give herewith a number of illustrations that show tools, etc., made by the Burton process. The initial letter of this article is an ordinary wrench made by drop forging. Fig. 6 gives a collection of hammered pieces. Fig. 7 shows a spring made by the coiling machine, and Fig. 8 shows some bolts with either hexagonal or round heads made by the rolling machine. Fig. 9 shows an ox shoe and a railroad spike made by electric drop forging.

Mr. Burton is to be congratulated upon his perseverance in endeavoring to solve the problem of electrical heating and on his success; and the Eddy Electric Manufacturing Company also deserve great credit for materially assisting Mr. Burton in designing the apparatus for producing the heat, apparatus which not a few electricians claimed to be impracticable and impossible.

ON THE LAW OF HYSTERESIS.[1]—I.

BY CHAS. PROTEUS STEINMETZ.

In the number 137, of December 17th, 1890, of The Electrical Engineer I published a short article under the title "Note on the Law of Hysteresis," where I showed that in a set of determinations of the loss of energy due to hysteresis by reversals of magnetism, for different magnetizations, made by Ewing, this loss of energy due to hysteresis can fairly well be expressed by the equation:

$$H = \eta\, B^{1.6},$$

where H is the energy consumed by the hysteresis during one magnetic cycle, in ergs per cubic centimetre, B the magnetization in lines of magnetic force per square centimetre, and η a numerical coefficient, in this case $= .002$.

Considering that even the simple law of magnetism—that is, the dependence of the magnetization B upon the magneto-motive force F has until now defied all attempts at mathematical formulation, it appeared a strange feature that the apparently much more intricate phenomenon of hysteresis, or rather of the consumption of energy by hysteresis, should yield to analytical formulation in such a simple way, to be directly proportional to the 1.6th power of the magnetization. At the same time the coincidence of Ewing's tests with the curve of the 1.6th power was near enough to be considered as something more than a mere incident, but at least as a clew to a law of hysteresis, the more as this law held not only for low and medium magnetization, but even for very high saturation, without showing any kink at that point where the magnetic characteristic goes over the bend or "knee" and thereby entirely changes its shape, nor any marked tendency of deviation of the extremest observed values from the calculated curve.

To study more completely this phenomenon of hysteresis and of the energy consumption caused thereby, I set about to make a number of determinations with different magnetic circuits and at different magnetizations.

To be enabled to carry out these experiments, I am highly obliged to Mr. Rudolph Eickemeyer, of Yonkers, N. Y., who being greatly interested in the laws of the magnetic circuit and having done considerable work himself in this branch of electrical science, not only put the large facilities of his well-known factory at my disposal, but also guided the experiments with his valuable advice. A part of the instruments used in the tests are of Mr. Eickemeyer's invention and covered by his patents.

To be able to deal with readings of considerable power-values, where a much greater exactness can be reached, and at the same time to determine the dependence of the hysteretic loss of energy upon the velocity of the magnetic cycles, I decided to use alternating currents, at least as far as this could be done, whereby the determinations of the energy consumed by hysteresis is reduced to a simultaneous watttmeter, voltmeter, ammeter and speed reading.

Suppose, around a magnetic circuit, an alternating current of N periods per second is sent in n convolutions.

Let C = the effective strength of the current,
E = the effective E. M. F. induced in the circuit by self-induction, after subtracting the E. M. F's induced by the self-induction of the instruments.
W = the energy consumed in the circuit, after subtracting the energy consumed by the electric resistance,

Then l being the length and s the cross-section of the magnetic circuit, all in centimetres, amperes, volts, watts, etc.,

Let B = the maximum magnetization in lines of magnetic force per square centimetre,
H = the loss of energy by hysteresis per cycle and cubic centimetre; then

$$W = l\, s\, N H \times 10^{-7}$$

hence

---

[1] Abstract of a paper read at the sixty-third meeting of the American Institute of Electrical Engineers, New York, January 19th, 1892.

$$H = \frac{W}{l\,s\,N} \times 10^{+7}$$ the hysteretic loss of energy, and

$$E = \sqrt{2}\,\pi\,s\,B\,N\,n \times 10^{-8}\text{; hence}$$

$$B = \frac{E \times 10^{8}}{\sqrt{2}\,\pi\,s\,N\,n}\ ^{(2)}$$ the maximum magnetism.

For higher frequencies, 80 to 200 periods per second, the alternating current was derived from a 1 h. p. 50 volt Westinghouse dynamo. This was driven by a 3 h. p. Eickemeyer continuous current motor. By varying the excitation of the motor field and varying the E. M. F. supplied to the motor, the speed, and therefore the frequency of the alternating current, could be varied within wide limits.

For low frequencies, this bipolar continuous current motor was used as a bipolar alternating dynamo, as shown in a patent of Mr. Stephen D. Field. On the continuous current commutator two sliding rings were mounted and connected with opposite commutator bars. In the ordinary continuous current brushes a continuous current was sent in, which set the machine in motion as an electromotor, while from the sliding rings by two separate brushes, alternating currents were taken off. By varying the E. M. F. supplied to the motor, the E. M. F. of the alternating current was varied, while a variation of the motor field gave the variations of the frequency. The curve of E. M. F. was very nearly a sine-wave, the ratio of maximum E. M. F. to effective E. M. F. found = 1.415, while the sine-wave requires 1.414—that is, exactly the same.

To determine whether the change of the shape of the alternating current by varying load and varying excitation had any influence upon the readings, the variations of the alternating E. M. F. were produced in several different ways.

But after having found that all these different ways of varying the alternating E. M. F. gave no perceptible difference whatever in the readings, I afterwards used the most convenient way to vary the excitation of the dynamo field and, where higher E. M. F's were needed, to increase the E. M. F. by an interchangeable converter.

For the electric readings, instruments of the electro-dynamometer type were used, zero-reading—that is, the movable coil was carried back by the torsion of a steel spring to zero position. These instruments were specially built for alternating currents, with very low self-induction and low internal resistance, using bifilar german silver wire as additional resistance.

In most of the readings sufficient additional resistance was used to make the correction for self-induction negligible. Only in a few readings where it exceeded 1 per cent. was it taken into account. These instruments were calibrated several times and their constants found to remain constant.

The speed indicator was calibrated carefully and its corrections added. Each reading consisted of an ammeter reading, a voltmeter reading, a wattmeter reading and a speed reading.

Before and after each set of readings the zero positions of the instruments were determined, and only those sets of readings used where the zero position had remained constant.

Before and after each set of alternating current readings a continuous current was sent into the circuit and a few readings for different currents taken. Voltmeter and ammeter readings combined gave the resistance of the circuit, and both combined with the wattmeter reading gave a check for the instruments, there being watts = volts × amperes. Only those sets were used again where an entire agreement was found, and with the alternating current first readings with small currents, then with large currents, and then again with small currents were taken, so that I believe that every possible care was exercised to avoid any errors in the tests.

The first sets of tests were made on the magnetic circuit of a small Westinghouse converter, which contained 917 cm.^{3} of iron, of a magnetic cross-section of 43.67 cm.^{3}

Further sets of readings were taken on a magnetic circuit, built up of very thin sheets of iron, in rectangular shape, very carefully insulated against eddy currents with layers of thin paper between the sheets, and excited by 100 turns of wire.

The whole volume of iron was = 155 cm.^{3}, its cross-section < = 3.784 cm.’, the thickness of the sheets $\delta = .0258$ cm. In one set of tests an open magnetic circuit was used.

In these readings, for the determination of the hysteretic loss, only voltmeter and wattmeter, but no ammeter, were used, and the susceptibility curve determined separately by voltmeter and ammeter.

THE GOVERNMENT TO CONTROL THE TELEPHONE IN BELGIUM.

THE government has notified the Bell Telephone Company, whose instruments are now used in Belgium and which is at present doing all the telephone service, that on and after the 1st of January, 1892, the government will assume and conduct the service.

Society and Club Notes.

NATIONAL ELECTRIC LIGHT ASSOCIATION.

MR. GEORGE F. PORTER, the secretary of the association, is rounding up non members in the central station field with the following practical appeal:

> "Great interest is being taken in the coming fifteenth convention of this association, to be held in Buffalo, N. Y., February 23d, 24th and 25th next. Knowing you to be interested in central station management, I take the liberty of calling your attention to the great benefits accruing from attending these meetings. The papers to be read at Buffalo are from men high in the science, and will treat on every valuable subject from 'How to Fire a Steam Boiler' to 'Electric Lighting from a Financial Standpoint,' including the steam engine, dynamo, switchboards, overhead and underground wiring, motors, etc. We would be pleased to enroll you among our already large membership, and hope to welcome your representative at Buffalo."

PHILADELPHIA NOTES.

THE WRIGHT & STARR ELECTRIC CO. has been incorporated in this city with a capital stock of $250,000. At a stockholders' meeting held last week Mr. B. F. Morley was elected president, and Mr. J. G. Dyer, secretary and treasurer, for the ensuing year. The company will act as sole agents for the Waddell-Entz Eelectric Co., of Bridgeport, Conn., for the States of Pennsylvania, Delaware, Maryland, District of Columbia, Virginia and West Virginia, and are prepared to equip street railways with their storage battery system. Their experimental car "Direct" has been running in Chester successfully for several months, and the batteries have proven to be very durable.

MR. OTIS K. STUART, the agent for the Germania Electric Co. in the Southeastern district, is receiving a large number of inquiries concerning the Freeman transformer. He says alternating current men like the circular form of this transformer and the "removable plug" which the fuses are arranged on. This plug can be wired in the station and when a fuse "blows" out it can be replaced without danger to the lineman.

MR. GEO. W. LA RUE, general sales manager for the Crocker-Wheeler Electric Co., made this office a call last week while on a business trip to all the coast cities between New York and the gulf. He reports a promising outlook for business.

MR. B. B. STODDARD, of the Germania Electric Co., paid a flying visit to this city this week. He says business is very good and that their company is making rapid progress in fitting out its large new factory in Marlboro, Mass.

WASHINGTON NOTES.

THE HANSON BATTERY CO., of Washington, D. C., have been remarkably successful with their new primary battery, they having accomplished with it everything thus far undertaken. A handsome electric launch is now being fitted up with their new batteries, which can soon be seen running on the Potomac.

CONGDON, BLISS & DANIELS, contracting and consulting engineers, have recently opened offices in the Atlantic Building, Washington, D. C. This new firm, which was organized the first of the month, has the agency for the Heisler system of lighting and the "Quaker City" dynamos and motors for the District of Columbia, Virginia, West Virginia, North and South Carolina, Kentucky, Tennessee. Florida, Alabama and Georgia. They will do expert work and contracting and will make a specialty of general electric work. Mr. Congdon has had large experience in the business world, having been employed as correspondence clerk for the Edison Machine Works, New York, Randolph & Clowes, Waterbury, Conn., and as Assistant Chief of the Supply Division, War Department, at Washington. Mr. Bliss is an expert electrician and was contracting agent of the Edison General Electric Co.; while Mr. Daniels, was electrician of the White House and State, War and Navy Department Buildings.

They are all men of energy and business capabilities and well known in the electric field. They make an announcement in this week's issue of THE ELECTRICAL ENGINEER to which attention is called.

CONGDON, BLISS & DANIELS, Washington, D. C., report extraordinary success. Among the many and important contracts in hand and closed are a complete plant of the Heisler system for Lambertville, N. J., $26,450; wiring of Oregon Flats, Typographical Union Building, and Ohio Bank Building; Norfolk and Washington Steamboat Company's steamer, "Geo. Leary," complete isolated plant.

THE WESTERN UNION TEL. CO. will have to pay $60,000 with interest and costs in the appeal of James E. Goodsell for an old press contract that was allowed to fall through about ten years ago and has been in litigation ever since.

---

[2] This formula holds rigidly only for the sine-wave, but, as shown in the following, the currents used in the tests were at least very near sine-waves. Besides, a deviation from the sine shape would not alter the results at all, but only slightly change the coefficient η.

TESTS OF MILLIKEN STREET RAILWAY POLES.

It has long been a question among engineers building electrical street railways as to what is the best form of pole to use, giving the greatest strength and least deflection. The questions of strength and deflection are of the greatest importance, for the reason if the trolley and guard wires are not tight and are not kept tight they will sag, and not only become dangerous but will need constant attention. What is wanted is a pole that will act like a bow or spring, and keep a tension on the line at all times and of sufficient amount to hold the trolley and guard wires in position at a fixed height above the tracks. With a view to ascertaining the best form and proportions of a pole adapted to street railway work, Messrs. Milliken Bros., of New York, have during the past year submitted this question to Prof. R. H. Thurston, of Cornell University, at Ithaca, N. Y., who has carried out a series of tests, the results of which are of great interest and importance to electric railway managers.

The object of the test being to find the pull the pole would stand, and its deflection, the base was placed on the platform of the transverse testing machine, and a fulcrum formed by a tie rod of iron bolted to the base of the scale, as shown in the accompanying engraving. The load was applied to pull the top of the pole up, which, acting against the fulcrum 5′ 9″ from the support under the base, caused a stress on the platform of the testing machine in the proportion of 187 to 50, as compared with the pull at the top. The tangent of the angle of curvature was measured by observing three points, one each side of the fulcrum and 25 cms. apart; by this the actual deflection was corrected, since this curvature would tend to increase the deflection of the pole by an amount equal to the length of the overhanging part into the tangent of the angle as compared with a perfectly rigid support.

The first tests were made on a side pole as first made by Milliken Bros., *i. e.* with the lacing in the centre extending only to a tie plate at ground level. The tests showed that the strain revolved around the tie plate at ground level and buckled the segments. It proved that by continuing the lacing to the butt of the pole and filling same with concrete, that the pole would develop considerably more strength and at the same time add little to its cost. This form of construction was therefore adopted for standard work. In order to get at the exact strength, and to compare them with other poles, 5 Milliken poles and 3 pipe poles were furnished to Cornell University for testing, and they furnished a chestnut pole. The following is an extract from the report of the test:

The Milliken poles differed among themselves in weight and the arrangement of the "lacing" and the various "gusset-plates" used in the construction. The differences are detailed in the following table:

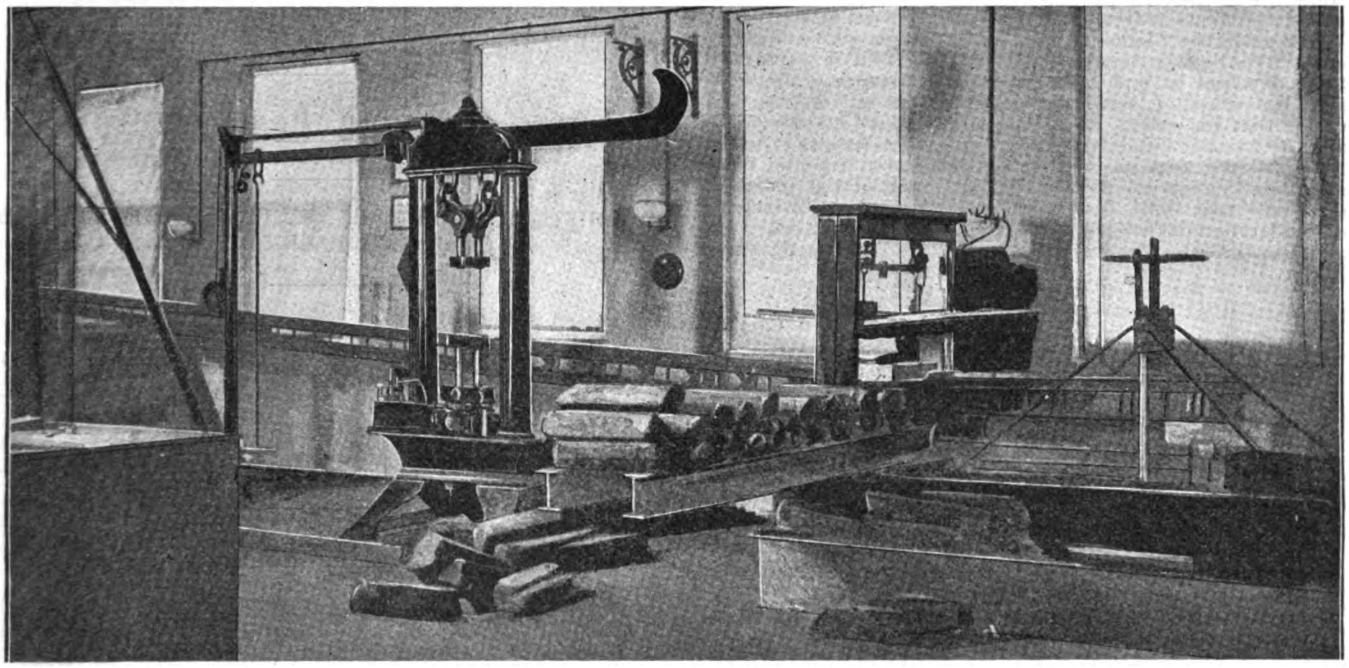
MILLIKEN POLES.

No. of Pole	II.	V.
Length over all	26 ft. 6 in.	28 ft. 6 in.
Length unsupported	20 ft. 7 in.	22 ft. 6 in.
Lacing from	Butt Plate.	Butt Plate.
To	Middle Plate.	Middle Plate.
Gusset-Plates between butt and top plates?	Yes.	No.
Butt filled with cement?	Yes.	Yes.
Standard Side Pole	Yes.	——
Stand Pull-Off Pole	——	Yes.

The "Pipe" poles are made by uniting three sections of steam or hydraulic pipe, of different sizes, telescope fashion. The joints are made in two ways according to the relative sizes of the pipes jointed; (*a*) by shrinking or forcing the large over the smaller, or (*b*) by driving a "liner" of proper thickness into the annular space between the two pipes. The principal dimensions of the pipe poles are as follows:

PIPE POLES.

No.	Length to Eye.	Length of Sections (apparent). I.	II.	III.	External Diameter. I.	II.	III.	Total Weight.
A.	27 ft. 3 in.	14 ft.	7 ft. 6 in.	5 ft. 9 in.	5½ in.	4½ in.	3½ in.	368 lbs.
B.	28 ft. 5 in.	14 ft.	7 ft. 1 in.	7 ft. 4 in.	6⅝ in.	$5\frac{9}{16}$ iu.	4½ in.	486 lbs.
C.	28 ft. 2½ in.	15 ft. 3 in.	5 ft. 9 in.	7 ft.	6⅝ in.	5½ in	4½ in.	750 lbs.
Chestnut	28 ft. 6 in,	About 10 in. at butt.						316 lbs.



View of Cornell Testing Room, Showing Milliken Pole During Test.

Poles II and V were filled in with Portland cement from the butt to a point 6′ from the butt. In all of the poles the unsupported length was from the eye to a point 6′ from the butt. The following are the results of the tests:

Pole	No.							
Pole	No. II	the elastic	limit	was	1540 lbs.;	corresponding	deflection,	10″
"	" V	"	"	"	3340 lbs.;	"	"	14′
"	" A	"	"	"	675 lbs.;	"	"	12.2″
"	" B	"	"	"	920 lbs.;	"	"	16.5″
"	" C	"	"	"	1420 lbs.;	"	"	13.6″
"	Chestnut	"	"	"	960 lbs.;	"	"	37″

When tested to destruction, Pole No. II broke by fracture of segments about 1′ 8″ in front of fulcrum. The segments were fairly pulled in two; plane of fracture at right angles to axis. Pole V gave a slight permanent set at fulcrum, preceded by cracking of cement near fulcrum. All pipe holes bent in second joint from one foot to three feet ahead of first joint or section of pipe. Chestnut pole yielded by opening slightly on under side, near fulcrum.

Referring to the tests, the pipe pole marked "A" is what is known as a 5″, 4″ and 3″ standard weight pipe, and is now not generally used in street railway work, as it is too light. Pole marked "B" is what is known as a 6″, 5″ and 4″ standard weight pipe, and is the one generally used in side pole construction of street railways. Pole marked "C" is what is known as a 6″, 5″ and 4″ extra strong pipe pole, and is used for pull off poles.

The Milliken side pole is thus shown to be stronger by 120 pounds than the extra heavy pipe pole, and the deflection of which is over 30 per cent. more than the Milliken. The Milliken Standard Side is 620 pounds stronger than the standard side pipe pole, and the deflection of the pipe is 65 per cent. more than the Milliken. The tests also show that the Milliken "Pull-off Pole" is 2¼ times as strong as the pipe pull-off pole, and the deflection of the same only measures $\frac{1}{16}$ of an inch more.

The conclusions deduced from experiments is best stated in the words of the report as follows (referring to the Milliken Standard Pole): "We now have a pole of as nearly homogeneous structure as possible, and for a given weight of iron of maximum strength." Referring to the Milliken Pull-off Poles, he states: "I reiterate my statement that the pole is stronger than can possibly be required for any work ordinarily connected with the carrying of wires."

Letters to the Editor.

A NOBLE SCOTCHMAN.

One of the New York electrical journals in referring to the honors recently conferred upon Sir William Thomson, says, among other things, that his "care for the bawbees results in frequent contentions with London cab drivers, etc." To the same cause is no doubt due a custom that Prof. Thomson has of treating his laboratory students to frequent excursions on board his handsome schooner yacht the "Lalla Rookh," where lunch, wine and cigars contribute to the enjoyment of the sail, Sir William paying all railway expenses to and from Glasgow, a distance of about 120 miles. His refusal of larger salaries from other universities, and the fact that his salary for those years in which his services in laying the Atlantic Cable interfered with his classes was returned to the university, together with an additional sum to found three scholarships in experimental physics, are some of the instances which show that Lord Thomson's mind is given exclusively to the consideration of the number of pennies in a shilling, when not engaged in enriching the world with his scientific investigations.

R. M.,
(Formerly student at the
Glasgow Physical Laboratory).

Baltimore, Md., January 17

PRAISE, PITH AND POINT FROM SIR HUBERT.

I have just finished my weekly perusal of the **Engineer** bearing date of to-day, and I cannot refrain from tendering my felicitations to you upon the very high grade of excellence reached in this number.

I think, taking it as a whole, and this after reading all the numbers which have ever issued, that this is the very best. The "Henry" article, is in its way so far as it has appeared, certainly a masterpiece, and though I question the propriety of making priority of discovery a question of National partisanship; and the expediency of asserting more for the great Henry than he did for himself, so far as I can ascertain; and though further, I think we already hold Henry so high that he requires no "vindication" to use your own word, yet I heartily admire the matter and manner of the article, as far as it has appeared.

The plea for the porcelain insulator by Mr. Jones equally enlists my sympathy; and I am glad to be able to cordially coincide with Mr. Park Benjamin in his sentiments regarding the necessity and the duty of keeping green the memory of William Gilbert, a man whom the great Galileo, the melodious Dryden, and the quaint Fuller alike delighted to honor.

I am glad for myself, to be able to say that I have always availed myself of opportunities to pay the tribute of full appreciation to the worth of Gilbert's services to electricity; and also to those of Gray, the discoverer of conduction and insulation.

Prof. S. P. Thompson, likewise, has manfully done his part for Gilbert, and before me at this moment, is a little book published last year by him, and entitled "Gilbert of Colchester, an Elizabethan Magnetizer," which proves that the sage is fully appreciated by Prof. Thompson, who moreover has rendered a public service in rescuing from comparative oblivion many interesting facts concerning another intellectual giant of the earlier days, William Sturgeon."

I have recently made some inquiries regarding the Gilbert society, and its translation of "De Magnete," and have been informed from thoroughly reliable sources, that the book is not lost sight of, and that the delay in its issuance is accounted for by the fact that its revisers are all very busy men who can only devote a small portion of time to that work.

Mr. Shaw's sketch and picture of Sir William Thomson compensate for what would seem to be the unnecessary slur of the Gilbert article upon the acknowledgment by the Crown of Sir William's great merit and ability, and I for one was profoundly interested in it, and consider myself favored in being permitted to read such an account so near first hand.

Thomas D. Lockwood.

Boston, Jan. 13, 1892.

VENTILATION AND THE SWEATING OF IRON ROOFS.

We note the communication in your edition of Jan. 7th, from Milliken Bros., in which they say that if an iron roof is properly ventilated that it will not sweat on the underside.

We dispute most emphatically this statement. The sweating process arises from the fact that cold air will not hold in suspension as much moisture as warm air. The warm air of the room coming in contact with the cold corrugated iron of the roof is cooled and as a result deposits a portion of its moisture on the underside of the corrugated iron, causing what is known as sweat or drip. Ventilation has nothing to do with it and will neither increase or decrease it. The only way to stop it is to put something under the corrugated iron to catch it or put some substance between the inside of the room and the corrugated iron which will act as a non-conductor and prevent the dripping.

In order to make a fireproof roof under these conditions this non-conducting material must be fireproof, otherwise you have not what might be called a strictly fireproof roof.

There are different ways of accomplishing this as already noted in former communications of ours.

Chas. M. Jarvis,
Pres. Berlin Iron Bridge Co.

East Berlin, Conn., Jan. 16, 1892.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JANUARY 12, 1892.

Alarms and Signals:—

Electrical Annunciator. W. F. Harte, 466,784. Filed July 25, 1891.

An automatic electrical hotel annunciator.

Automatic Electric Heat Alarm, M. S. Pierce, L. H. Desisle and O. C. Oliver, Filed Dec. 15, 1890.

Adapted for use in the journals of machines where injury is liable to be occasioned by overheating. See p. 96.

Annunciator, D. Heineman, 466,870. Filed Mar. 16, 1891.

A drop annunciator for hotels, etc.

Dumb Waiter Signal, F. J. Zahner, 467,073. Filed Aug. 14, 1891.

An electric signal for dumb waiters.

Conductors, Conduits and Insulators:—

Electric Insulator for Boilers, P. Decker, 467,085. Filed Sept. 25, 1891.

Claim 1 follows:

An electric insulator introduced in a pipe connection between a steam boiler and a steam engine to break an electric circuit between them.

Dynamos and Motors:—

Brush-Holder for Commutators for Dynamo-Electric Machines, I. H. Bartholomew, 466.972. Filed Aug. 13, 1891.

Method of readily adjusting the commutator brushes to compensate for wear.

Electric Motor, J. H. Palmer, 467.048. Filed March 28, 1891.

A motor in which the armature and field-magnets are both free to revolve in opposite directions.

Galvanic and Thermo-Electric Batteries:—

Electric Battery, J. S. Nowotny, 466,798. Filed Mar. 23, 1891.

Has for its principal object to obtain a maximum of surface for contact with the battery liquid.

Battery-Zinc and Method of Making the Same, J. Beattie, Jr., 466,820. Filed March 30, 1891.

An element for galvanic batteries consisting of an alloy of zinc, mercury and magnesium.

Heating:—

Electrical Heating Apparatus, A. E. Appleyard, 467,075. Filed Jan. 16, 1891.

Combination of a resistance, a rigid holder of refractory heat-conducting, insulating material, a metallic shell enclosing the holder and an outer metallic shell independently secured to the handle.

Measurement:—

Electric Indicator, C. W Holtzer & G. E. Cabot, 466,787. Filed Apr. 6, 1891.

Indicates variations of the electromotive force of currents in electric light and power installations.

Ammeter, C. F. Brush, 466,953. Filed Nov. 21, 1889.

An ammeter in which the strength of the current is measured by means of the different expansion of two dissimilar metals.

Metal-Working:—

Method of Electric Welding, P. Gendron, 466.825. Filed June 17, 1891.

A method of welding which restores the enlarged portion of the weld to the original size and shape of the pieces welded.

Miscellaneous:—

Electric Steam Engine Governor, F. M. Garland, 460,781. Filed Feb. 26, 1891.

An arrangement by which the work of the engine is automatically regulated according to the output of the dynamo.

Electric Switch, E. W. Rice, Jr., 466,802. Filed Feb. 13, 1891.

Employs a circular track with a series of double inclines and a rotary cross-arm for connecting the contacts.

Electric Fuse or Detonator, P. Ward & E. M. Gregory, 466,856. Filed May 13, 1890.

Machine for Covering Wire, Cables, &c., and for Making Tubing and Cord, V. & J. Royle, Jr., 466,910. Filed Aug. 1, 1891.

Attachment for Phonographs, J. F. Ott, 466,922. Filed Dec. 29, 1890.

Electric Converter, G. Pfannkuche, 466,937. Filed Sept. 28, 1889.

A core made of two piles of blanks, each consisting of a long and a short arm, and coils wound around the long arm of each set of blanks.

Electric Elevator, W. Baxter, Jr., 466,973. Filed Sept. 8, 1888.

Relates to means of electrically actuating the switch of an electric motor operating an elevator.

Lightning Arrester, G. W. Spittle, 467,023. Filed Sept. 3, 1891.

Railways and Appliances:—

Wire Support for Electric Railways, W. Q. Prewitt, 466,800. Filed March 26, 1891.

An improved trolley track-hanger for electric conduits.

Electric Trolley, E. A. Sperry, 466,807. Filed June 24, 1891.

Employs a vertical helix for the erecting spring of the trolley.

Electric Motor Car, E. B. Phillips, 466,882. Filed Jan. 6, 1891.

A motor for street cars employing gearing with intermediates symmetrically disposed with reference to the driving pinion in order to balance the stress of transmission.

Electric Railway Motor, C. F. Winkler, 466,914. Filed March 26, 1891.

A motor adapted to be geared directly to the axle and in which the size of the machine is large in proportion to the size of the gear wheel on the axle with which its armature shaft engages.

Bracket for Trolley Wire Supports, etc., E. P. Russell, 466,956. Filed Sept. 11, 1891.

Rheostat, F. O. Blackwell, 467,078. Filed Jan. 12, 1891.

A rheostat adapted especially for use on electric railway cars, and in which a series of metal plates are set edgewise and cut into or out of circuit by a traveling contact.

Trolley for Electric Railways, J. Kuehnle, 466,981. Filed Sept. 5, 1891.

The trolley arm consists of a rigid lower section and a flexible upper section connected by a spring hinge.

Electrically Controlled Car Switch, B. I. Potter, 467,050. Filed Jan. 13, 1890.

Relates to means for electrically controlling the movement of a switch point from an electrically operated car.

Telegraphs:—

Printing Telegraph, J. E. Wright, 466,858. Filed Sept. 5, 1891.

Has for its object to relieve the electromagnets connected with the main line of as much load as possible.

Telephones and Apparatus:—

Nautical Signal or Sea Telephone, E. Huber & F. J. Kneuper, 467,102. Filed April 25, 1891.

An apparatus for the detection of sounds proceeding from any object in contact with water.

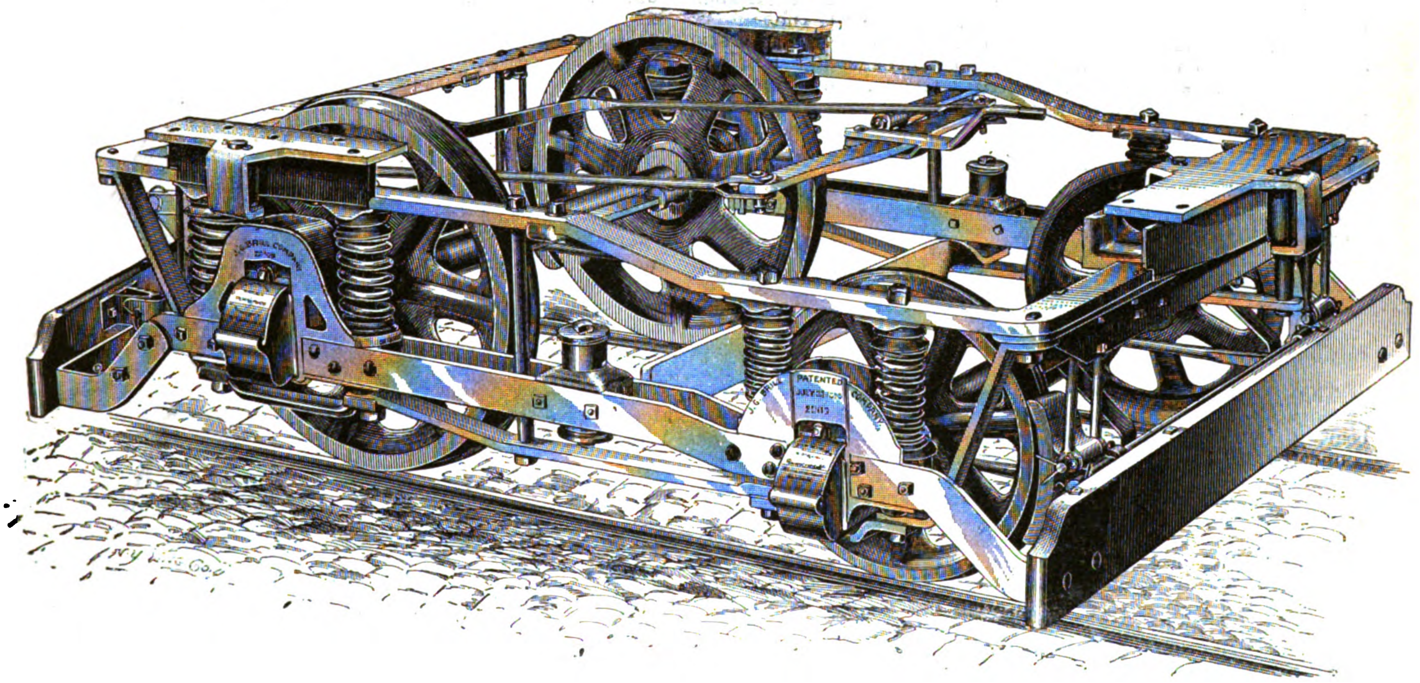
MR. JOHN A. BARRETT.

THE article on "Berliner Electrodes" in the last issue of THE ELECTRICAL ENGINEER has attracted considerable attention, as it well deserves, for a more ingenious and skillful, if not convincing, argument has rarely been advanced in support of a master patent. Our readers will be interested to know that Mr. Barrett has now established himself as an electrical expert and consulting electrical engineer, at 18 Park Row, and we have no doubt there are many who will be glad to avail themselves of his advice and long experience, as shown in his "Electrode" article.

FREDERICK WARNE & Co., N. Y., are issuing at a popular price "Electricity Up to Date for Light, Power and Traction," clearly explained, with diagrams, etc., for non-scientific readers, by John B. Verity, M. Inst. E. E. (London).

BRILL'S EUREKA MAXIMUM-TRACTION PIVOTAL TRUCK.

ONE of the most useful inventions in pivotal trucks for electric propulsion was Mr. John A. Brill's maximum-traction truck, in which many disadvantages heretofore existing were overcome and a gain made of 42½ per cent. in traction. A reduction of ten inches in the height of the car body was obtained, and thus the necessity for double steps obviated, while a shortening of wheel base was effected, and the required power reduced 30 per cent. An objectionable feature, however, was that the pivotal centre, or drawing point which comes over the axle, was in the way in removing the motor and had to be taken off. This trouble was solved by use of a movable spider. But being the pioneers in the field of electric trucks the J. G. Brill Company determined not to stop improving until they had approached more nearly to perfection, and have now produced their new model called the Eureka maximum-traction truck, shown in the accompanying illustration, in which the above-named objection has been overcome. It has no mechanical pivot and is specially adapted for the waterproof and "ironclad" types of motors which have their upper portion hinged so that they can be raised when it is necessary to get at the armature or other parts of the motor. The space above that occupied by the motor is free and clear, so that when the trap doors in the cars are raised the whole of the motor can be reached and the armature taken out, without disturbing any part of the truck. A further reduction of height of the car to the extent of one and a half inches is also obtained, and the weight of truck reduced by one hundred and fifty pounds.



BRILL'S EUREKA MAXIMUM-TRACTION PIVOTAL TRUCK.

The pivoting in this truck is accomplished by the combination of rollers on the side of the rub plates on the upper part of the truck. The drawing (draught) of the truck and car body is done from the small end of the truck, and this feature affords additional means of keeping the small wheels from climbing the rails. Since the introduction of the maximum-traction truck several hundreds of them have been sold and are in operation.

THE ROBERTSON CONDUIT SYSTEM.

A NOVEL system of conduit railway is that recently devised by Mr. A. J. Robertson, president of the Robertson Electric Railway Construction Company of this city. The conduit is made of hard burned, vitrified fire-clay, forming a continuous insulator within which the wire lies, and from which it is lifted by the trolley as the car passes. The trolley is made in two parts which separate for the purpose of lifting or dropping the wire at will.

An important feature of this system is that the conduit is laid directly upon the ties, and can be readily put in without tearing up the street.

ANNOUNCEMENT has been made that the *New York Sun* will withdraw from the Associated Press, of which it was one of the original members, and that it will hereafter take its news from the United Press.

AND MECHANICAL DEPARTMENT.

The advertiser keeps the field of force constant around his customers.

THE "P. D. O." ELECTRIC HEAT ALARM.

CENTRAL station managers have frequently been caused an immense amount of trouble and expense, through the overheating of bearings, either on an engine, a line of shafting, or a dynamo or motor. Frequently serious accidents arise from this trouble causing the shutting down of circuits, the destruction of armatures, and an immense amount of annoyance and delay. These accidents occur often even in the best conducted stations, employing first-class engineers, where the bearings are frequently examined and the best of oil cups used. A bearing may be running perfectly cool at one moment, and yet in a few minutes time may become dangerously hot entirely unknown to the engineer in charge. It will be at once seen, therefore, that any reliable method by which the engineer could be notified, that a certain bearing in the station was getting hot, before it got to the danger point, would be of immense use, and would meet the approval of all engineers, and we therefore present to our readers a new system of electric heat alarm, the joint invention of Messrs. Pierce, Desisles, and Oliver, engineers on board the S. S. "Sappho," which is being introduced by the Electric Heat Alarm Company, of 113 Devonshire street, Boston, of which Mr. F. S. Palmer, well known to central station managers, and recently of Bangor, Me., is general manager.

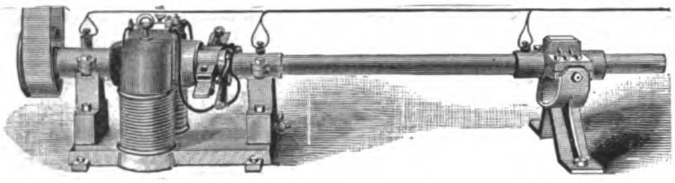

FIG. 1.—ELECTRIC ALARM FOR HOT BEARINGS.

The system consists of an automatic device which is situated on the bearing, and which closes a local battery circuit when the bearing reaches a certain temperature. This battery circuit is connected to a drop annunciator with an alarm bell, which may be situated in the engineer's office, or in any convenient place, the annunciator having a number on it for every bearing equipped with the device. As soon, therefore, as the alarm bell rings, the engineer has but to look at the annunciator, to learn at a glance, which bearing is running hot, and by quick attention, can either cool off the bearing, or at least prevent any damage from accruing. In Fig. 1 we show the application of this device to a dynamo or motor, and Fig. 2 shows how it may be applied to a line of shafting. In order to better understand the working of the automatic circuit closer, we show the device in Fig. 3, which is half as large again as the original, and Fig. 4 shows the same in section. Referring to Fig. 4, the lower half of the device is a Bessemer steel cup, $\frac{1}{32}$ inch thick and $\frac{1}{2}$ inch deep inside, into which is firmly pressed a piece of hard fibre B $\frac{5}{8}$ inch diameter, $\frac{7}{8}$ inch long, shaped as shown in the drawing, and having at the bottom $\frac{1}{16}$ inch clearance from the steel cup. The hole through the centre of the fibre is tapped at the upper end for the reception of the screw C, $\frac{7}{32}$ inch clearance, which is turned down at its lower end, the hole in the fibre being also very much smaller at the lowest end,—being bored with a number 60 drill. This screw C is connected at its upper end by means of the nut to the wire leading from one pole of the battery. A is a reservoir, which is filled with mercury, which also enters the small hole in the fibre, the top of this hole, being however $\frac{1}{16}$ inch higher than the top of the mercury chamber. At the right hand of the engraving is shown another screw, which is connected to the wire from the other pole of the battery by means of a small set screw, and forming electric contact with the mercury. The action of the device is extremely simple, depending upon the expansion of the mercury, which as the heat increases rises in the small hole in the fibre and makes contact with the lower end of the screw C, closing the circuit and sounding the alarm-bell. The amount of heat necessary to set off the alarm can be varied by moving the screw A up or down, and when its position for a certain temperature is fixed, it is firmly held in its place by a small set-screw shown in Fig. 4. The system has been in practical operation successfully for some time and can be seen in operation at the offices of the company in Boston, and as its action is sure and positive, without any complicated mechanism, it may be safely asserted that it will be largely adopted.

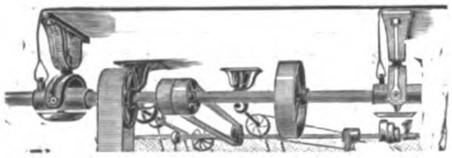

FIG. 2.—ELECTRIC ALARM FOR HOT BEARINGS.

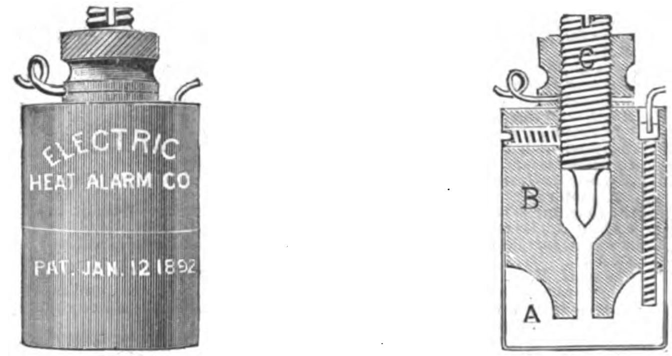
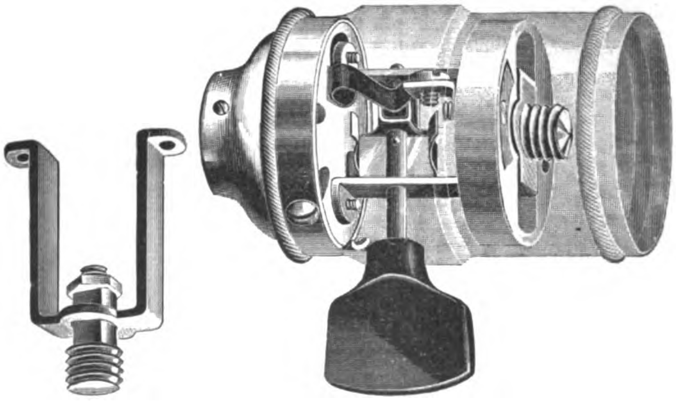


FIGS. 3 AND 4.—ELECTRIC HEAT ALARM.

THE CROWN SOCKET.

THE CROWN ELECTRIC COMPANY, of Bridgeport, Conn., have placed on the market their new socket, which embodies two new ideas.

The first of these is, a device which will keep the socket always intact. Where, as sometimes happens, the diameters of the thread of the lamp and of the contact screw are not alike, considerable force is needed to fasten the lamp, and when necessary to take the lamp down, the contact screw, being round, simply revolves in the yoke, making it necessary to break the apparatus in order to free the lamp. In the Crown socket the yoke has an oblong section and the contact screw, as it passes through the yoke, is flattened so that no matter how tightly the lamp fits, the contact screw furnishes sufficient resistance to enable the lamp to be unscrewed. The porcelain top is made to correspond to the above. This idea is shown in Fig. 1.



FIGS. 1 AND 2.—THE CROWN LAMP SOCKET.

The second point is that of the contact. The circuit is closed positively until the click is heard, and is then opened very quickly. There is no chance for an arc to be formed, and the maintaining of either a closed or open circuit is arranged by a ratchet which most effectively controls the whole thing. This is shown in Fig. 2. The contact block is made in one piece and is patented, as is also the peculiar shape of the controlling spring. The metal parts of the socket are so placed with reference to each other that there is no possibility of short circuit. The socket is made for all styles of lamps.

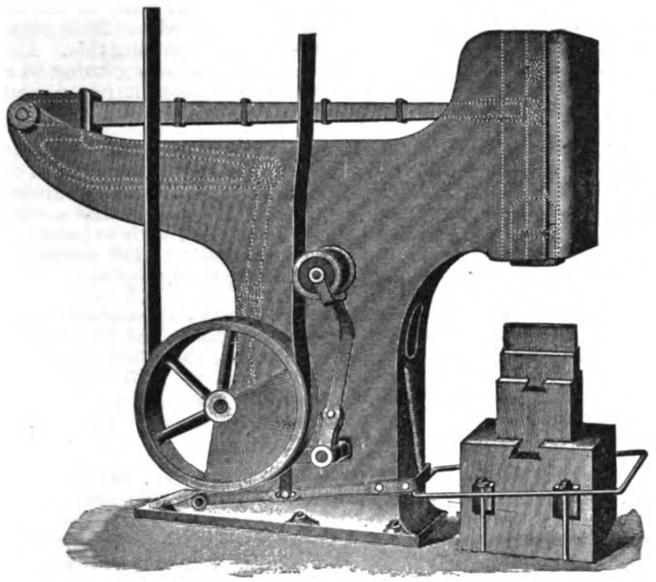
This company will shortly bring out other specialties.

DETROIT ELECTRICAL WOKKS.

NOTICE has been issued by the above-named works that Mr. Frank B. Rae is no longer in the service of the company, and that his patents under which the company has been operating in the electric railway field have been assigned to them.

THE ANDERSON POWER HAMMER.

In the manufacture of electrical apparatus, there is a general necessity for all kinds of machine tools. Not a few parts of electrical apparatus are stamped out or forged down from metal bar or rod, and any new device for forging or hammering must be of practical interest to manufacturers. In the accompanying engraving we show the Anderson power hammer which is one of the most recent types of hammers put on the market. This hammer is a rigid and effective machine made of few pieces and working on good mechanical principles. The blow is not deadened by transmitting the power to the hammer through rubber cushions or leather straps, the elasticity of the blow being obtained by the spring of the helve or handle, which is hung in such a manner as to strike effectively either on the edge or the flat side of a piece of iron, without adjusting, or in other words it will strike as an effective a blow 8 or 10 inches away from the anvil as it will close down to the anvil. The ram and guides are long and have no set screws to rattle loose, the wearing surfaces being so large that no adjustment is necessary. The helve is of hickory which can be easily and quickly replaced when after long wear it may finally give out. The anvil base is entirely separate from the hammer and is placed on a separate foundation. Between the lower die and the anvil base are two section blocks either or both of which can be removed when the hammer is to be used in upsetting a piece of metal the length of which requires it.



The Anderson Power Hammer.

These hammers are manufactured by Albert and J. M. Anderson, of 21 Hamilton street, Boston, where they can be seen in daily operation.

THE RIES ELECTRIC SPECIALTY COMPANY OF BALTIMORE, MD.

The above company, Elias E. Ries, president, were awarded the first premium and medal at the electrical exposition, recently held at Augusta, Georgia, for their well-known Regulating Socket for alternating current incandescent lamps. This Company is deserving of this honor, as their regulating socket is doing much toward making incandescent lighting universally popular. The Ries Regulating Socket is being generally adopted throughout this country and abroad, and on all sides one hears only good words for it.

"IDEAL" ENGINES.

In a handsome private hotel building known as the "St. Lawrence" near Madison Ave., built by Messrs. J. W. Weir & Son, are to be installed two 55 H. P. Ideal Self-oiling automatic engines. This contract comes through W. R. Fleming & Co. the New York Office for the Harrisburg Foundry and Machine Works, at 174 Fulton St. There are now about twenty of these engines running in New York City.

M. J. FRANCISCO & CO.

The offices of M. J. Francisco & Co. and the Rutland (Vt.) Electric Light Co. were much damaged by the fire in the Herald Building in that town on January 5. The offices, which were on the ground floor, were fitted up very handsomely only last June, and were said to be by far the handsomest in the town. In view of Mr. Francisco's business of fire insurance, there is a grim element of melancholy humor in his being hoist by his own petard, so to speak.

ELECTRIC MERCHANDISE CO.

Owing to the great satisfaction given by the Burton electric heaters which have lately been sent to foreign countries by the Electric Merchandise Co., Mr. W. R. Mason has been requested by some large capitalists in England to visit London with a view to the use of these heaters in connection with some large enterprises now under way. It may be stated that these heaters have gone to England, Germany, Switzerland and other foreign countries.

THE HAWAIIAN CABLE.

The United States fishing and surveying steamship Albatross has arrived at San Francisco from Honolulu. The steamer has been engaged in surveying a line of cable from here to the Hawaiian Islands, and reports that a practical route has been found. The first trip of the Albatross for the purpose of sounding for a cable line was made from Monterey. Seven hundred and fifty miles from San Francisco the line was taken out and 200 miles of the Monterey survey were accomplished, and then soundings were conducted to the Hawaiian Islands.

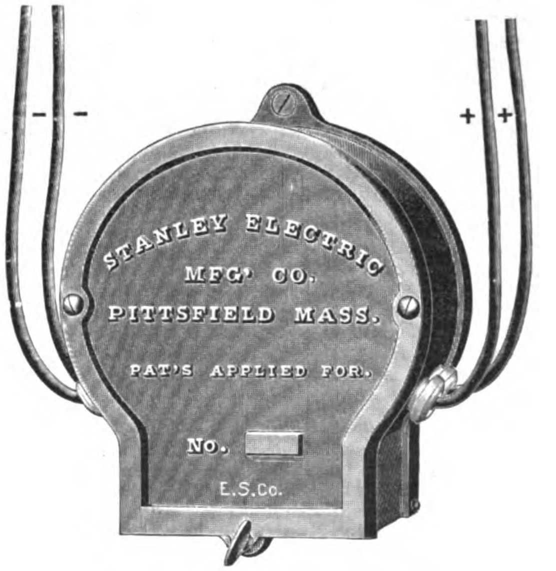
The deepest soundings were 3,000 fathoms, or three miles, and the average will show a depth of about 2,500 fathoms. At Monterey Bay, Cal., was found the best place to land the cable on this side. At Honolulu a place was found at a suburb of Honolulu named Waikiki, about four miles south of the metropolis.

THE NEW STANLEY PRIMARY FUSE BOX.

Wherever a branch is taken off the main primary wires of an alternating circuit it is very desirable to fuse it, so that if a short circuit occurs on that branch the lights supplied by it will alone be affected. If the fuse is not so used, a short circuit anywhere on the primary wires may blow the main fuses in the station, and so occasion a much more serious interruption to the service.

The unique and very safe and convenient form of fuse on the Stanley transformer having created a demand for the same style of box separate from the transformer, the Stanley Electric Manufacturing Co., of Pittsfield, Mass., are therefore now manufacturing them as shown in the accompanying illustration.

Each fuse is in a separate porcelain chamber, so that there is no danger of the current short-circuiting from one pole to the other when the fuse blows. A fuse can be replaced on a live line with perfect safety and in a very short time without the use of screw-driver or wrench. The porcelain plugs in all boxes are interchangeable, so that by having an extra plug or two no work is necessary while on the pole.



- -
+ +
STANLEY ELECTRIC
MFG. CO.
PITTSFIELD MASS.
PAT'S APPLIED FOR.
No.
E.S.Co.

New Stanley Primary Fuse Box.

This fuse box is suitable for use on the primary circuits carrying current up to 15 amperes, and is claimed to be the safest and most convenient box made. Its interior construction is the same as the fuse box on the Stanley transformer, which is now too well known to need description here.

NEW YORK NOTES.

H. Ward Leonard & Co., as electrical contractors are installing the plants named below:

Mail & Express Building, New York City, Catherine Bradley Building, New York City, Geraldine Building, New York City, Germania Insurance Building, New York City, DuVivier & Co. Building, New York City, F. O. DuLous Building, New York Franklin Building, Brooklyn, Fifth Avenue Theatre, New York City, Columbia Theatre, Brooklyn, Graham Hotel, New York City, Mr. J. H. Inman's residence, Fifth Ave., New York City, Curtis residence, Greenwich, Conn.

Among the leading concerns for whom they are acting as Consulting Engineers are the following: Otis Elevator Co., New York City, Wm. Sellers & Co., Philadelphia, Ingersoll-Sergeant Drill Co., New York City, Eastern Electric Co., Limited, St. John, N. B., Providence Journal Co., Providence, R. I., Middletown Music Hall, Middletown, Conn., Rock Hill Electric Light Co., Rock Hill, S. C.

The Riker Electric Motor Co., Brooklyn, whose new type of slow-speed motor was recently placed on the market, are meeting with excellent success in sales of it. The following recent orders uphold their claim to an efficient and common-sense machine; For the Kingsley mill at Honduras one 60 light slow-speed dynamo of 825 revs. The Peake Piano Works one 6 h. p. elevator motor. The Leake Coffee Mill, Atlantic avenue, Brooklyn, one 2 h. p. motor; one 16 light dynamo to be coupled direct to a gas engine. At Williamsburg, N. Y., one ⅛ h. p. dental outfit; Day's brass foundry, Pearl street, N. Y., one 4 h. p. motor; four 2 h. p. motors coupled to 42 inch fan blowers for Newark, N. J.; one 16 light dynamo to the La Salle University, New York; a special dynamo for storage work for the Franklin Electric Co. N. Y. One 3 h. p. for J. Y. Johnson printing office Murray street, N. Y., and one 1 h. p. for Cobb, Danby, & Knott, Electrical Exchange Building, N. Y.

The Easton Electric Company, Brooklyn, N. Y., have just completed the successful installation of two thirty-light Easton arc dynamos, with forty Easton arc lamps, and forty Bernstein series 25 c. p. lamps on seven circuits, for the Diamond State Iron Company of Wilmington, Delaware. The extensive new mills built upon the site of those recently destroyed by fire are now brilliantly lighted throughout, and work is carried on by night as readily as by day. The iron company are as proud of their purchase from the Easton Company as they are of their new mills.

H. W. Miller, Jr., & Sons, of Philadelphia, manufacturers of asbestos pipe covering, have received a flattering letter from Messrs. Palmer & Ballard, proprietors of the Philadelphia Steam Heating Co., in which they state that after an exhaustive test of different coverings manufactured, the architects have decided to use their covering. The test of several coverings was made at the new Almshouse and this particular kind will be used throughout. This report it is claimed has had a stimulating effect on the New York business.

The Storage Battery Supply Co. have recently added an entirely new department to their business, and besides being sole agents in New York City for the Consolidated Electric Storage Co., are now bidding for the supplying stored electric power for all purposes. They report that the demand has grown so that their present supply of charged batteries is at all times exhausted. A large addition to the present plant is being made, this will enable them to supply all demands for portable lights, etc., at shortest notice.

Dr. Elisha Gray and Mr. F. W. Cushing have been in New York during the past week, busily occupied. Dr. Gray is beginning active work on the Electrical Congress and has already formulated various plans to secure publicity for the work and co-operation in it. Mr. F. W. Cushing is somewhat a man of leisure just now, having lately sold out his interest in the Central Electric Co., whose large interests have engaged his whole time for the last few years.

The Imperial Porcelain Works, of Trenton, N. J., have recently opened an office in this city. Mr. Chas. E. Chapin, well known to the electrical trade, has been appointed selling agent. The new office is located at 417 Electrical Exchange Building, 136 Liberty street. This is a desirable arrangement and will no doubt be greatly appreciated by New York buyers, as it obviates the necessity of their making a special trip to the works.

Underwood Manufacturing Co.—During the month of December one of the salesmen of the Underwood Manufacturing Co. sold to one concern an order of 40 of their cotton leather belts all of good sizes and ranging from 25 to 800 feet long for each width sold. The Engineering Equipment Co., 143 Liberty street, are their New York agents. The Chicago office is at 33 South Canal street.

Connellsville, Pa.—I learn that the Connellsville Electric Railway Co. has been organized at Connellsville to build 7 miles of single track electric road. Mr. John L. Gans, the engineer, room 10, Weihe Building, that city, is the secretary.

The Safety Insulated Wire Co., of West 29th street this city, has lately completed a large contract on the new Western Union headquarters—the finest of the kind in the country with everything else up to the same high standard. Mr. E. T. Barberie, as an old telegraph expert, being familiar with the requirements of the work, was able to meet them exactly. But Mr. Requa, the general manager of the company, is perhaps equally pleased with the contract for wiring the new United States cruiser "New York." The exacting nature of naval work is well known, and the fact that "Safety" was selected speaks volumes. Moreover it is specially happy and fitting that this wire is a product of the city after which the great new fighting ship has been named. The Safety Co. is making great strides in its manufacturing departments, and has now succeeded in serving three coats of rubber, seamless and without joint, over its insulated wire. It is stated that it is the only concern that has succeeded in doing this. Altogether the Safety Co. is active all around, and is beginning to repeat outside of New York the enormous success it has already made while limiting its efforts to this region.

Day's Kerite.—It is understood that this old and important specialty in wires and cables will hereafter be handled in the West by Mr. F. W. Cushing, who will have charge of its agency in Chicago, and will begin to push it at once in that section. Kerite is one of the things we have always had with us, and it is just as likely to be in favor 25 years hence as it was 25 years ago and is now. The selection of Mr. Cushing is admirable.

The W. S. Hill Electric Co. have certainly inaugurated a successful beginning in their New York office. The demands for Mr. Hill's well-known specialties are taxing their factory to such an extent that larger quarters are imperative. A factory in the vicinity of Boston will probably be built at once. In recent tests of large sizes of the Hill motors, the speed remained practically constant under all changes of load.

Beacon Vacuum Pump and Electric Co., Boston.—Mr. Kaliske, business manager, and Mr. Nickenson, the expert of the Beacon Vacuum Pump and Electric Co., have been in New York during the past day or two, and it is not unreasonable to expect that company to make a more prominent appearance than heretofore in New York at an early day.

The Engineering Equipment Co. will shortly introduce to the trade a special new style of hard fibre pipe for use in underground work. This pipe, it is claimed, will decrease the cost of underground work about 25 per cent. It is durable and a perfect insulator.

The Edison Co., and the underwriters are not quite agreed as to the safety of the practice of "grounding the neutral." Under the rule of the Board here, against grounded wires, no building can be given insurance in which such a method is resorted to.

Mr. J. W. Mackay is making a strong fight in a writ brought against him for $75,000 by E. S. Stokes, the litigation being based on claims due to old dealings in the Postal and other telegraph properties.

Mr. Francis G. Daniell, late of the Short Electric Railway Co., has become connected with the firm of Barry & McTighe, of 52 and 54 William street, this city, as electrical engineer.

Mr. M. E. Baird, well known throughout the country as the general representative of the Eddy Electric Manufacturing Co., spent a few days in the city last week.

Mr. W. O. Cook, inventor and patentee of the Cook portable switch or car replacer, for replacing derailed electric and horse cars, is in the city.

Mr. Wm. Bracken, president of the Consolidated Electric Storage Co., is absent from the city on a business trip through the West.

Burlington, N. J.—The president of the Board of Trade is ready to receive proposals for lighting the streets by electricity.

PHILADELPHIA NOTES.

Alfred F. Moore, the manufacturer of insulated electric wire and cables, gives notice that his house has withdrawn its agency in Chicago, which has until recently been controlled by Mr. G. A. Harmount, of the Monitor Electric Co., Chicago. All communications or orders should now be addressed direct to Mr. Moore at the office and works at 200 North Third street, Philadelphia.

Mr. William N. Famous, formerly with Vallee Bros. & Co., has accepted a position as traveling salesman for the Pennsylvania Electric Engineering Co.

Mr. Norman Marshall has resigned from the position of treasurer of the Star Electric Co., and is succeeded by Mr Alexander Hamilton.

NEW ENGLAND NOTES.

The Electric Mutual Insurance Company, of Boston, is deceased, after a life of about 18 months. The outstanding business of the company has all been reinsured by the Home Insurance Company, of New York, one of the largest companies of its kind in the country, having assets of about $10,000.000. The net premium receipts of the Electric Mutual during 1890 aggregated $26,895, and its risks in force at the end of that year amounted to nearly $2,900,000. There is, however, now in progress the formation of a syndicate, who will write electric risks, composed of the Home Company and six others. A more complete system of inspection will be made, and the local agencies of the companies will make out the policies, tariff rates being adhered to. Mr. Barton, for the present, will conduct the management of the syndicate from the office of the Electric Mutual Company, in Boston, but will probably later move to New York. This method will effectually get rid of the difficulty of legal entrance into any of the States and will broaden out indefinitely the field of work.

A Remarkable Test.—Fifteen months ago, the Gould & Watson Co. caused a moulded mica bell, of the old Sprague pattern, to be put under water, where it remained until a few days since. The object sought was a demonstration of their insulation regarding its waterproof qualities. At the end of this long immersion the bell was connected to a 220-volt current, a wire being fastened to each brass nut. A low-reading Weston voltmeter showed no leakage. A delicate galvanometer being then attached, showed a deflection of the needle, while the bell was still wet. At the end of half an hour, the same current gave no deflection of the galvanometer, the surface water having by that time evaporated. So severe a test as this is of course unnecessary as a demonstration, but it was with much gratification that the firm learned that moulded mica is indeed waterproof, after 15 months under water.

The Benedict and Burnham Manufacturing Company, of Waterbury, Conn., are achieving great success with their new "Benedict" wires and cables, and they are evidently manufacturing a superior wire which fills a felt want. The "Benedict" wire is very substantially made, and every fibre of its texture is thoroughly saturated with their special compound, making a wire of unusually high insulation, and of great toughness and capability of resisting abrasion. Their Boston office has recently moved into more convenient and commodious quarters at 26 Oliver street, only a short distance from their old store, and will continue to carry a full line of all their high-class goods. All inquiries will be courteously attended to by Mr. Rugg, their well-known Eastern representative.

The Gould Packing Company, of East Cambridge, the original and only manufacturers of the genuine Gould's packing, have done a remarkably good business during the past year and are in receipt of many very flattering testimonials as to the solid worth of their goods. They have recently received a number of large orders for government work and are also supplying a large number of electric light and power stations with their packing for steam engines. Other packings similar in appearance to the Gould packing are sold, but there is none genuine or similar in quality except that sold by the Gould Packing Company, who furnish nothing but the best quality which is always the same and always up to standard.

The New England Printing Telegraph Company are now ready to do a regular telegraph business, between Boston, Providence, Woonsocket and Danielsonville, over their own lines which have just been completed into the city. The offices of the company are situated at Nos. 99–101 Milk street, Boston, No. 19 South Water street, Providence, R. I., office *Woonsocket Reporter*, Woonsocket, R. I., and Quinnebaug Store, Danielsonville, Conn.; where messages will be received for transmission, and messages received at these offices will be delivered throughout the cities by messengers. The tariff rate will be 15 cents for 10 words, and one cent for each additional word, address and signature free.

The Hubbell Portable Electic Lamp and Power Company.—In a recent issue, it was stated erroneously that the Consolidated Electric Motor Company had secured control of the Hubbell battery. This was a mistake, as it appears that the above company is entirely distinct from the Consolidated Motor Company and will soon open offices of its own at 116 Bedford street, Boston. It is proposed to move the whole manufacturing plant from New York to Boston, and manufacture hereafter in this city.

The New England Screw Company, of Brockton, Mass., will shortly move into a new factory in Boston, and there continue the manufacture of all kinds of rolled thread screws for the electrical trade. Mr. C. H. Mavers is president, and Mr. T. P. Swift, treasurer, and they will push the business to even larger proportions than before.

Mr. P. H. Alexander, of New York, was in Boston last week, enlarging on his favorite topic of A. B. C. He is now after the rest of the alphabet.

The Revere Rubber Company, of Boston, are pushing the sales of the "Elliott" trolley line insulator, and the "Elliott" pull-off, in addition to their regular line of hard rubber insulating goods. The rubber which they use for the Elliott insulators is of a special nature, being extremely strong, of high insulating property, and unbreakable. Mr. C. B. Elliott is the manager of the electrical department, and will be glad to afford any information regarding these goods.

Mr. J. M. Orford, of Bridgeport, does not often come as far East as Boston. He prefers the society of New York, and does not yet appreciate the tone of the Hub. When seen lately, however, in this city he appeared to be enjoying himself as well as looking after the interest of the Union socket—and rumor has it that he was heard to remark in a moment of forgetfulness, "Of some things only the best are worth having."

The Tropical American Telephone Company, Limited, has secured the agency of the Viaduct Manufacturing Company, of Baltimore, and will hereafter keep a full line of all goods at their new headquarters at 95 Broad street, New York. Mr. Frank Harrington, as before, will look after the interests of the company in New York, and Mr. Howard, the general manager, will divide his time between New York and Boston.

The H. E. Swift Manufacturing Company, of Boston, continue to do a very large business in push-buttons, annunciators, bells, lamp bases, and general electric fittings. Their factory is at present driven to its utmost capacity, and their goods are meeting with general approval by the trade. Mr. T. P. Swift has recently been elected as secretary and treasurer of the company.

Mr. George Cutter, of Chicago, was circulating 'round among his friends in Boston, this week, and talking of "big things" to come in the Windy City in '93. The latest about Mr. Cutter's street hoods is that they are an '*owling* success.

Mr. E. K. Gilman, of Chicago, favored Boston with a fleeting visit, and then hied himself away to more congenial latitudes.

Mr. Norman Marshall, of Philadelphia, was in Boston this week looking after the interests of the Star Electrix Company.

CINCINNATI NOTES.

The Le Boiteau Fan Motor Co., are busily engaged in manufacturing a large supply of their universal revolving fan motors for the large demands which will be made on them shortly, as these fans fill a long felt want in distributing a breeze not only in one direction as with the old fan motors, but in all directions to all parts of a room.

The Card Electric Motor & Dynamo Co., Second and Plum streets, Cincinnati, are installing a number of very fine motor plants which are giving eminent satisfaction, and Mr. Wilshire, president of the company, reports that every sale leads to several more, as parties using the motors are quick to recommend them to their friends.

The Electric Supply & Contracting Co., Nevada Building Cincinnati, are doing a large amount of repair work for electric street railways, rewinding armatures, etc., and have received a number of the most flattering testimonials regarding the reasonable price and excellence of their work.

The Lunkeheimer Brass Manufacturing Co. still continue to flood the market with their brass specialties which are known and used by almost all power users.

Jones Bros., Cincinnati continue to furnish general electrical supplies for all kinds of electrical work and are doing a good and prosperous business.

NEW YORK SUBWAYS.

The year's work under the Board of Electrical Control comprises the removal of 5,224 poles and 7,152¼ miles of wire and the construction of 114 miles of subways. The capacity of this subway work is as follows: 47 miles for electric light service, 721 miles for telephone and telegraph service, and 121 miles for Edison light service. There are now in use in the city 1,420 miles of subways, divided as follows: Electric light subways. 578 miles; telephone and telegraph subways, 721 miles, and Edison subways, 121 miles.

WIRES IN NEW YORK.

Mayor Grant in his annual message points out that only one death through overhead wires occurred in New York City in 1891, and that that was due to the fall of a telegraph pole. There are now 143 high tension circuits, making 528 miles of electric light conductors underground, and 383 miles of low-tension lighting in the Edison circuits. Mayor Grant recommends the establishment of a central municipal telegraph and telephone exchange.

WESTERN NOTES.

THE ELECTRIC APPLIANCE COMPANY are meeting with large success in the introduction of their latest specialty, the "Standard lamp." To remove any erroneous impression that may be abroad, the company desires to state that this is a new lamp and manufactured by an entirely new company having in its employ some of the most experienced lamp men in the country. They are putting out an elegant lamp in every respect and one that is a credit to any factory. Great claims for life, efficiency and non-discoloration are made on every side by those who have tested and adopted the lamp. The Electric Appliance Company also report large sales of Paranite wire and its hearty recommendation by all users.

MR. W. L. ADAMS.—The above-named gentleman, who is very well known in electrical circles, has just been elected secretary and treasurer of the Electric Merchandise Co., with which concern he has been connected as traveling representative for some time past. Mr. Adams is a keen business man, bright and energetic, and is to be congratulated on his advancement to so prominent a position in a company which has achieved so extended a reputation as exclusive dealers in electric street railway supplies.

THE ELECTRIC MERCHANDISE COMPANY continues to fill orders for Burton electric heaters. The merits of this device are widely known, and worn-out stoves are quite generally being replaced by them. Orders have been received from several Western mining companies for use in their plants. The diploma for efficiency has recently been awarded the Burton electric heaters by the Canadian Electrical Exposition committee.

THE DETROIT ELECTRICAL WORKS have opened a Chicago office at No. 431 Rookery, in charge of Mr. L. E. Myers who is an old electric railway man and well known in the business, having been associated with the Sprague and Edison Companies several years. There is no doubt that, managed by so experienced and genial a gentleman as Mr. Meyers the Chicago office will be a success from the start.

MR. H. K. GILMAN, vice-president and general manager of the Great Western Electrical Supply Co. of Chicago, has returned from an exceedingly prosperous business trip East on which he secured some very large orders. He reports the outlook for a very large business as highly encouraging, and states that his company are keeping well abreast of the times in the number and magnitude of their shipments.

MR. WM. HOOD is installing a number of Mosher arc lamps for incandescent circuits in different parts of the city. The lamps are giving good satisfaction, and burn with a clear, steady white light and with an economical consumption of current. Mr. Hood is also receiving a great many orders for the Jewel incandescent lamps, which seem to be becoming great favorites all over the country.

THE D. M. STEWARD MFG. CO., of Chattanooga, Tenn., continues to note a marked improvement in business, and being already very active finds that it is beginning to run behind its orders. This is a very gratifying sign of better times in the light and power industry. Lava insulators long since became one of the staples of the trade, by which general conditions may be gauged.

CENTRAL THOMSON-HOUSTON.—The regular annual meeting of the Central Thomson-Houston Company was held at the office at 264 W. Fourth street, Cincinnati, Jan. 4th. The officers for 1892 are: Franklin Alter, president; H. P. Piper, vice-president; Paul T. Brady, treasurer and general manager; W. F. Hayes, assistant treasurer; A. B. Champion, secretary.

THE MATHER ELECTRIC CO., which is represented by Mr. Julius Andrae, have just closed one of the largest motor deals in the country through their Mr. F. A. Baux, their Chicago agent. The plant comprises a 350 h. p. generator, some 23 motors and one 800 incandescent light machine. The plant is to be installed in the Blatz brewery.

THE DORMAN DYNAMO CO., of Chicago, was incorporated December 17. It is rumored that among other factories the late Belding Motor Company is being negotiated for. It is the intention to build dynamos of all descriptions, from the smallest sizes to 2,000 h. p. Mr. Dorman still remains electrician to the Standard Electric Co.

FRASER & CHALMERS, of Chicago, have presented the Western office of THE ELECTRICAL ENGINEER with an exceedingly handsome, framed engraving of the Masonic Temple Building, Chicago, for which this well-known firm have furnished the boilers, engines and machinery, the total weight of which is stated as 325 tons.

THE ILLINOIS ELECTRIC MATERIAL CO. are placing on the market a new flexible duct for drawing in wires for interior lighting, which is meeting with considerable success.

MR. F. W. CUSHING has resigned the secretaryship of the Central Electric Co. and will probably devote his time to marketing the telautograph in which he is interested.

MR. R. MORRISON, engineer of the Winona Lumber Co., Winona, Minn., has made the show window of Morrison & Johnson in that city very attractive by fitting up a small motor with a revolving incandescent lamp, so that a ball of fire appears to be flying around incessantly before the bewildered spectator.

PROF. J. P. BARRETT has returned from his recent visit to New York, as hale and hearty as ever. The Gothamites endeavored to induce the professor to remain with them, but he thinks Chicago a pretty good place to live in and no amount of persuasion could induce him to desert the "Garden City."

BLISS & SODEN, of Chicago, well-known consulting electrical engineers, are kept quite busy attending to various expert testing work and drawing specifications for construction work. These gentlemen are well known among the electrical fraternity for their ability in consulting electrical engineering work.

THE ILLINOIS ELECTRIC MATERIAL CO. have had quite a run during the past week on their various novelties. A miniature motor operated by a battery contained in the base and used to drive all kinds of cardboard figures has been a marked attraction and sold faster than they could supply the demand.

MR. J. R. MARKLE, one of the veterans of the electrical business in the West, was a caller at the Western office of THE ELECTRICAL ENGINEER last week. He is now devoting the principal portion of his time to consolidation of electric lighting, railway and gas company interests.

THE WESTERN ELECTRICAL SUPPLY CO., 619 Locust street, St. Louis, are doing a flourishing business. Amongst recent large orders shipped is one to the Lincoln (Ill.) Water, Light and Power Co. of 20 miles of K. K. wire and full equipments for their arc and incandescent circuits.

MR. J. F. KESTER, of the Kester Electric Co., manufacturers of automatic incandescent dynamos, automatic motors, electric supplies, etc., Terre Haute, Ind., was a welcome visitor to Chicago last week, and reported that he was doing a good business for his company.

MR. GEORGE CUTTER the electrical specialist of Chicago, has gone East to arrange details regarding the recent million-foot order of Simplex wire with the Simplex Co. of Boston. He also has the felicity of handing them another similar order for the same amount.

THE CENTRAL ELECTRIC CO. report since taking the agency for the Interior Conduit & Insulation Company, that they have secured an order for 50,000 feet of one size tube. It certainly can be said that they have started in well.

THE ILLINOIS ELECTRIC MATERIAL CO. have recently obtained the Western agency for the Draper oiler, Redding watchman's clock and fire gongs, and Tregoning tell-tale for use on circuits to notify station men when a line breaks.

THE SHORT ELECTRIC RAILWAY CO., of Cleveland, have recently sold an equipment of 120 gearless motors to the Minneapolis Street Railway Co., and also twelve to the Grand Rapids Street Railway Co.

THE GREAT WESTERN ELECTRIC SUPPLY CO. are receiving large orders from various parts of the country for general electrical supplies for lighting, power and other electrical work.

MR. D. C. SIMS has been appointed manager of the Western Union Telegraph Co., at Atlanta, Ga. He will be succeeded as manager of the Mobile office by Mr. P. K. Garner.

THE KNAPP ELECTRICAL WORKS are catching their usual share of business and are shipping large numbers of Perkins lamps and some good orders for safety wire.

MR. L. W. MOYER has accepted a position as city salesman with the Knapp Electrical Works.

JULIUS ANDRAE has sold a 250 light incandescent Mather machine for Krans & Co.

CLAY, PEPPER & REGISTER DISSOLUTION.

THE firm of Clay, Pepper & Register has been dissolved by mutual consent. The business will be carried on as heretofore by the remaining partners under the firm name of Pepper & Register.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

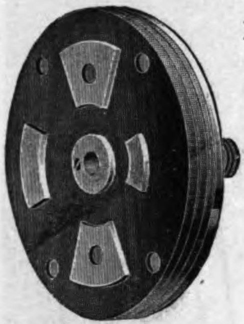
THE
Electrical Engineer.

VOL. XIII. FEBRUARY 3, 1892. No. 196.

THE JOHNSON SWITCH.

BY

Edw. H. Johnson



NLY considered as a bit of mechanism, this switch is almost identical with the ordinary mechanic's vise, differing therefrom simply in the means provided for automatically shutting the jaws when they have been sufficiently opened by the hand to release the outer jaw from the restraining stops. The stops employed are at one and the same time the contacts and the ratchet shaped stops which determine and limit each movement of the switch.

The power employed for effecting the automatic shutting of the vice is a helical wire spring put under tension by each throw of the switch handle and operative to throw the released jaw back to its normal position with such force as to effect a positive wedging of the jaws, alternately locking the circuit closed and locking it open. The releasing of the lock is effected as in an ordinary vise by simply turning the screw-threaded handle until the free jaw is withdrawn sufficiently to permit it to move over the stop [contact] faces.

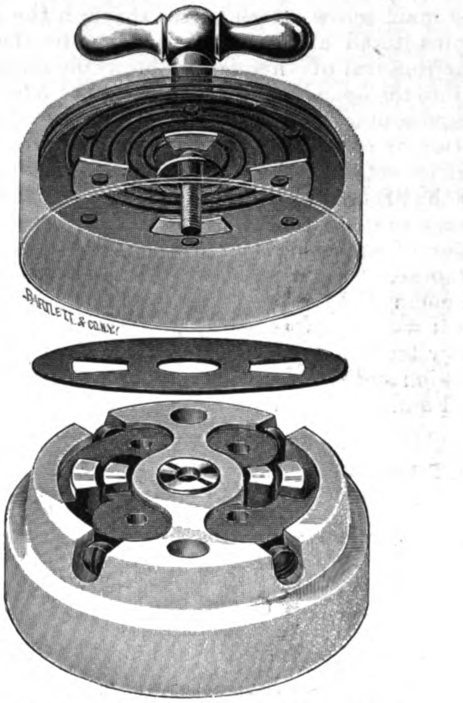
Considered as an electric circuit-controlling device, this switch employs a principle not hitherto made available in snap switches, that is, the substitution of perfectly rigid contacts for contacts dependent upon spring pressure, and the wedging of these rigid contacts between two immovable jaws instead of between yielding springs. The mechanical arrangement thus established is precisely the same as would result from cutting a wire in two, flattening the severed ends, placing them the one upon the other and then wedging them tightly together in a bench vise. Of course it can be seen at a glance that electrically considered we have contacts which under heat must, by natural expansion, be more perfectly united and hence effect a reduction of the heating, thus practically removing the contact surfaces as factors of carrying capacity and raising the capacity of the switch to the actual safe-carrying capacity of the metal employed in the terminals; whereas in all other snap switches, spring pressure being the only opposing factor, the effect of contact heating is diametrically opposite; the heat is communicated to the contact springs, which, in consequence, lose their temper and therefore their pressure thus lessening the contact surface, increasing the heat and effecting the quick destruction of the switch. The carrying limits of all such switches is thereby confined to the safe non-heating limit of the contact surfaces, and even this is an indeterminable because variable quantity, it being subject to the omnipresent element of surface corrosion.

The "breaking" capacity is so high as to render the switch practically independent of any electromotive force ordinarily employed in multiple systems of distribution, whether for light or power. The reason for this is twofold:

1st. The gun-trigger quickness and positiveness of the break, and

2d. The fact that the arc traverses a path twice the length of the switch movement. The means by which this result is accomplished are simple, and are shown on the face of the contact terminals.

A test of the 100 ampere switch on a 500 volt railway circuit showed that the switch would break a current of 100 amperes and 500 volts. Each wire as will be seen in Fig. 1, is fitted with a terminal and these are arranged in two groups or pairs with their contact surfaces parallel with each other; these surfaces are slightly beveled, presenting somewhat of a ratchet form. It is obvious that if each pair of these parallel pieces are bridged by holding a separate metal plate across their faces, the circuit will be closed; these separate plates are carried upon the inner surface of the movable jaw [see Fig. 2.] They are so held and shaped as to give them a slight rocking motion to the end that they may seat themselves with equal firmness upon each of the lower terminals. The smaller plates in Fig. 2 are merely stops so arranged as to seat upon but a single one of each pair of the terminals thus failing to bridge or unite the pairs and consequently leaving the circuit locked open. Fig. 3 is merely an insulating shield. It will now be apparent that if the two plates are united by means of the screw which passes through the handle, or main vise screw, [Fig. 2] and the upper plate is turned on



BARTLETT & CO. N.Y.

FIGS. 1, 2 AND 3.—THE JOHNSON SWITCH.

its operating screw, the two plates will wedge together and since the contact surfaces are slightly raised above the general surface that this wedging will take place on the contact faces. Whether the first action will be to effect a closing of the circuit by bridging the terminals with the broad plates, or to leave the circuit open by wedging the non-bridging terminals, depends simply upon the chance relation of the parts when put together. In either event it is evident that whether the switch is open or closed it has attained a dead stop and no amount of effort to turn it beyond this point will avail. But now if instead of turning the plate itself, the handle be turned, we will have the upper plate gradually withdrawn until the jaws are wide enough apart to permit the contact plates to pass over the highest portion of the beveled terminal faces; the upper plate is thus freed to rotate with the screw and does so with the vigor and snap of a gun trigger by virtue of the tension spring connecting it with the handle and located on its top surface away from the contact surfaces of the switch. The effect of this quick rotation of the plate on its screw is of course to run it down again on the screw to its wedging position and consequently to stop it there with the switch open or closed as the case may be. Each alternate movement always in the same direction thus effects an alternating opening and closing of the circuit.

The entire arrangement of the switch is happy in that each and every part is readily accessible from the face of the switch, and they are all exposed by the removal of a single main screw which passes through the switch handle and pins it and all the working parts to the base plate; by the removal of this screw the whole switch movement falls into the open hand, thus leaving the base plate with its terminal contacts perfectly unobstructed, and rendering the insertion or removal of the wires a most convenient matter.

The inventor of this switch has had for more than five years the firm conviction that the use of spring contacts was contrary to good practice, and so long ago as 1886 made a number of experimental switches in which he sought to incorporate the new principle. Press of other duties, however, compelled the laying aside of the work until recently when it was again taken up and satisfactorily concluded. He now tenders this device to the electrical engineering profession and the electrical industry in the firm belief that a good and valuable service has been rendered.

ELECTRIC DRILL OF THE BERLIN ALLGEMEINE ELEKTRICITAETS GESELLSCHAFT.[1]

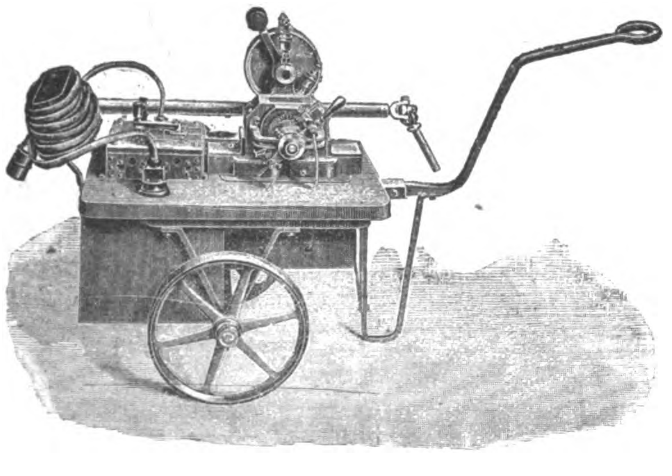


Fig. 1.—Portable Electric Drill.

In order to show the direct applicability of electric motive power to the driving of the tools in machine shops, the Allgemeine Elektricitäts Gesellschaft in Berlin some time ago equipped its entire establishment with electric motors which drive all the shafting, the current being obtained from the central station. One of the latest applications of portable electric tools introduced by them is that exhibited in the engraving, Fig. 1, which shows a portable drill which has already proved of great value in the workshops. The drill is mounted on a platform which also carries the starting box. The power of the motor is transferred to the drill through the medium of reducing gears which can be thrown in or out by means of a lever. The drill is attached to the driving-shaft by means of a universal telescope joint so that the motor and carriage need not be disturbed when the position of the drill is changed. In order to vary the speed of rotation of the drill to correspond to different sizes of holes, the drill spindle is provided with a reduction gear, so that the speed can be reduced from 195, the maximum, to 65 revolutions per minute, at which speed holes 1¼ inch in diameter can be bored. Our illustration, Fig. 2, shows a view in the shops of the company with the machine in operation drilling holes in an engine frame, and also the overhead traveling crane operated by electric motor.

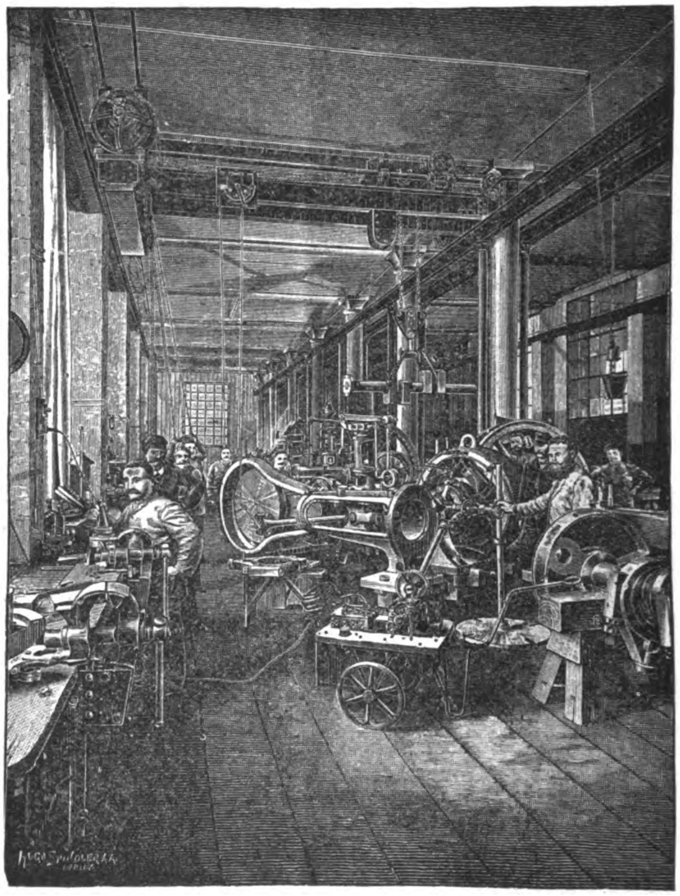

Fig. 2.—Portable Electric Drill at Work.

"L'ELECTRICIEN."

Our Paris contemporary, *L'Electricien*, announces that from January 1, it will be under the management of an editorial committee consisting of Prof. Monnier (École Centrale des Arts et Manufactures), Prof. Éric Gérard (Institut Électrotechnique Montefiore), M. Félix Lucas, M. Emile Dieudonné, M. Eugène Meylan, M. Montpellier (founder of the *Rèvue Internationale de l'Electricité*). The chief object of the appointment of a committee is to secure absolute impartiality.

AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—III.

BY

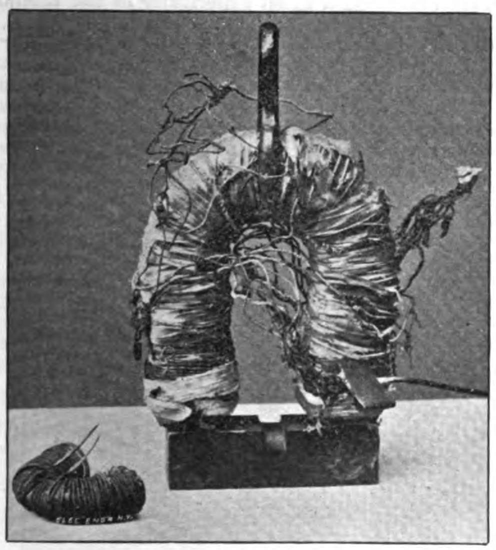
Mary A. Henry

In every well-ordered library stand the volumes of Silliman's *Journal of Science*, the chief repository of the labors of the pioneers, the scientific investigators of our earlier years. If it has been pleasant to dwell in our own words upon Henry's experiment which answered the great question: Can Magnetism produce Electricity? let us now allow him to tell his own story; let us find in the *Journal* the paper we saw him hurriedly preparing for its pages in those last days of June, after reading the brief notice which told him of Faraday's success. It is dated July, 1832. We give it entire, breaking the thread of the narrative here and there for comment:

ON THE PRODUCTION OF CURRENTS AND SPARKS OF ELECTRICITY FROM MAGNETISM.[15]

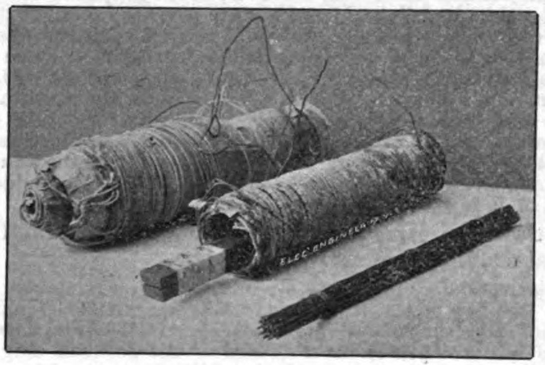
Although the discoveries of Oersted, Arago, Faraday and others, have placed the intimate connection of electricity and magnetism in a most striking point of view, and although the theory of Ampère has referred all the phenomena of both these departments of science to the same general laws, yet until lately one thing remained to be proved by experiment, in order more fully to establish their identity; namely, the possibility of producing electrical effects from magnetism. It is well known that surprising magnetic results can readily be obtained from electricity, and at first sight it might be supposed that electrical effects could with equal facility be produced from magnetism; but such has not been found to be the case, for although the experiment has often been attempted, it has nearly as often failed.

Henry's discovery was no accidental stumbling upon a fact. He believed with all his heart that electricity could produce magnetism before he put the matter to experimental test. From the very beginning of his researches he had the subject in view.



ELECTROMAGNET WITH WHICH THE DISCOVERY OF MAGNETO-ELECTRIC INDUCTION WAS MADE BY HENRY; NOW IN THE CABINET OF THE COLLEGE OF NEW JERSEY.

It early occurred to me, that if galvanic magnets on my plan were substituted for ordinary magnets, in researches of this kind, more success might be expected. Besides their great power, these magnets possess other properties, which render them important instruments in the hands of the experimenter; their polarity can be instantaneously reversed, and their magnetism suddenly destroyed or called into full action, according as the occasion may require. With this view, I commenced, last August,[16] the construction of a much larger galvanic magnet than, to my knowledge, had before been attempted, and also made preparations for a series of experiments with it on a large scale, in reference to the production of electricity from magnetism. *I was however at that time accidentally interrupted* in the prosecution of these experiments, *and have not been able since to resume them until within the last few weeks*,[17] and then on a much smaller scale than was at first intended. In the meantime, it has been announced in the 117th number of the *Library of Useful Knowledge*, that the result so much sought after has at length been found by Mr. Faraday of the Royal Institution. It states that he has established the general fact, that when a piece of metal is moved in any direction, in front of a magnetic pole, electrical currents are developed in the metal, which pass in a direction at right angles to its own motion, and also that the application of this principle affords a complete and satisfactory explanation of the phenomena of magnetic rotation. No detail is given of the experiments, and it is somewhat surprising that results so interesting, and which certainly form a new era in the history of electricity and magnetism, should not have been more fully described before this time in some of the English publications; the only mention I have found of them is the following short account from the *Annals of Philosophy* for April under the head of "Proceedings of the Royal Institution."



APPARATUS MADE BY HENRY, WITH WHICH HE REPEATED THE EXPERIMENT OF FARADAY. NOW IN THE CABINET OF THE COLLEGE OF NEW JERSEY.

> Feb. 17, Mr. Faraday gave an account of the first two parts of his researches in electricity; namely, volta-electric induction and magneto-electric induction. If two wires, A and B, be placed side by side, but not in contact, and a voltaic current be passed through A, there is instantly a current produced by induction in B, in the opposite direction. Although the principal current in A be continued, still the secondary current in B is not found to accompany it, for it ceases after the first moment, but when the principal current is stopped then there is a second current produced in B, in the opposite direction to that of the first produced by the inductive action, or in the same direction as that of the principal current.
>
> If a wire connected at both extremities with a galvanometer, be coiled in the form of a helix around a magnet, no current of electricity takes place in it. This is an experiment which has been made by various persons hundreds of times, in the hope of evolving electricity from magnetism, and, as in other cases in which the wishes of the experimenter and the facts are opposed to each other, has given rise to very conflicting conclusions. But if the magnet be withdrawn from or introduced into such a helix, a current of electricity is produced *whilst the magnet is in motion*, and is rendered evident by the deflection of the galvanometer. If a single wire be passed by a magnetic pole, a current of electricity is induced through it which can be rendered sensible.[18]

So far, Henry's paper is introductory. It now gives two series of experiments, *the one made before, the other after* seeing the brief account of Faraday's result. In the first series we find the experiment we have sketched, and if made before April, 1832, the date of the notice, then, before August, 1831, when Henry's experiments stopped.

Before having any knowledge of the method given in the above account, I had succeeded in producing electrical effects in the following manner, which differs from that employed by Mr. Faraday, and which appears to me to develop some new and interesting facts. A piece of copper wire, about 30 feet long and covered with elastic varnish, was closely coiled around the middle of the soft iron armature of the galvanic magnet, described in vol. xix, of the *American Journal of Science*, and which, when excited, will readily sustain between 600 and 700 pounds. The wire was wound upon itself so as to occupy only about one inch of the armature, which is seven inches in all. The armature, thus furnished with the wire, was placed in its proper position across the ends of the galvanic magnet, and there fastened so that no motion could take place. The two projecting ends of the helix were dipped into two cups of mercury, and there connected with a distant galvanometer by means of two copper wires, each about 40 feet long. This arrangement being completed, I stationed myself near the galvanometer and directed an assistant at a given word to immerse suddenly, in a vessel of dilute acid, the galvanic battery attached to the magnet. At the instant of immersion, the north end of the needle was deflected 30 degrees to the west, indicating a current of electricity from the helix surrounding the armature. The effect, however, appeared only as a single impulse, for the needle, after a few oscillations, resumed its former undisturbed position in the magnetic meridian, although the galvanic action of the battery, and consequently the magnetic power, was still continued. I was, however, much surprised to see the needle suddenly deflected from a state of rest to about 20 degrees to the east, or in a contrary direction, when the battery was withdrawn from the acid, and again deflected to the west when it was reimmersed. This operation was repeated many times in succession, and uniformly with the same result, the armature the whole time remaining immovably attached to the poles of the magnet, no motion being required to produce the effect, as it appeared to take place only in consequence of the instantaneous development of the magnetic action in one, and the sudden cessation of it in the other.

---

[15] From Silliman's *American Journal of Science*; July, 1832; vol. xxii, pp. 403-408.

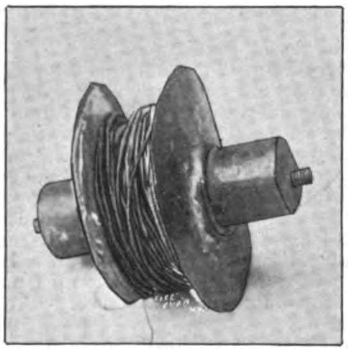
[16] That is, August, 1831, since the paper was published July 1, 1832. M. A. H.

[17] The last two weeks in June (see latter part of the paper) an interval of ten weeks between the cessation and resumption of the experiment. M. A. H.

[18] *Phil. Mag. and Annals of Philosophy*; April 1832: vol. xi, p. 300.

Notice here Henry's instant recognition of the fundamental conditions of the phenomenon.

This experiment illustrates most strikingly the reciprocal action of the two principles of electricity and magnetism, if indeed it does not establish their absolute identity. In the first place, magnetism is developed in the soft iron of the galvanic magnet by the action of the currents of electricity from the battery, and secondly, the armature, rendered magnetic by contact with the poles of the magnet, induces in its turn currents of electricity in the helix which surrounds it; we have thus as it were electricity converted into magnetism and this magnetism again into electricity.



APPARATUS USED BY HENRY FOR INVESTIGATING EFFECT OF ROTATION OF IRON CORE WHILE SUBJECTED TO INDUCTION.

Another fact was observed which is somewhat interesting inasmuch as it serves in some respects to generalize the phenomena. After the battery had been withdrawn from the acid, and the needle of the galvanometer suffered to come to a state of rest after the resulting deflection, it was again deflected in the same direction by partially detaching the armature from the poles of the magnet to which it continued to adhere from the action of the residual magnetism, and in this way, a series of deflections, all in the same direction, was produced by merely slipping off the armature by degrees until the contact was entirely broken. The following extract from the register of the experiments exhibits the relative deflections observed in one experiment of this kind:

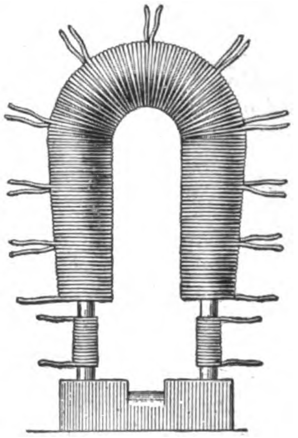
At the instant of immersion of the battery, deflection	40° west.
At the instant of emersion " " "	18° east.
Armature partially detached " " "	7° "
Armature entirely detached " " "	12° "

The effect was reversed in another experiment, in which the needle was turned to the west in a series of deflections by dipping the battery but a small distance into the acid at first and afterwards immersing it by degrees.

From the foregoing facts, it appears that a current of electricity is produced for an instant, in a helix of copper wire surrounding a piece of soft iron, whenever magnetism is induced in the iron; and a current in the opposite direction when the magnetism ceases; also that an instantaneous current in one or the other direction accompanies every change in the magnetic intensity of the iron.

The paper now proceeds to give the series of experiments, made in the last weeks of June, 1832, *after* seeing the brief notice of April of Faraday's results.

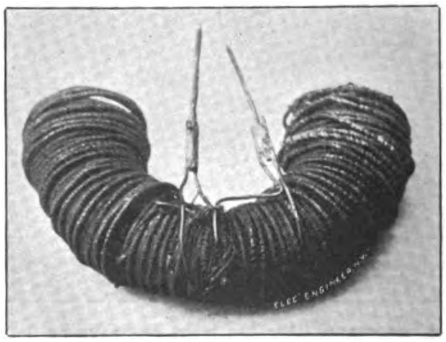
Since reading the account before given of Mr. Faraday's method of producing electrical currents, I have attempted to combine the effects of motion and induction; for this purpose a rod of soft iron ten inches long and one inch and a quarter in diameter, was attached to a common turning lathe, and surrounded with four helices of copper wire in such a manner that it could be suddenly and powerfully magnetized while in rapid motion by transmitting galvanic currents through three of the helices; the fourth being connected with the distant galvanometer was intended to transmit the current of induced electricity; all the helices were stationary while the iron rod revolved on its axis within them. From a number of trials in succession, first with the rod in one direction then in the opposite, and next in a state of rest, it was concluded that no perceptible effect was produced on the intensity of the *magneto-electric* current by a rotary motion of the iron combined with its sudden magnetization.



HENRY'S APPARATUS FOR INCREASING MAGNETO-ELECTRIC EFFECT.

The same apparatus, however, furnished the means of measuring separately the relative power of motion and induction in producing electrical currents. The iron rod was first magnetized by currents through the helices attached to the battery, and while in this state one of its ends was quickly introduced into the helix connected with the galvanometer; the deflection of the needle in this case was seven degrees. The end of the rod was next introduced into the same helix while in its natural state and then suddenly magnetized; the deflection in this instance amounted to thirty degrees, showing a great superiority in the method of induction.

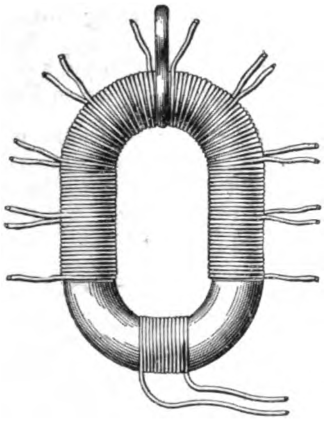
The next attempt was to increase the *magneto-electric* effect while the magnetic power remained the same, and in this I was more successful. Two iron rods six inches long and one inch in diameter, were each surrounded by two helices and then placed perpendicularly on the face of the armature, and between it and the poles of the magnet, so that each rod formed as it were a prolongation of the poles, and to these the armature adhered when the magnet was excited. With this arrangement, a current from one helix produced a deflection of thirty-seven degrees; from two helices both on the same rod fifty-two degrees, and from three, fifty-nine degrees; but when four helices were used the deflection was only fifty-five degrees, and when to these were added the helix of smaller wire around the armature, the deflection was no more than thirty degrees. This result may, perhaps, have been somewhat affected by the want of proper insulation in the



ARMATURE USED BY HENRY TO PRODUCE THE ELECTRIC SPARK. NOW IN THE CABINET OF THE COLLEGE OF NEW JERSEY.

several spires of the helices, it however establishes the fact that an increase in the electric current is produced by using at least two or three helices instead of one. The same principle was applied to another arrangement which seems to afford the maximum of electric development from a given magnetic power; in place of the two pieces of iron and the armature used in the last experiments, the poles of the magnet were connected by a single rod of iron, bent into the form of a horseshoe, and its extremities filed perfectly flat so as to come in perfect contact with the faces of the poles; around the middle of the arch of this horseshoe, two strands of copper wire were tightly coiled one over the other. A current from one of these helices deflected the needle one hundred degrees, and when both were used the needle was deflected with such force as to make a complete circuit.

When two clouds approach each other in the summer sky, the electricity in them is manifested by the lightning which leaps from one to the other. Henry desired a similar manifestation of the electricity he could make his magnets produce, and in the next experiment he obtains this in *the electric spark*.



Apparatus Employed by Henry for Producing the Magneto-Electric Spark.

But the most surprising effect was produced when, instead of passing the currents through the long wires to the galvanometer, the opposite ends of the helices were held nearly in contact with each other and the magnet suddenly excited; [see illustration] in this case a small but vivid spark was seen to pass between the ends of the wires, and this effect was repeated as often as the state of intensity of the magnet was changed.

In these experiments the connection of the battery with the wires from the magnet was not formed by soldering, but by two cups of mercury which permitted the galvanic action on the magnet to be instantaneously suspended and the polarity to be changed and rechanged without removing the battery from the acid; a succession of vivid sparks was obtained by rapidly interrupting and forming the communication by means of one of these cups; but the greatest effect was produced when the magnetism was entirely destroyed and instantaneously reproduced by a change of polarity.

It appears from the May number of the *Annals of Philosophy* that I have been anticipated in this experiment of drawing sparks from the magnet by Mr. James D. Forbes of Edinburgh, who obtained a spark on the 30th of March; *my experiments being made during the last two weeks in June*. A simple notification of his result is given, without any account of the experiment, which is reserved for a communication to the Royal Society of Edinburgh. My result is therefore independent of his, and was undoubtedly obtained by a different process.

The paper closes with the discovery of the "extra current", which we have shown Henry making in 1829, distinctly inserted here, we ask the reader to notice, as a phenomenon of the same order. Five years later, in 1834, this fact, rediscovered by Faraday, formed another star in his crown.

ELECTRICAL SELF-INDUCTION IN A LONG HELICAL WIRE.

I have made several other experiments in relation to the same subject, but which more important duties will not permit me to verify in time for this paper. I may, however, mention one fact which I have not seen noticed in any work, and which appears to me to belong to the same class of phenomena as those before described; it is this: When a small battery is moderately excited by diluted acid, and its poles, which should be terminated by cups of mercury, are connected by a copper wire not more than a foot in length, no spark is perceived when the connection is either formed or broken; but if a wire thirty or forty feet long be used instead of the short wire, though no spark will be perceptible when the connection is made, yet when it is broken by drawing one end of the wire from its cup of mercury, a vivid spark is produced. If the action of the battery be very intense, a spark will be given by the short wire; in this case it is only necessary to wait a few moments until the action partially subsides, and until no more sparks are given from the short wire; if the long wire be now substituted a spark will again be obtained. The effect appears somewhat increased by coiling the wire into a helix; it seems also to depend in some measure on the length and thickness of the wire. I can account for these phenomena only by supposing the long wire to become charged with electricity, which by its reaction on itself, projects a spark when the connection is broken.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—III.

BY

Francis B. Crocker and S. S. Wheeler.

Electrical Connections.—As already stated these should be very carefully cleaned and this may well be carried to the extent of rubbing them vigorously with clean cloth or chamois skin. Any of the metal surfaces used in making electrical contacts which are tarnished should be brightened with fine sandpaper or by scraping them, but all sand, metallic particles, etc., must be carefully removed afterwards. Particles of sand or dirt are often left accidentally between surfaces which should be in perfect contact.

Wiring.—It is very desirable to have a thoroughly competent lineman or electrician to connect a dynamo or motor to the circuit, see that everything is properly arranged and start the machine the first time.

The connections should all be made in a substantial and permanent manner. Good quality of insulated wire should be used and should be properly arranged and laid.

Temporary, loose or poorly insulated wires or connections are very objectionable. All circuits exposed to moisture should be supported on glass, porcelain or other waterproof insulators. Circuits of over 250 volts even where not exposed to moisture should also preferably be carried on porcelain or similar insulators, as shown in Fig. 4, and out of reach if possible, and the best insulated wire should be used.

Low-voltage circuits of 230 volts or under may be run in wooden moulding or cleats where entirely unexposed to moisture. Where wires pass through walls, floors, over pipes or are otherwise liable to injury they should be protected by hard-rubber tubing or other equally good covering. No wire smaller than No. 8 B. & S. gauge should be used for the arc current of 10 amperes, and other wires should be in proportion; that is, they should have from 800 to 1,200 circular mils per ampere. The former figure (800) is for small wires, in cool places; the latter figure (1,200) is for wires carrying heavy currents or high voltage and wires in hot places such as ceilings of kitchens, etc. No wire smaller than No. 16 should ever be laid to carry any current from a dynamo (smaller wires may be used for primary battery currents) no matter how small the current may be.

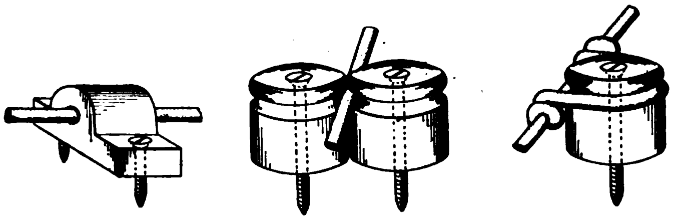


Fig. 4.—Wires Carried on Porcelain.

The above sizes of wire are rather larger than are generally given but it is wise to have an ample margin. Failure to allow a proper margin or factor of safety has been the cause of most of the troubles in all branches of electrical work.

In addition to the above allowances for current capacity or the ability of wires to carry the current without overheating, it is also necessary to consider the fall of potential or "drop" on wires. This loss ought not to exceed 5 per cent. in isolated plants, 10 per cent. in central station systems, and about 20 per cent. in long-distance transmission. That is to say, the voltage at the most remote point on the system should not fall below the voltage at the dynamo by more than these percentages. A "wiring table" is given at the end of this work for determining the size of wire required in various cases. A simple rule derived from Ohm's law applicable to all cases is, that the lost voltage obtained by multiplying the current in amperes at full load by the total resistance of the circuit in ohms must not be more than the given percentage of the voltage at the generator.

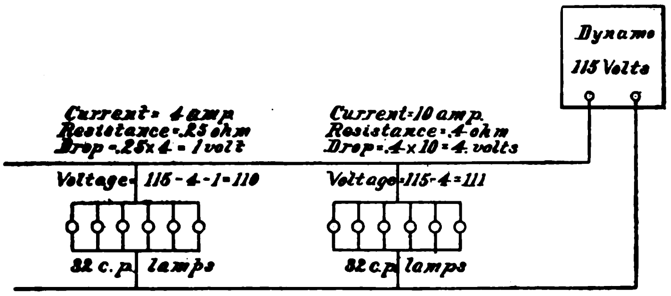

FIG. 5.—"DROP" ON BRANCHING CIRCUITS.

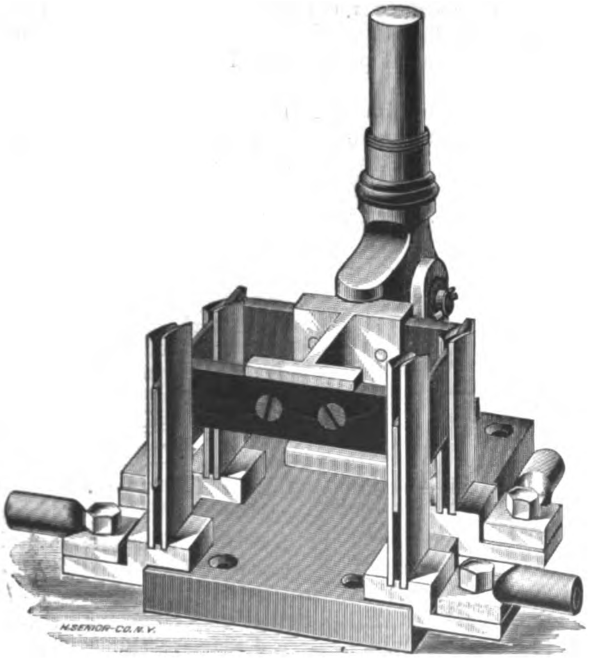
In the case of a branching circuit, shown in Fig. 5, or other case where the current is not the same throughout, the separate parts should be treated separately as indicated in the diagram. This calculation applies particularly to motors which are often put at the end of a long circuit or branch.



H.SENIOR-CO.N.Y.

FIG. 6.—DOUBLE-POLE QUICK-BREAK SWITCH.

Switches and Cut-Outs.—The bases of all switches, cut-outs, etc., should be of slate, porcelain or other fire-proof, non-porous, insulating material. On all constant-potential or multiple arc circuits, double-pole fusible cut-outs should be put where each branch starts. On all constant-current or arc circuits, double-pole cut-out switches should be put where the circuit enters any building and also near any motor or group of lamps on such circuits. All high-voltage circuits and any low-voltage circuit carrying more than three amperes should be controlled by double-pole switches or cut-outs which entirely disconnect both sides of the circuit, and they should also preferably have a "quick break," especially with direct currents.

The exceptions to this rule are first,—constant-potential dynamos which usually have single-pole knife switches, the other pole being permanently connected to the circuit; and second, constant-potential motors which generally have single-pole switches on the starting boxes, the other pole being always connected to the circuit. In the latter case, however, it is recommended to also put a double-pole quick-break switch in the circuit, as shown in Fig. 6.

Diagrams of Connections are given in each important case to show the actual connections which are necessary. But when a machine is to be "connected up" a competent electrical engineer should be consulted or an exact diagram should be obtained from the maker of the machine, as its connections may be peculiar and cause serious trouble. Diagrams merely represent the path of the wires in the simplest way, the important thing in electrical connections being *which* parts or wires are connected, not *how* they are connected. Whether the path be straight or crooked, vertical or horizontal, etc., is of no consequence. Diagrams of the three most important cases of dynamo connections are here given. The other diagrams of dynamos and motor connections are given hereafter.

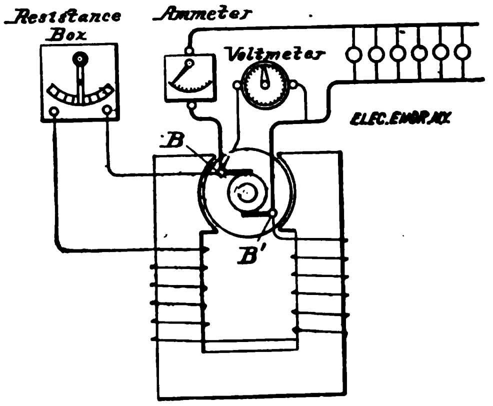


FIG. 7.—SHUNT DYNAMO ON CONSTANT POTENTIAL CIRCUIT WITH LAMPS IN PARALLEL.

Shunt Dynamo on Constant-Potential Circuit is represented in Fig. 7 with the necessary connections. The brushes B and B, are connected to the two conductors forming the main circuit, also to the field-magnet coils *through* a resistance box to regulate the strength of current and therefore the magnetism in the field. A voltmeter is also connected to the two brushes or main conductors to measure the voltage or electrical pressure between them. One of the main conductors is connected to an ampere meter which measures the total current on the main circuit. The lamps are connected in parallel between the main conductors or branches from them.

FRANKFORT EXHIBITION SURPLUS.

THE surplus, after paying all expenses, amounts to $38,000. Out of this sum the town of Frankfort and the local Chamber of Commerce will receive back their guarantees, whilst to the exhibitors will be returned a large amount of the costs for space and power.

THE COMPOUND ENGINES OF THE BUFFALO RAILWAY CO., OF BUFFALO, N. Y.

BY

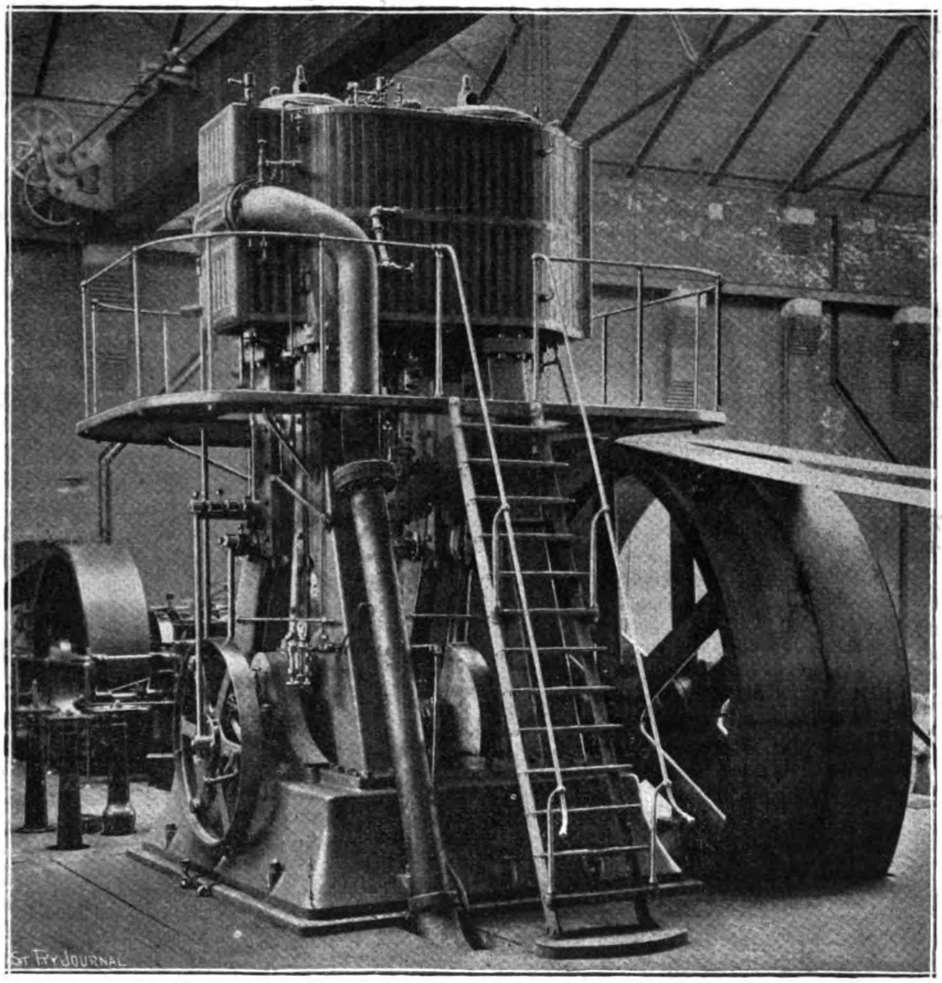
C. J. Field.

THERE has been recently installed in the power house of the Buffalo Railway Co. the first of two engines which have been specially designed for electric railway work. The result is that the engine differs in detail from most engines used on this class of work. The general type is that of a vertical 2-crank compound condensing, with cranks at 90° to facilitate starting and stopping. The engine was designed to run condensing or non-condensing, and is running in the latter manner to-day on account of the condenser house being as yet unfinished, and is giving perfect satisfaction.

The engine, which is illustrated in the engraving, Fig. 1, drives two No. 60 Edison railway generators by means of two 24 inch belts from the fly-wheel of the engine, which is 12 feet in diameter and weighs 36,000 pounds. The total weight of engine is about 90,000 pounds. This engine has a rotative speed between that of a Corliss and high-speed engine, running 138 revs. per min., but with a piston speed of 600 feet per min. The high-pressure cylinder is 17 inches in diameter; the low 33½ inches, and the common stroke is 38 inches; on 125 lbs. initial pressure the engine develops 450 horse power.

The steam distribution is effected by means of four light, flat, double-ported and perfectly balanced valves to each cylinder, the exhaust valves being controlled independently from the steam valves, and giving different degrees of cut-off and compression. The clearance is cut down to as low as consistent with necessary compression, being 8 per cent. in the high and 4 per cent. in the low pressure cylinder.

The high-press cylinder is fitted with a "liner" and steam-jacketed, and the receiver is located between the cylinders. The steam valves on the low-pressure cylinder have a peculiar, quick motion, caused by a neccentric operating through the intervention of a set of rocker arms, thus giving a sharp cut-off on the low pressure cylinder.



COMPOUND ENGINE OF THE BUFFALO RAILWAY CO.

The speed of revolution of the engine is regulated by means of a shaft governor. All are aware of the necessity for good regulation in any engine under sudden changes of load, and especially in electric railway work. The steam valves on the high pressure cylinder are controlled directly by this shaft governor.

There has been a question raised as to the possibility of governing the speed of such a large unit as this engine represents by means of a centrifugal shaft governor so arranged that it could move the valves direct and yet be sensitive to changes of load. That it is possible is shown by the fact that this engine is operated in this very manner and varies only by $\frac{1}{2}$ revolution in a change of load from 360 to 700 amperes. The governor itself is very sensitive having only one weight, two arms and four pivoted joints.

The details of the engine have been very carefully worked out. The cross-head slippers are babbitted and set out by means of liners instead of wedges. The cross-head is forged solid on the end of the piston-rod. The crank end of the connecting rod is of the standard marine type and the cross-head ends are forked. All bearings are babbited, and in the case of the main bearings have cast iron babbitt-lined shells, around which water is circulated to prevent serious trouble in case of overheating. The back of the slides is also water-jacketed.

The lubrication of the different parts is effected by means of grease instead of oil; it is distributed in pipes by pressure from a central reservoir, very much like an accumulator in a hydraulic plant, the grease being forced to every part on the engine and controlled in amount by stop cocks at each bearing. The second engine of this type is now being erected at the station.

These particular engines were built for the Buffalo plant by the Lake Erie Engine Works, of Buffalo, and they are building a standard electric railway and lighting engine in compound and triple expansions embodying the features of the Buffalo engine and which are used for direct connection to multipolar generators, up to 5,000 horse power.

The Buffalo engine was installed through the Field Engineering Co., who designed and equipped the entire railway system in Buffalo for the Buffalo Railway Co., of which Col. Henry W. Watson is president, and Mr. H. H. Littell general manager.

THE THEORY OF THE PERRET MAGNETIC FIELD.

BY

Frank A. Perret

MR. H. R. WELLMAN'S criticism in THE ELECTRICAL ENGINEER of Jan. 20, refers, I suppose, to the description of my method of multipolar field magnet construction as stated in Sec. 2 of an article in your issue of Jan. 6. It is evident that he has misunderstood the purport of the claims for superiority as therein described. The writer of that article had no intention of going exhaustively into the subject and possibly clearness was sacrificed to brevity. Lest others should also be misled, allow me to state that it is not claimed for this design of magnetic circuit that it ensures lower speed than the ordinary multipolar type *independently of the quality and lamination of the iron.*

The advantages claimed for it are:

1, the use of separate magnets presenting both poles to the armature and isolated magnetically one from another except through the medium of the armature core, instead of double the number of magnets uniting in a common yoke.

2, the employment of only half the usual number of field magnetizing coils and

3, the lamination of the field magnets.

Besides the advantage of simplicity this construction is most effective in securing an equal magnetic distribution.

I find that the section referred to above is based on an article written by me in the year 1890, in which I attempted a simple explanation of how, in multipolar machines, a lower speed is obtained than in machines of the bipolar type. In practice, all the lines of force do not enter and leave the armature at the consecutive field poles, but the number of lines crossing the "entrefer" or air-gap to or from each pole is exactly the same as if they did so and the result, as Mr. Wellman shows, is precisely the same. It was not thought necessary at the time to point this out, as the diagram clearly and correctly indicated the path of the magnetic flux in the machines of my design.

What we call lines of force are not *lines*, having individuality. The magnetic flux from one pole divides in the armature into two streams, one of which re-enters the same magnet at its opposite pole and the other reaches the adjacent pole of the neighboring magnet (having traversed a path of the same length and the same reluctance as the first) and loses its identity in the stream generated by that magnet. It will thus be seen that the diagram is a correct representation of the magnetic circuit in question and that in no other way can it be properly shown.

THE STANLEY AND KELLY ALTERNATING MOTOR.[1]

IT has appeared necessary to us that any system of power distribution by alternating currents of electricity to be commercial, should be operated on the existing systems of current supply, viz., the multiple transformer system of standard frequency. In order to produce a motor to fit these conditions we have studied an ordinary continuous current motor when supplied with alternating currents, for it is evident that if the electrical reactions produced by alternating currents in a motor are similar to those produced by continuous currents, the problem would be a comparatively simple one.

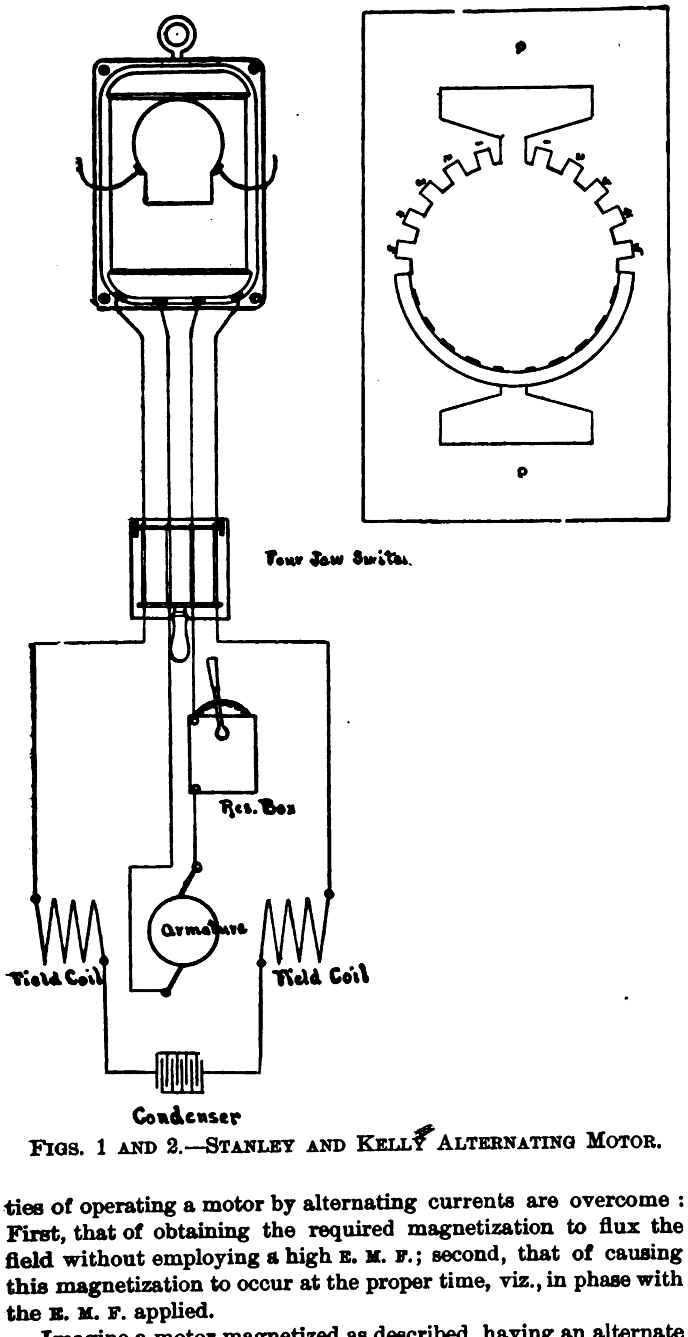
The motor described below is the invention of Mr. William Stanley, Jr., and Mr. John F. Kelly, and is the outgrowth of a motor in which a condenser is used in the field circuit. The present form makes use of the condenser and embodies several important improvements. In general the motor is of the two or four pole type (although the number of poles is not restricted) having a well laminated field and armature. The field coils are of comparatively few turns, which may be placed on the poles as in the ordinary type of direct current Motor, and are connected either in series or multiple, through a condenser to a source of alternating current, as shown in Fig. 1. The armature is of a specially wound closed circuit type, having an ordinary Gramme commutator on which bear two brushes placed on the neutral line or lines. These brushes are connected to the source of alternating current supply. The transformer furnishing current to the shunt type of motor has two secondaries, one of which supplies the field with a constant current, while the other supplies a variable current to the armature.

Before taking up the description of the motor in detail, let us see the effect of applying an alternating E. M. F. to a continuous current shunt wound motor. We will consider a motor wound with 3,000 turns on its field, which when in circuit furnishes the necessary magnetizing power of 500,000 C. G. S. lines of magnetism through the armature. Just as in a transformer the reactive effect of the magnetism on the primary coil develops a counter E. M. F. of self-induction, so also the effect of the field magnetism on the field coils develops a counter E. M. F. which practically annihilates the impressed E. M. F., and by preventing nearly all the current from flowing through the field circuit greatly reduces the magnetism.

It is of course possible to apply a sufficiently high E. M. F. to give the required field magnetization, but a brief calculation shows that under the conditions assumed, this E. M. F. would be about 9,000 volts, a pressure entirely out of the question. The magnetization set up through a given circuit is approximately proportional to the product of the number of turns and the current, viz., the ampere turns, which product may, of course, be obtained with a fewer number of turns and a larger current. This has an important bearing in reducing the applied E. M. F. on the field. Instead of 3,000 turns suppose we take 250; to give the same magnetization the current will have to be twelve times as great, and calculation shows the necessary E. M. F. to be about 750 volts. Fortunately it is not necessary to employ this as an impressed E. M. F. from the transformer, for by inserting into the field circuit a condenser of proper size (dependent on the number of alternations, the reluctance of the circuit, the turns, etc.) there is developed an E. M. F. between the condenser terminals that always opposes the E. M. F. of self-induction in time and value, and destroys all effects of self-induction, allowing the same amount of current to flow as if the circuit were supplied with a continuous current, neglecting of course losses due to extra apparent resistance by hysteresis and Foucault currents. By inserting a condenser in the field circuit any low E. M. F., as 100 volts, may be used to magnetize the field, thus obviating the use of high potentials. The employment of the condenser has also the advantage of reducing the lag of the current behind the applied E. M. F., a result which would take place if a field E. M. F. of 750 volts were used, and no condenser was in circuit. Thus two of the difficulties of operating a motor by alternating currents are overcome: First, that of obtaining the required magnetization to flux the field without employing a high E. M. F.; second, that of causing this magnetization to occur at the proper time, viz., in phase with the E. M. F. applied.

---

[1] Abstract of a paper read before the Chicago Electric Club by Wm. Stanley, Jr.



FIGS. 1 AND 2.—STANLEY AND KELLY ALTERNATING MOTOR.

Imagine a motor magnetized as described, having an alternate current applied to its armature; there will be a lag of the current in the armature behind its E. M. F. as was the case of the field current. To give the maximum amount of power and torque for given values of currents in the field and armature they must flow in unison; for if there be a lag between the field magnetization and armature current, during that part of an alternation in which the currents coincide, the pull will be in one direction, and during that part of the alternation in which the currents are opposed, the pull will be reversed. To overcome this difficulty we have wound about the armature parallel to the direction of the field magnetization a number of short circuited coils sunk in slots in the field poles, as shown in Fig. 2. This short circuited winding is only acted upon by the current in the armature coils, and as a short circuit in the secondary coil of a transformer destroys the self-induction of the primary circuit, so the currents induced by the armature current in the short circuited coils reduce the self-induction of the armature coils, and consequently the lag in the armature current, and bring it in phase with the applied E. M. F. Clearly the E. M. F.'s applied to the field and armature coincide (because they come from the same transformer), and as there is no lag in either the field or armature current, it is evident that the field magnetization and armature current must coincide, and that the torque of the motor must always be in one direction. Thus another difficulty is removed.

If a motor made as described be supplied with alternating currents it will start from rest with the same torque as if supplied with continuous currents. If it is run free of load the current in the armature will be small, and as load on it is increased the current in the armature will increase in like proportion. In short, it will behave exactly like a continuous current motor.

MASSAGE WITH CURRENTS OF HIGH FREQUENCY.[1]

BY H. NEWMAN LAWRENCE, M. I. E. E.

THE paper by Mr. Nikola Tesla, which you publish in your last issue, is very interesting, and, doubtless, as it comes from the other side of the water, will attract some attention in English medical circles.

The suggestion set forth is not, however, so entirely new as the author seems to suppose. Raising the temperature of the human body for curative purposes by "connecting it with a source of rapidly alternating high potential" has been practised by myself for some time past, and I believe by others also. I do not say that we have gone so far as to thoroughly warm a nude body with the surrounding air at freezing point, but we have frequently produced a pleasant glow over the whole body, and warmed chilled extremities.

As regards the therapeutic value of such treatment, my own experience, gained mainly at the late Institute of Medical Electricity, Limited, leads me to conclude that though this method is valuable to a certain extent, yet it is more useful as an adjunct to, than as a substitute for, other forms of treatment. In saying this, I must admit that the method under which I work falls far short of the conditions referred to by Mr. Tesla. I speak of results obtained from the use of an Apps coil, giving a difference of potential of about 10,000 volts, and whose alternations could hardly be called "rapid" in this connection. It is only fair to assume that the effects observed would be much increased by increased rapidity of alternation.

The title Mr. Tesla has chosen for his paper is somewhat misleading, and it is hard to see the connection between the word "massage" and the matter dealt with. I presume he means that the effect produced by electricity thus used is similar to that obtained by massage. If so, the comparison is a very superficial one, for the effects can only be in a small degree similar, though undoubtedly the raising of the surface temperature is an accompaniment of both. I might add that in many cases I find the best effects obtained from the use of massage in addition to or in combination with the high potential coil currents above referred to.

"FAR SUPERIOR."

THE general manager of a large central station in Pennsylvania writes us, in renewing his subscription: "I desire to express my appreciation of your magazine. I think it is far superior to any other electrical paper published in the country."

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, FEBRUARY 3, 1892. No. 196.

The discoveries of inductive science need no apparatus. They are made and matured in the brain; and to record them is the only physical incident to their existence or development.—Edward N. Dickerson.

ELECTRICITY IN THE HOUSEHOLD.

AN advance copy of a most interesting little pamphlet has just reached us, from the pen of Mr. H. Ward Leonard, on the subject of "Electricity in a Modern Residence." As a matter of fact the pamphlet is not quite so broad in treatment of the subject as might be gathered from the title, but seeing that it deals with questions of light, heat and power, it will be admitted to cover all the principal ground that at present falls within the province of electrical engineering.

The issuance of this brochure is so timely and suggestive as to invite more attention than is generally bestowed on literature of its class. It marks very definitely the beginning of a new period in electric lighting, that, namely, in which current is brought within command of the ordinary household, whether it inhabits a "modern residence" or is fortunate enough to occupy one of the old-time mansions that compensate in dignity and comfort for what they lack in stained glass and frenzied decoration. Mr. Leonard points out that the illuminating companies have been slow in reaching residential districts, and says truly that it is because paying loads have chiefly been found in business sections of the town or city. Taking a business area with a capacity of 10,000 lights and a dwelling area of 10,000 lights—in the former instance the steady load will run up to even more than 7,500 lights, while in the latter it often may not reach 1,000 lights. Now as expenses in each case are the same, which field of work should an illuminating company cater for when it starts? There can be but one answer to the inquiry. But when a station has worked up to a good degree of its possible load in a business region, it begins to be worth while to keep up the load line more hours and at a higher ampereage, utilizing the station capacity to the fullest; and here the residence field comes in. A great many stations are just at this point now, we think, and they could not do better than circulate Mr. Leonard's pamphlet among their possible customers, especially those who, after sitting under the cheerful incandescent lamp in their offices and factories, do not wish to go home and stifle in the vitiated atmosphere of gas.

Mr. Leonard puts the price of electricity and gas on a par. That is about right, but, of course, depends on local conditions. Even if electricity cost a little more, as it may in some places, people are ready and willing to pay the slight difference. They get it back in better health, purer air, and a longer freshness of paint, furniture, pictures and books. The price of wiring, Mr. Leonard estimates to range from $1.50 to $4 per lamp, or $2.50 per lamp on the average. The question comes in, who is to pay for the wiring? We say, not the company. If the business is so profitable that they can afford to do it, let them lower the price of current instead. For the operation of various power devices, Mr. Leonard allows $50 a year, even when used a good deal. That ought to be enough. The price of a ventilating fan complete he puts at $25; an ice cream freezer, and motor, $100 to $200; an automatic electric pump, $200; a dumb-waiter complete with motor of ¼ h. p. about $150. But it strikes us that some of these might be run by the same motor. To these he adds an electric elevator costing $2,000 to $3,000 and taking about five dollars' worth of current a month. Stairs are a barbarism, but an elevator must evidently remain a luxury except in houses of some pretensions. But even then, there are at least a thousand residences in New York City alone, where electric elevators could well be afforded by their wealthy occupants. We note that Mr. Leonard proposes to run the bells from the lighting circuits. For country houses, especially along the coast, he proposes an equipment combining a windmill and storage batteries, the whole costing about $1,500. We know of no clinching argument against such an outfit.

As might be expected, Mr. Leonard touches also on electric heating, and electric appliances for cooking, ironing, etc. We see now and again some very flat-footed proofs that electric heating is enormously costly, but the estimates never make any allowance for the space required by a coal cellar and furnace that will occupy at least one-tenth of a house renting at $3,000 or $4,000 a year; nor do they touch on the cost of bringing in coal and removing ashes; nor on the wear and tear of furnaces, ranges and stoves; nor on the little extra payment of $3.50 a month to a man from outside to look after the furnace. The same estimates leave out of sight the fact that two or three rooms in the house are up to boiling point, without relief, while in other rooms iced water can always be made on the spot. These estimates again, if they deal with steam heating, forget the terrific bombardments between the United States and Chili that go on inside the heaters, and are always worst in the midnight hours when one is desperately sleepy.

Electric heating is the beau ideal of warmth as electric lighting is of illumination. And as we have already "arrived" with light and power, the day is certainly not far distant when the electrical engineer will "get there," too, with electric heat, as one of the boons that his art and skill provides for a welcoming public.

THE LAUFFEN-FRANKFORT TRANSMISSION.

The electrical event par excellence of the year 1891, was undoubtedly the successful accomplishment of the transmission of power by alternating currents of high potential between Lauffen and Frankfort, a distance of some 112 miles. The special committee appointed to test this installation have not yet made their official report, but the interest with which the large body of electrical engineers has followed these experiments is such as to warrant us in bringing forward a preliminary statement of the results obtained at Frankfort, as they appear in an article in the *Schweizerische Bauzeitung* by Mr. Emil Huber, director of the celebrated Oerlikon Works. According to Mr. Huber, the average potential used in the experiment was 16,000 volts, and only towards the end of the experiment was it increased to 30,000. The fears at first expressed that the oil insulators would not stand this pressure proved groundless, for as an actual fact only a single insulator broke down, and that under a strain of 30,000 volts.

Two other disturbances were caused by the breaking of a wire and by a defective insulator, due to a fault in the manufacture, respectively. It is interesting to note that the cost of the installation per effective horse-power—on the assumption that 300 h. p. was delivered to the line at Lauffen, and that the whole amount of this energy was available in Frankfort—was $300, of which the line itself involved a cost of $210!

But the next most interesting question from the electrical engineer's standpoint is that of the efficiency of transmission obtained in the Lauffen-Frankfort installation.

During the experiments, regular readings were taken at both ends of the line, and voltmeter readings were taken between one conductor and the neutral point in each of the three circuits, which averaged 54 volts, the currents reading 500, 490 and 500 amperes respectively in the primary circuits. Leaving out of consideration the lag between the current strengths and the potentials, the mean electric power delivered to the line was 80,500 watts. At the same time, the Frankfort end of the line delivered current for 1060 incandescent lamps of 16 c. p., which absorbed 58,000 watts. According to this estimate, therefore, the installation showed an efficiency of 72 per cent. Mr. Huber, however, points out that in reality the efficiency was actually higher, due to this lag, and he estimates it to be about 5 per cent.

Regarding the doubts which were at one time expressed as to the influence of rain and foggy weather, it was shown that these phenomena had no material influence on the working of the line, no direct leakage to earth having been observed, the instruments showing the same indications both in wet and dry weather; so that, if there actually was such a loss, it was negligible. The losses due to condenser action of the insulators were also found to be but very small. In general it is claimed that no abnormal phenomena were developed in this transmission which could not be calculated and allowed for in advance for any similar installation to be made in the future, and that the losses are similar to those occurring in low-tension systems and which can be determined by Ohm's law.

In the absence of the official report of this installation, the results, as stated above, coming as they do from an interested party, must still be considered of a tentative nature, but if they should be substantiated by the official report of the commission, the Lauffen-Frankfort transmission may well claim a high place among modern feats of engineering.

ELECTRIC POWER IN MILLS AND FACTORIES.

Closely succeeding the development of the electric railway field, has come the exploitation of electric mining, which is now going on apace. A new department of work, has opened up, however, that in some respects, combines the features of the other two departments of work, and bids fair to equal either in importance and magnitude. We refer to the use of electric power in mills and factories, with the object of driving elevators, locomotives, fans, shafting, tools, machinery, all from a central station that may also furnish light. Plants of this kind are springing up right and left, and the article that we publish in this issue on the successful utilization of electric power on these lines at the big Edison Schenectady Works emphasizes the extent to which the new departure has already been carried as a mechanical and economic revolution. Here, for example, in works covering not less than 12 acres and employing from 3500 to 4000 men, we find nearly 50 electric motors of a capacity of about 1500 h. p. delivering power on the call and with instant regulation at the generating point. And so it goes—in tile works at Zanesville, O.; in roller mills at St. Paul; in the Fraser & Chalmers shops in Chicago; on the World's Fair grounds; in candy factories at New Haven, breweries at Milwaukee, and all along the line of American industry.

PORCELAIN vs. GLASS INSULATORS.

The appeal to the porcelain manufacturers of America, issued through our columns by Mr. Francis W. Jones, has served to bring out several interesting communications on this subject, two of which appear in this issue. Mr. Stott gives the results of tests on what is known as the Johnson fluid insulator. The excellent quality of this type of porcelain insulator was already established, but if anything were wanting to confirm it still more it could be found in the results of the Lauffen-Frankfort transmission in which this type of insulator was used exclusively. As a matter of fact, only one single insulator "broke down" electrically. Indeed, it may be safe to say that for high tension transmission, where it is desirable to avoid appreciable leakage, the fluid insulator will be used exclusively.

On the other hand, Mr. C. Colné, a well-known glass and porcelain expert, who has been a U. S. commissioner to foreign expositions, on this subject, makes a plea for glass, and raises a number of very important points on the glassmaker's side.

PORCELAIN INSULATORS FOR OVERHEAD LINES.

BY

C. Colné.

JUDGING from your editorial of the 20th instant on "Porcelain Insulators for Overhead Lines" you seem to think the subject of much importance. It may, perhaps, interest your readers to discuss it a little further.

The requisites of a good porcelain insulator Mr. F. W. Jones says are, that it should be made "of simple earths only, both in body and glaze, and of the same material without any metallic oxides, the body and glaze to be vitrified together at a high heat. It must be resistant to all influences of heat, cold, dampness, acid or alkaline fluid or gases."

Not having read the authorities quoted by Mr. Jones—the works of Messrs. Pope and Preece and Sivewright—I am unable to judge whether the requisites for a good porcelain insulator agree with his views.

In comparing glass insulators with those made of porcelain we should first compare the component parts of each material. Glass used for insulators, the common green glass, is usually made up of silica (sand), lime and soda (carbonate or sulphate). The sand used usually contains oxide of iron, which colors the glass green. The lime used is more or less pure and often contains also oxide of iron. The practice here is to use carbonate of soda, while in Europe it is almost invariably the sulphate.

Silica, the principal component part of glass, represents from 30 to 80 per cent. of its weight, according to the nature of the glass. It is quite insoluble in water, and resists all acids except hydrofluoric acid. If glass contains a large proportion of alkali it is very apt to absorb moisture and thereby injure its insulating qualities. Should the sand used contain also a large proportion of iron its insulating virtues are also impaired. The same may be said of lime. Taking for granted that a dense or hard glass should be the best for insulators, glass manufacturers should always make insulators of glass rich in silica, with but little alkali and fuse it at a high temperature. Unfortunately the temptation for having glass which "works easy" is too great, and alkalies are often put in the batch in excess to save time and labor, and save the care of maintaining the furnaces at a high temperature.

If Mr. Jones is correct in his statement regarding the quality of a good porcelain insulator, that it should have a good smooth surface, be perfectly vitrified throughout so as to be homogeneous, impervious to moisture and free from flaws, I am sure good hard glass well vitrified and as free as possible from oxide of iron and alkalies should meet the purpose as well as porcelain.

Mr. C. H. L. Smith's commercial appeal to those using porcelain insulators to pay the proper price for a good article may be of value to him, but in my opinion there should be but little difference in the price of glass and porcelain insulators, the difference, however, to be in favor of the latter.

Good hard porcelain ("porcelaine dure" of the French), such as Mr. Smith says he is making, is usually composed of kaolin, plastic clay, feldspar, sand and chalk. These materials exist in abundance in the United States, as I had occasion to find when I wrote the report of the United States Commission on glass at the Paris Exposition of 1878. It is true, however, that their preparation costs more than the materials used in glass. The same impurities are found in them as those existing in glass materials. Hard porcelain materials being less fusible than those used for glass, a higher degree of heat is necessary to vitrify them. Vitrification, however, never attains the same degree as in glass. Hence, if thorough vitrification is required, as stated by Mr. Jones, glass should be superior to porcelain. Porcelain may be looked upon somewhat as a semi-fused opaque glass. The resistance to acids, moisture, heat, cold and alkalies in porcelain is about the same as in glass.

I do not quite understand Mr. Smith's statement that glaze is unnecessary in porcelain insulators, and that the only use of glaze is to keep them from soiling. Since he says that he has "thoroughly and carefully investigated the whole matter," I am a little diffident in disagreeing with him. It must be apparent, however, that if porcelain unglazed becomes more quickly and readily soiled, it is owing to its porousness, which is the result of a partial vitrification only. The glaze is a thorough glass enamel which covers the pores and prevents moisture from penetrating—a better vitrification than the porcelain itself. This, it seems to me, is quite necessary for good insulation. Neither do I agree with him that porcelain insulators are not used because of "first cost." I believe that our pottery manufacturers, if they are assured of a market, will find a way to make porcelain insulators of good quality at a slight advance upon the price of glass. As for the tariff question preventing the purchase abroad, I am glad it does, because we have everything here to make good porcelain insulators, and we should make them and keep our money at home. This may not be good Free Trade doctrine but it appeals to the national pocket, which oftentimes is a more sensitive article than the national heart. I should be pleased to see this discussion of insulators continued in your paper. I should especially be pleased to have an explanation from some electrician showing why porcelain is a better insulator than glass, and a positive definition of the requisites for a good insulator. I do not think that Messrs. Jones and Smith have been sufficiently explicit upon this point, as I have shown in a rough manner that glass possesses the qualities said to be needed, as well as, and somewhat better than, porcelain. Faites jaillir la lumière electrique on this subject.

ACCUMULATOR CARS PROPOSED FOR GLASGOW.

IN view of the termination of the Glasgow Tramway Company's lease with the Town Council, says the *Electrician*, and the probable resolution of the corporation to work the local tramway system as a municipal concern, the tramways committee have lately given their special consideration to the mode of traction which they should recommend the town council to authorize. So far as they have been able to formulate their views on the subject, they have come to a resolution in favor of electric traction; and if they get the sanction of the corporation to proceed further, it is highly probable that they will make a beginning with at least 50—possibly 100—accumulator cars, which it is proposed to place on one or more of the east and west tramway lines, all of which are practically level. The General Electric Power and Traction Company have offered to the Glasgow Corporation Committee on Tramways to work the cars for 5d. per car mile, a fact which has given great encouragement to the Committee.

"L'INDUSTRIE ELECTRIQUE."

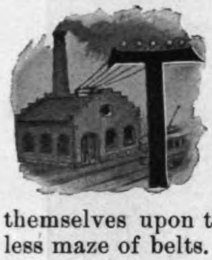
THIS is the title of the new French electrical journal, the first number of which has just reached us. With M. E. Hospitalier as editor-in-chief and M. G. Roux as secretaire de la redaction, it is hardly necessary to remark that the new journal will be found to be well abreast of the times and accurate in all its details. The size and general get-up of the new journal is almost identical with that of THE ELECTRICAL ENGINEER, thus making it extremely handy for reference and filing. We note among the founders of the journal some of the best-known electricians and electrical firms in France. *L'Industrie Electrique* is published by M. A. Lahure, No. 9 Rue de Fleurus, Paris, France, and will appear on the 10th and 25th of each month. The subscription price is $5 per annum.

THE UTILIZATION OF ELECTRIC POWER AT THE SCHENECTADY EDISON WORKS.

BY

T. C. Martin

I.



TWO features have been conspicuous in the construction and operation of nearly all American mills and factories up to the present time. If steam is the motive power, long and heavy lines of shafting obtrude themselves upon the eye, combined with an endless maze of belts. If water is the prime energy, not only is the mill begirdled with whirring belts and gridironed with heavy shafts, but it is huddled down close to the stream, sacrificing light and air for the sake of cheap power.

Hitherto it has been taken for granted that these conditions are permanent and must be dealt with in all power transmission within buildings. The assumption is, however, so far from the truth that any new mill equipping for power transmission by other than electrical methods may safely be said to illustrate the ideas of the past rather than the practice of the future; and the work of transition has already been begun with such vigor that even now the adoption of electric motors for mills and factories promises to be as rapid as the introduction of the electric light. But ten years ago the use of electricity as an illuminant in a mill was discussed as a suspicious innovation. To-day it is without a rival in popularity. A similar course of events may be looked for with regard to the use of electricity for power transmission, except that the stages of advance will be the more rapid because in a great many instances the existing circuits for lighting are of capacity enough to carry ample current for motors also.

But it may reasonably be asked—What are the peculiar advantages that electric power has as compared with methods so long approved? The answer is, that electricity is at once safer, more convenient, more flexible and more economical. All the various services of driving machinery, operating elevators, propelling freight cars, running pumps and furnishing ventilation may be performed from the one set of wires; whereas, with any other power, isolated engines, all under separate government are necessary. It goes without saying that the wires are far less bulky or burdensome than long lines of shafting and extended systems of steam pipes. In many mills, the shafting, badly put up, alone consumes 30 or 40 per cent. of the whole power available, while it must be a poor electric power plant that cannot show 75 per cent. efficiency in the transmission. Even if it be desired still to run lines of shafting, a motor can be attached to each line and thus the benefit be secured of having smaller units each free to continue, no matter what may happen on any other section or floor. Not a few manufacturers want power right at the machine to be operated, while others desire the power to be movable at will from tool to tool. This electricity answers for most admirably, with the added recommendation that in its use each lessening of the load on the generating plant is responded to immediately in a smaller consumption of current and fuel. Another noteworthy economic feature is, that in order to bear big shafts, mills often need stronger and more expensive walls, or are supplemented by belt towers or have belt holes pierced from floor to floor, allowing fire to travel freely and quickly.

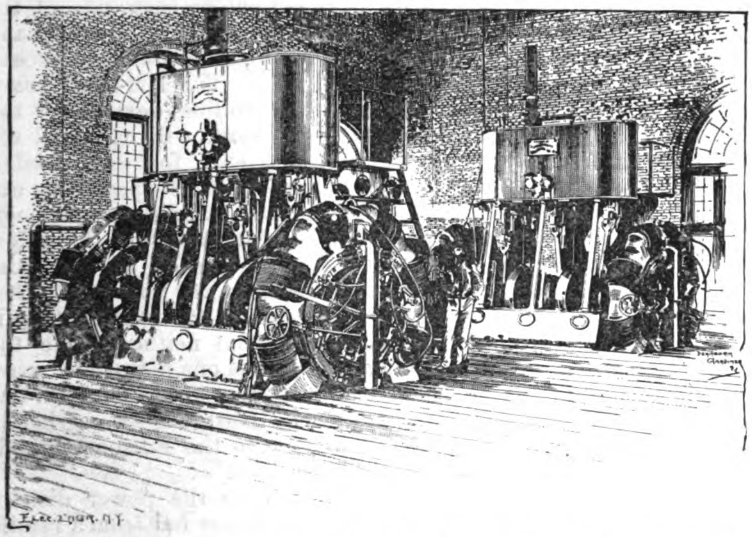


FIG. 1.—PORTION OF THE POWER HOUSE, EDISON WORKS, SCHENECTADY.

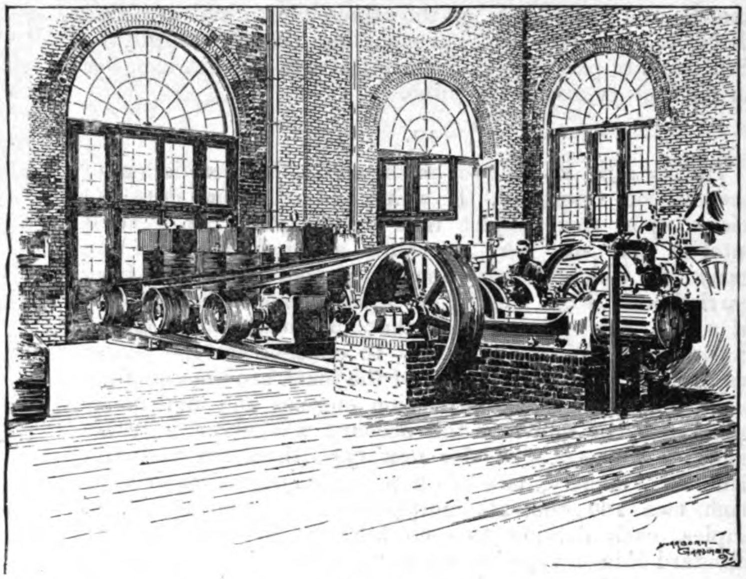

FIG. 2.—PORTION OF POWER HOUSE, EDISON WORKS, SCHENECTADY.

II.

A great many more points of superior merit in electric power transmission might be cited, but in this instance as in every other of the kind, the proof of the pudding is in the eating. As a matter of fact several mills and factories are now running in which the arguments outlined above are fully borne out, but the public still has little conception of the extent to which the principle has been accepted and carried. This general ignorance is excusable, considering that very few electrical people are aware of the fact that at the huge works of the Edison General Electric Company at Schenectady, N. Y., employing about 4,000 men, over 1,900 h. p. is to be transmitted by wire from a central station. The plant in question is already so large and does such a variety of work that a little study of its peculiarities will repay any one. It is beyond doubt the largest example to-day in the world of the advantages of electric power transmission, but so striking have been the gains from it that it is evidently destined to help mark the beginning of the new era in large mills and factories. The work done at Schenectady is, perhaps, the more interesting from the fact that with the current from these circuits all the various power apparatus in actual use or under test for mill work, mining, ventilating, etc., is run. There is thus obtained a wonderful range of experience that is not to be secured anywhere else; and certainly one of the most remarkable spectacles that ever greeted the eye of the engineer is this vast aggregation of mechanisms at their regular daily task or under trial, all in one factory, all driven by the same unseen energy, and all responsive to the slightest movement of a switch. The central plant furnishes current to scores of little $\frac{1}{10}$ or $\frac{1}{16}$ h. p. motors on one floor, while on an adjoining floor it is driving motors of 15 or 25 h. p. on the same circuits, and attached direct to a ponderous tool or machine. In other words, the Schenectady plant shows at once the uses of electric power in the factory and in the mine.

III.

During a recent visit to Schenectady, by permission of the Edison Company, the writer obtained some data and views upon this subject that should prove of general interest and are here presented as an evidence of the extent to which the principles suggested above have been carried out. Figs. 1 and 2 are illustrations of the interior of a fine new power house that has been built at the Schenectady Works expressly to concentrate the power supply. A leading feature of the plant are the combinations of Edison triple expansion engines and multipolar generators, of which a full account was given in these columns last year. Of this new type there are virtually four sets, namely, two 300 h. p. triple automatics driving each two 100 kilowatt multipolars, and two 150 h. p. triples, each driving two 60 kilowatt generators of the standard Edison type known as "the 1885." In addition to these are found one Armington & Sims engine 10 x 12 of 150 h. p. driving one 100 kilowatt railroad generator and two 100 kilowatt standard generators; another Armington & Sims of 150 h. p. driving a 50 kilowatt reserve generator and one 100 kilowatt; and a third of the same make of 25 h. p. running three generators of the 1885 type, each of 8.5 kilowatt capacity. This makes a total of 1,115.5 kilowatt capacity, or just about 1,500 h. p. The plant is not yet complete, however. When it is the capacity will fall not far short of 1,900 h. p. with the ability to increase it 50 per cent. at any time. The maximum output of the plant so far has been slightly over 700 kilowatts. Steam is supplied to the engines from three boilers of 500 h. p. each and three of 250 h. p. each, making a total at present of 2,250 h. p. Provision has been made for three more boilers of 250 h. p. each. The power house itself is a spacious building with generous elbow room, and has two handsome brick smokestacks each 130 feet high.

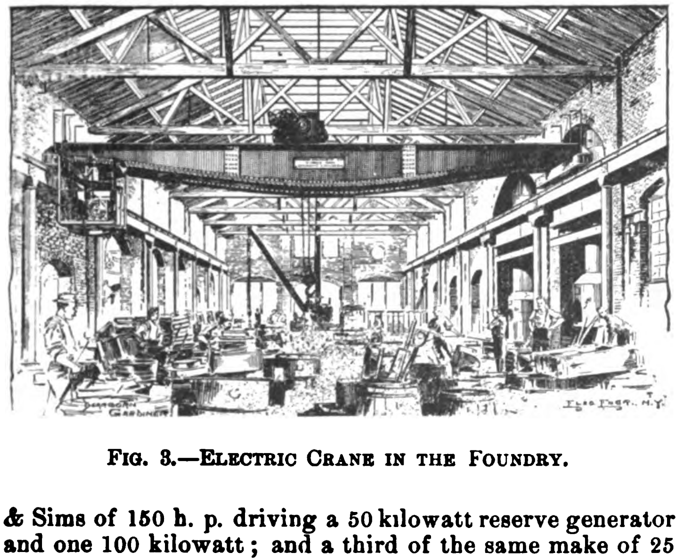

FIG. 3.—ELECTRIC CRANE IN THE FOUNDRY.

IV.

From this central power plant, situated conveniently on the main avenue that runs straight through the Works from the entrance gates, the current is carried to all the various departments. The entire electrical apparatus is to be controlled from two switchboards each 24 feet long by 15 feet high. These boards are arranged one on each side of the central door through the wall that divides the dynamo and engine rooms from the boiler-rooms, and, for easy access, are placed four feet from said wall. The left-hand board contains all the switching and controlling devices for the dynamos, while that on the right hand will carry all the switches, ammeters, safety fuses, etc., for each feeder. Each of the boards is so arranged that all operations can easily be performed by an attendant standing on the floor. From these switchboards the current passes to the different shops over about 10,000 feet of line on the two-wire system, the supply for power being at 250 volts while that for the ordinary lighting circuits is 125 volts. This is exclusive of the interior wiring, but neither inside the shops nor on the outside avenues does one notice any wires except for the overhead trolley system of locomotives. As a matter of fact, the circuits are almost wholly carried in the familiar iron tubes that belong to the Edison methods of undergrounding the wires in cities.

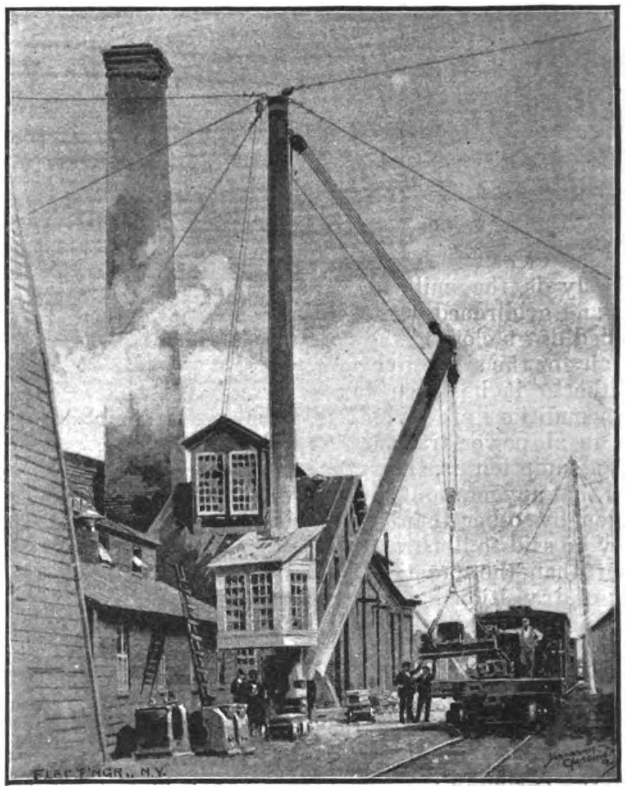

FIG. 5.—ELECTRIC DERRICK AT THE EDISON WORKS, SCHENECTADY.

It is needless to point out that were the power distributed by means of shafting or by engines fed from a ramification of steam pipes, the mechanism of distribution would be much more *en evidence*, and would be much more expensive and cumbersome.

V.

The electric current thus generated and distributed goes to no fewer than 43 stationary motors of the standard Edison bi-polar upright type scattered throughout the Works. These motors are of different sizes. Their total capacity is 1,324 kilowatts, but the demand for current by no means reaches that amount at any time as it is practically an impossibility that in any factory every different machine or tool will be in use up to its limit of capacity at the same moment. A great many of these motors run the lines of shafting to which the various wood-working, metal-working, wire-braiding and other tools and appliances are connected, so that all told the sections of shafting amount to 5,260 feet in the shops, which cover a floor area of 11.84 acres. To put it tersely, just one mile of shafting is run by electric motors at Schenectady. Yet all this shafting is so subdivided and so independent that it is possible to throw on or off 99 per cent. of it without the slightest interference with the remaining one per cent., or without any effect on the central generating plant except in the immediate adjustment of the dynamos to the lighter or heavier

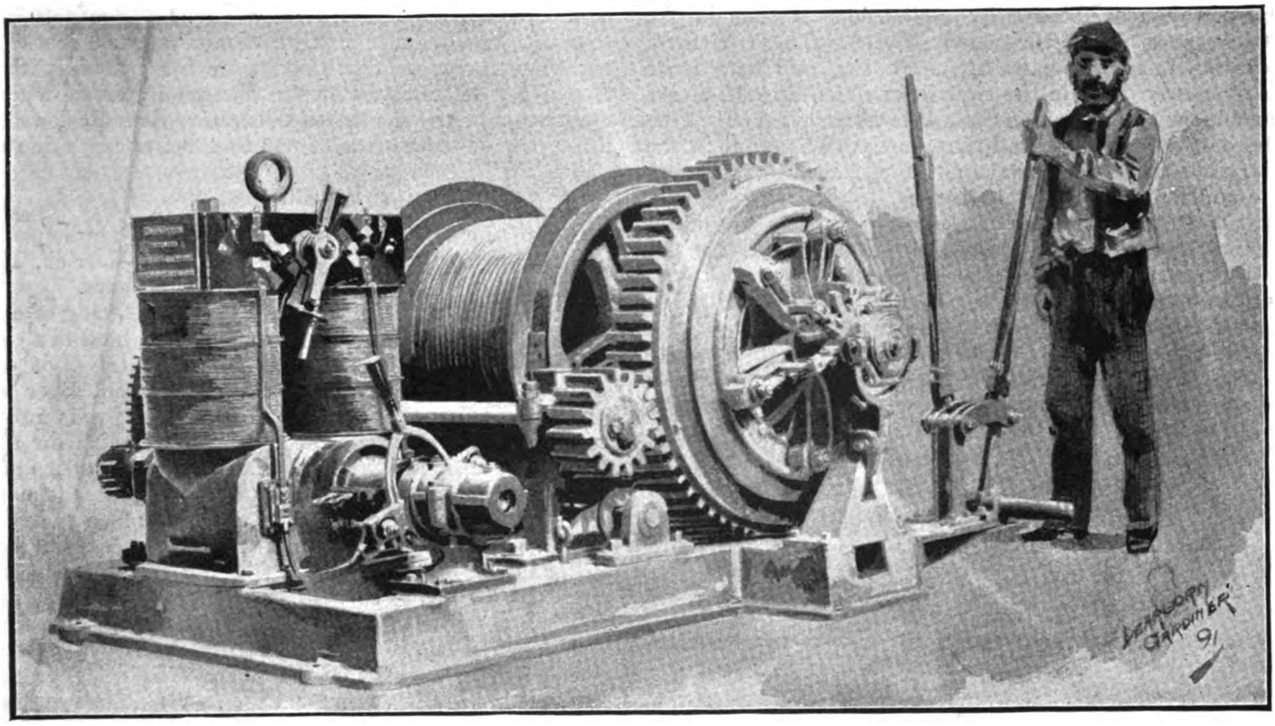

Fig. 4.—Electric Hoist at the Edison Works, Schenectady.

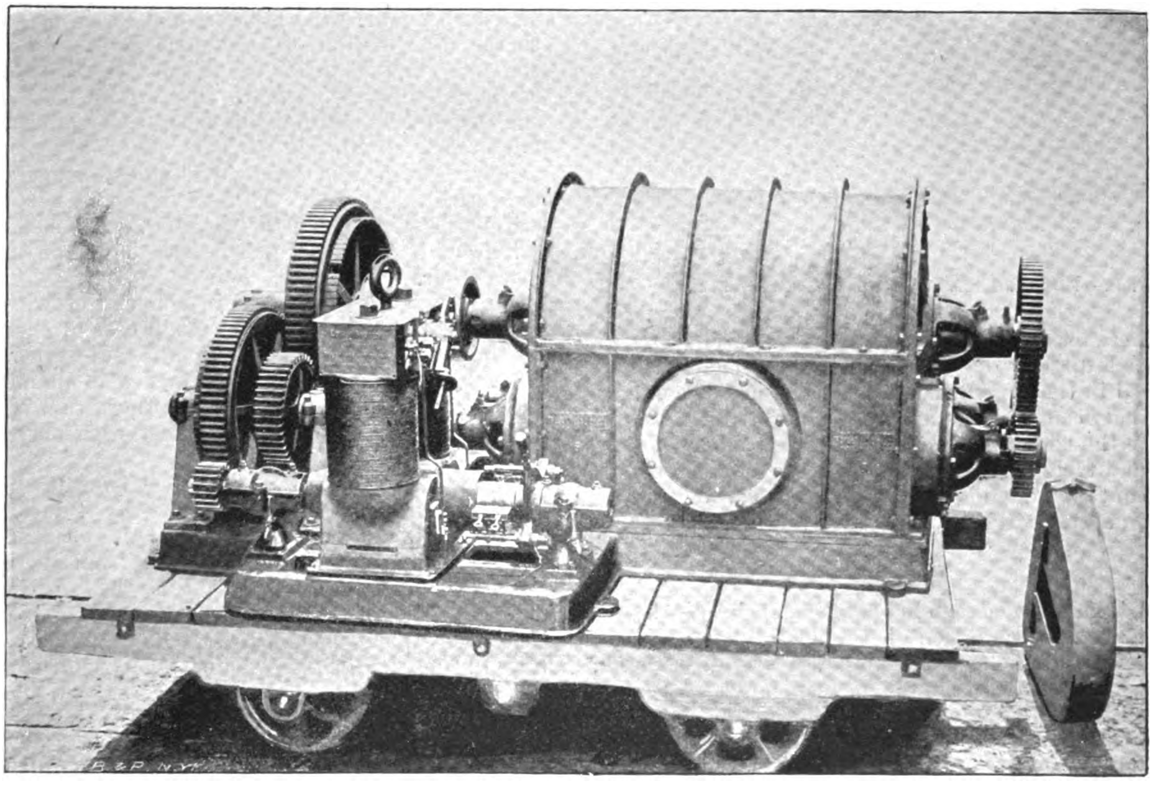

Fig. 6.—Baker Air Blower at the Edison Works, Schenectady.

load. New motors are added daily, as, for example, those in the fixture and appliance shops recently erected.

VI.

One of the most noteworthy applications is seen in the electric cranes, here illustrated, Fig. 3. These perform heavy duty in various parts of the Works, and save large sums of money daily in the expeditious handling of pieces of machinery that otherwise could be transported only with the help of several men, and that slowly. The crane in the foundry has no less a span than 47 feet 2 inches; and that in the boiler shop, 23 feet 10 inches. Both will swing a weight of 10 tons with the utmost ease; all that is required of the workman is a gentle, coaxing pat as he steadies the load down into its desired place. The crane proper consists of two transverse beams mounted on a two-wheeled trolley at either end. These trolleys run on rails laid the length of the shops. The three movements of the crane—traveling, hoisting and transversing—are accomplished with three separate motors, though it is not necessary to have as many, it being possible to operate with one or two motors. This is sometimes done. The motors are located conveniently for each distinct operation, and all are controlled by levers placed in the cage at the side. The use of conducting cables between the cage and the transversing motor is obviated by the use of a board carrying a number of copper strips and fastened on the inside of one of the girders. A sliding contact is made on these strips by carbon brushes attached to an arm carried by the transversing carriage.

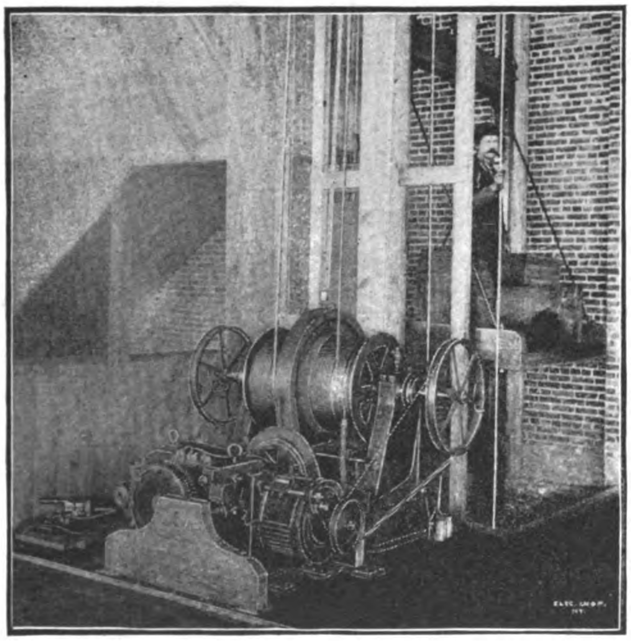

FIG. 8.—EDISON ELEVATOR WITH CONTROLLER.

VII.

The electric hoists to be seen in operation at the Works are a very effective demonstration of the flexibility of electric power. That which is here illustrated, by way of example, Fig. 4, is a sturdy mass of simple mechanism equal to any task that is likely to be imposed on it. The motive power is a 20 kilowatt Edison motor, standing in the same bedplate, and geared through an intermediate shaft to a large clutch gear on the drum shaft. The drum is keyed to the shaft which engages the gear by means of a friction clutch, operated by an upright hand lever; while a similar lever is used to operate the motor switch, connected with a suitable resistance box. The levers are so arranged that the motor can only be started when the clutch is engaged. The drum is provided with a band brake operated by a foot lever, and placed within easy reach of any one standing at the hand levers. One end of the intermediate shaft is provided with a winch. It is a compact appliance, as the cut shows. The bedplate is only about 5 feet, 10 inches square. The drum will wind in one layer 260 feet of five-eighths inch rope. These hoists are being made with positive clutch as well as with the friction clutch shown in the engraving. Such a hoist as that above described will raise 1,500 pounds at the rate of 350 to 400 feet per minute.

VIII.

One of the most novel and interesting appliances seen in the Works yard is the new electric derrick, Fig. 5, swinging heavy loads to and from freight cars.

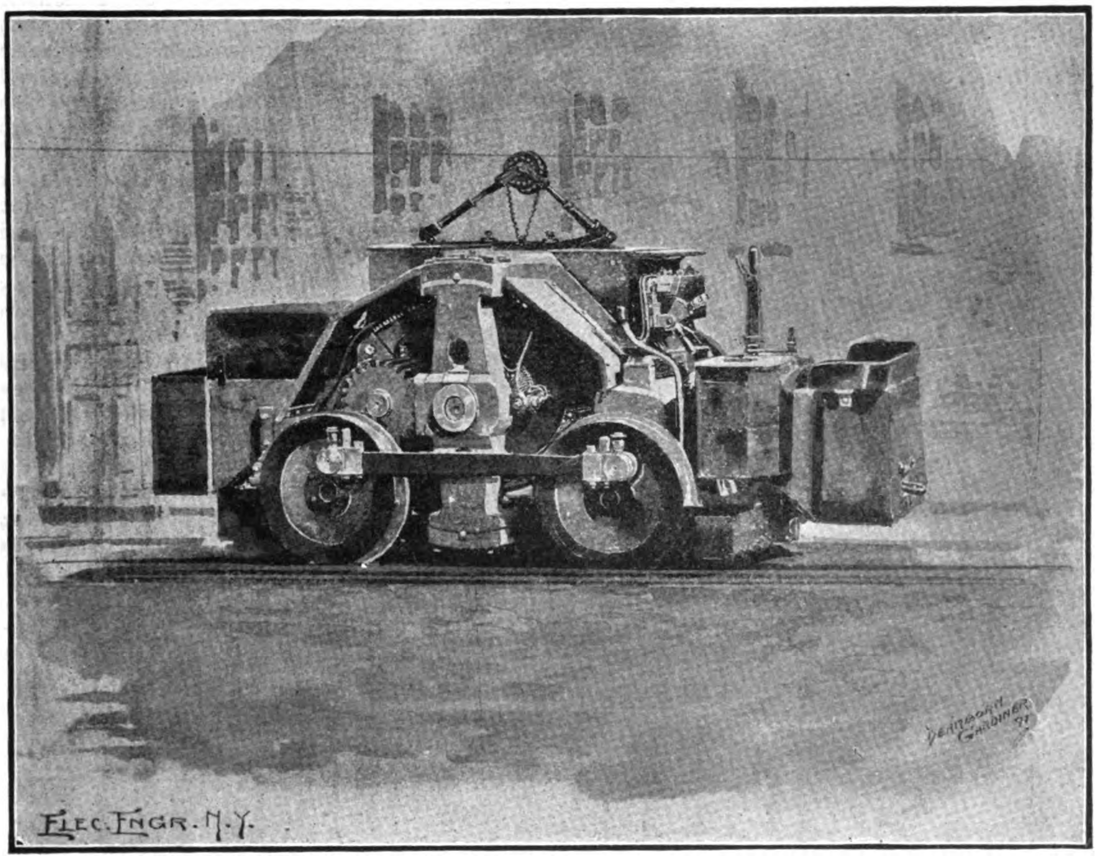
The derrick is of the ordinary type, consisting of a vertical post, or mast, rotatable on its axis and held in a vertical position by guy ropes from the top. At the foot of the mast, a jib, or projecting arm, is fastened, over which passes the rope carrying the load. The jib is provided with a block and tackle so that there is facility for swinging a load horizontally, as well as hoisting. The iron frame which carries the ordinary windlass attachment used on this type of derrick is removed, and its place taken by a similar iron frame of Edison make which carries an electric motor in combination with a winding drum. This frame is arranged so as to carry a standard "1885" type motor, which is fitted with a special bedplate and an extra pillow block. A worm on the armature shaft drives a worm wheel, fastened on the end of a short intermediate shaft, which is held in position by a special angle bracket bolted to the main frame. Upon the other end of this intermediate shaft, a bevel pinion meshes into a bevel gear wheel keyed on the intermediate shaft of the hoisting drum. The drum shaft is provided with a large gear wheel which engages with a pinion on its intermediate shaft, as is usual in this form of hoist. The motor is compound, but is provided with a specially wound series field, so that it may be started up by a regular starting and reversing switch without the intervention of resistance coils. As regards the connecting cables, it has been found the best practice to put them under the ground, allowing the end of the iron tube through which they are taken to come up by the side of the mast, so that it projects about a foot above the ground. From this point a flexible connection can be made with the switch. This arrangement keeps the wires entirely out of the way for working. A housing frame is built around both motor and switch to give protection from the weather.

The following particulars in connection with this particular derrick may be of interest in case of changes being contemplated in steam derricks of the same type. The mast is of wood, 50 feet high, and 26 inches in diameter at the bottom. The diameter of the winding drum is 18 inches, and about 160 feet of $\frac{3}{4}$ inch steel rope may be wound about it.

The motor housing frame is 7 feet from the ground, the size of its base being 6 feet 6 inches by 4 feet. It has a slanting roof, the extreme height being 9 feet 5 inches, and the least height 6 feet 5 inches from its base. The reversing switch used for controlling the hoist in operation is placed 3 feet 6 inches above the ground, so as to be easily accessible. This derrick is built to deal with loads up to 12 tons, and is operated by an $8\frac{1}{2}$ kilowatt motor—a little over 11 h. p.

IX.

One of the problems of mill and mining work is that of ventilation. Very often its solution is neglected because of the difficulties connected with the operation of the apparatus, but where the electric current is available, as at the Edison shops at Schenectady, there is no trouble whatever. Here is a view of a Baker air blower, Fig. 6, encountered in our peregrinations and it strikes one immediately that the combination must be a great boon not only in mills and mines but in iron smelting furnaces, tunnels, &c. The blower before us is a simple apparatus. Its working parts consist of three turned and balanced drums so arranged that their centres lie at the corners of an equilateral triangle. The motor driving it is geared through an intermediate shaft with the upper drum which does the actual work of blowing and exhausting, the lower drums simply acting as valves, their relative positions being maintained by the gears at the end. These gears are protected by a cast iron cover. On the intermediate and upper drum shaft they are fitted with wooden teeth, so as to avoid noise. In the particular combination under notice the armature shaft of the motor runs 10.5 times faster than the lower shaft. Running free, the blower at a motor speed of 1400 revolutions per minute will pass 3300 cubic feet of air in that time.



ELEC. ENGR. N.Y.

FIG. 7.—LOCOMOTIVE FOR HEAVY TRACTION.

X.

The applicability of the electric locomotive to mill or mining work is well illustrated in the motor seen under test by the writer and here illustrated, Fig. 7. As was the case with every other piece of mechanism about the Works, it derived its power from the central station. It is obvious that both steam locomotives and the cable are undesirable and even objectionable around a mill or factory. The cable of course is always traveling in the same direction, so that a mill cable car must always be headed one way. Moreover the cable system under such conditions proves extremely expensive. With regard to steam locomotives, it may be pointed out that the cost of handling and maintenance is heavy, that there are the features of smoke and dirt to contend with, and that in mills where fabrics are treated there is risk of setting fire to the surrounding materials, whether wool or cotton. The use of a steam locomotive indoors is, in fact, not a prospect that one contemplates with equanimity.

On the other hand, the electric locomotive is easy to govern and manipulate, is quiet and cleanly, and is compact for its power, while it runs freely back and forth in either direction on the same track at the will of the attendant, who may be and often is the budding electrical genius to be found in well nigh every American factory—a mere boy of 15 or 20. The locomotive here shown is of a very solid and serviceable type, designed specially for mining work but easily applicable to any class of factory employment, whether within the walls, or on the tracks communicating with the main lines of steam railroad. This locomotive will handle a train of 120 tons at a speed of from 7½ to 12 miles an hour. The motor is of the four pole type, with magnets and armature protected from injury by iron casings. The power is transmitted from the armature to one axle by heavy gears and the wheels on this axle are joined to the others by connecting rods, as on a steam locomotive. The track gauge is 3 feet 8 inches. The speed is governed by a special controlling switch, and the seat of the driver is so arranged that he can easily look in either direction.

XI.

Elevator service is a very important matter in most factories, and often necessitates individual outfits. But with a central electric power plant, it is easy to run any number of elevators in buildings widely scattered. There are two elevators being installed in Schenectady, in the No. 23 building, and one is already in daily use, Fig. 8. It consists of a Graves direct hoisting elevator operated by a slow speed 15 H. P. motor, and the motion of this elevator is governed by a controlling device such as that used on Edison railway motors. It is composed entirely of iron, mica and brass, so that although designed for a steady current of 15 amperes, it can be run for quite a time on very much higher currents and attain quite a high temperature without danger of burning out.

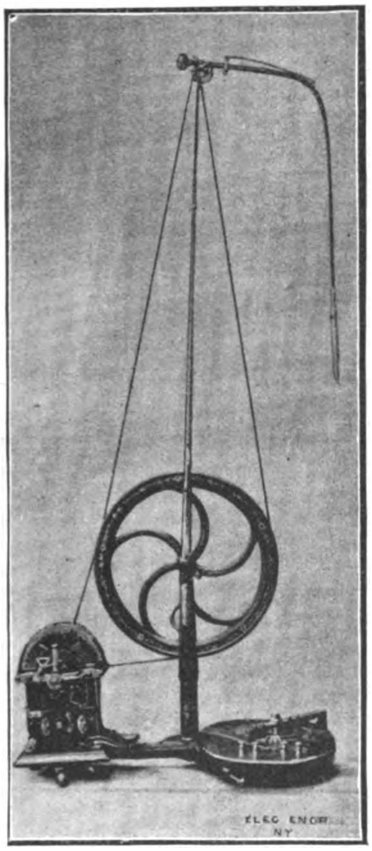


FIG. 9.—EDISON DENTAL DRILL.

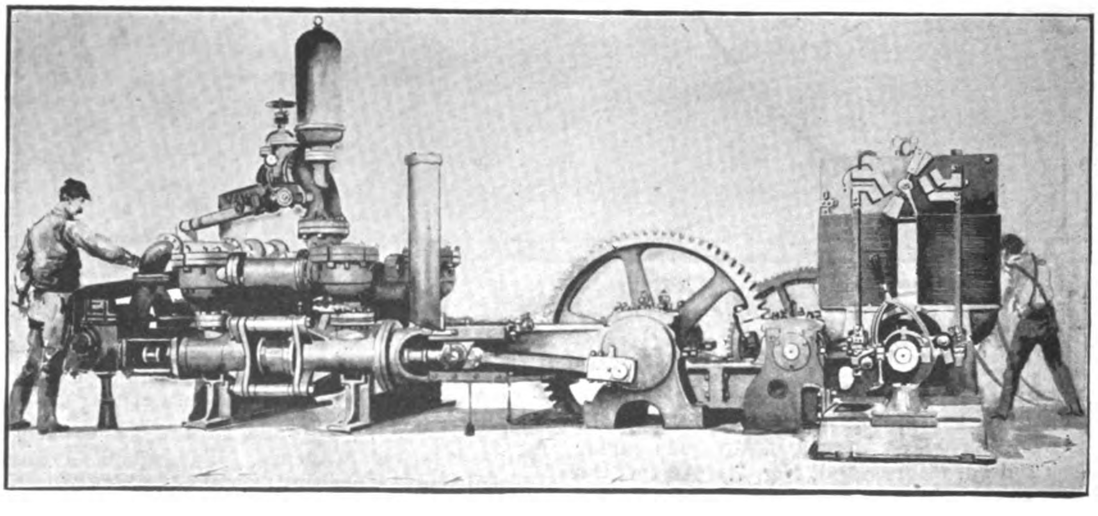

FIG. 10.—KNOWLES PUMPS COUPLED WITH EDISON MOTOR.

The second elevator is an hydraulic elevator consisting of a pump operated by means of belting from a motor. In this case the Edison Co. have adopted belting on account of their being able to produce thus a noiseless combination suitable for office, building or hotel purposes. The pump feeds directly into the high pressure cylinder into which the piston carrying the elevator car moves. The operation is as follows: If the car is to be raised from one floor to the other, the motor is started by means of the controlling device mentioned in connection with the other elevator. The pump then forces water into the cylinder at a pressure of 80 lbs. to the square inch. This water expels the piston and in this manner lifts the elevator. On reaching the next floor the motor is stopped by means of the controller, and when it is desired to descend, the operator on the car opens a valve which allows the water to escape from the cylinder into a tank. The same water is used again when the elevator is required to ascend on its next trip.

In both cases the controlling devices operating the motor are controlled by the man on the elevator by means of ropes passing through the elevator in the same manner as is done with any other elevator, or, in other words, by pulling the rope up or down, the motor is stopped or started, and in the case of the hydraulic elevator, the valve allowing the water to escape from the cylinder is opened and closed.

XII.

It would be difficult to match the demonstration of the range of electric power given in the fact that the central station at the time of our inspection was furnishing current at one and the same time to the 120 h. p. motor running the big Knowles double mining pump, and also to the tiny little one-twelfth horse-power motor operating a dental outfit. Surely the force of contrast could no further go. Details with regard to the pump are given in another section of this article. With respect to the dental drill, Fig. 9, it may be here stated that they take the ordinary dental drill and remove the foot lever and crank, making use of the old pivot to fix a strip of steel upon which can slide the $\frac{1}{12}$ h. p. motor, arrangement being made to clamp it in any position so that the belt which is placed around the fly-wheel and pulley of the motor can be kept at any desired tension. The motor, therefore, occupies one of the legs, and the other two legs are utilized to support the reversing and resistance switch. The handle of the switch is of special construction so that the operator can use it as readily as the treadle. It is arranged to project over the edge of the resistance coil, and the operator can, by a slight movement of his foot, switch it over to either side, so that the motor runs in either direction at will. If the arm is in the central position, the current is off. If between the central position and one side, the motor runs in one direction, but not at full speed. Catch clips are arranged so that the operator can tell immediately he has reached either the "off" position or the "full on" position on either side. He can also obtain four different speeds under full speed. The connections of the apparatus are very simple. The motor is designed to run on 125 volt circuit, so that it can be used on a local electric light circuit. A wall socket is fixed near the dental chair and a flexible cord led from this to two terminals on the motor.

Yet this was hardly all, for a large number of the small Edison motors may always be seen at the Works, as they were then, going through their paces, prior to shipment. It would be easier in these days to tell what small electric motors *don't* do than what they do, as the general availability of current has found them endless occupation in the trades and industries that are fostered by our great modern cities.

XIII.

Another interesting piece of machinery that we chance upon in going our rounds is an electric pumping outfit, just referred to, intended primarily for use in mine work, but useful also in many other situations. This combination consists a 25 h. p. series motor and a Blake double-acting pump, upon the same bedplate. The armature shaft of the motor is connected by a worm driving a large gear wheel to a pair of crank discs one on each side of the machine. Wrist-pins, placed at an angle of 90° to each other, carry the connecting rods operating the plungers of the double-cylinder pump. Each pair of plungers being connected together by outside rods, work together like one plunger; and the connection with the crank discs being at an angle, one pair of plungers is drawing while the other is forcing water,—thus making them double acting. The size of each cylinder is 5 inches diameter by 12 inches length. The regulation of the speed of the driving motor is effected by commutation of the field-coils, which are divided into three sections. If we wait long enough we can see the machine put through its paces. Taken, thus, at an off-hand test, to satisfy our casual curiosity, it will be run at various speeds. At 35 strokes a minute and a pressure of 75 lbs. per sq. in. it will deliver 143 gallons per minute a height of 173 feet. At 26 strokes and 175 lbs. pressure, it will raise 106 gallons a height of 404 feet. Of course in actual work, the size of pipe and number of bends determines the delivery, but this is evidently good work.

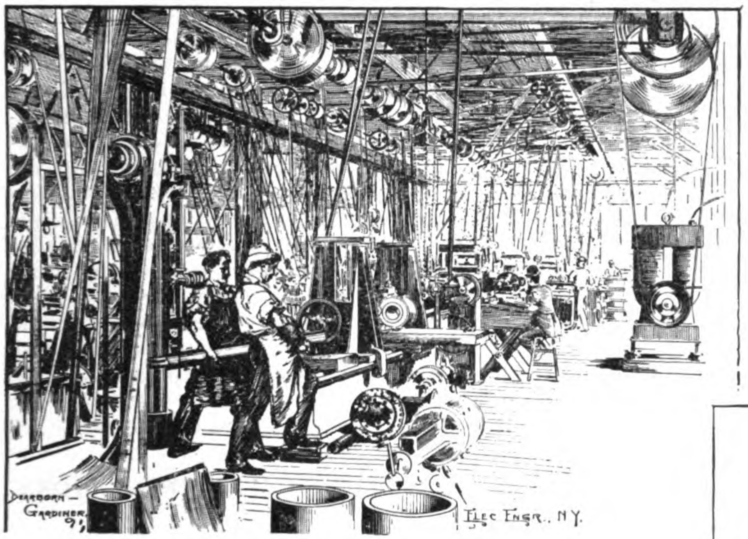

Fig. 14.—View in One of the Machine Shops.

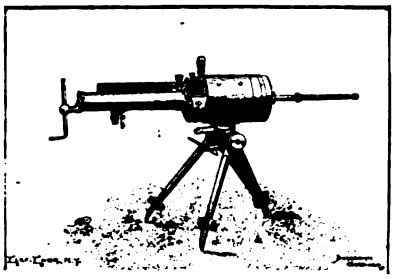

Elec Engr. N.Y.

Fig. 11.—Edison Reciprocating Drill.

Interesting as is the performance of the pump above mentioned it falls short, in regard to the magnitude of the work done, to the pump here illustrated, Fig. 10, and which was under trial at the time of our visit,—being run from the central station already described. This pump has now gone into the Poorman Mine of the Cœur d'Alene Silver Lead Mining Co., near Burke, Idaho, where the Edison Co. has installed a plant of between 400 and 500 h. p. for a variety of mining operations. It consists of two Knowles double-acting centre-packed, outside plunger pumps, in combination with two 10 inch double-acting suction pumps, and is driven by a 100 kilowatt 250 volt compound wound Edison motor of the 1885 type. As arranged for the test, both suction and plunger pumps drew from and discharged into the same tank. The suction pump worked against a 7 foot head corresponding to the pressure of 3.08 lbs. per square inch, and the plunger pump against a 10 ft. head, which corresponds to the pressure of 4.4 lbs. per square inch. The diameter of the cylinder of the suction pump is 10 inches, and the piston rod is 2¾ in. in diameter, so that we have an effective working piston area in the suction of 75.57 square inches. The diameter of the cylinder of the plunger pump is 9½ inches, and the shaft being 2¾ inches in diameter, after deducting twice the area of the piston rod, we obtain the effective working area of 64.943 square inches. The pump has a capacity of 500 gallons, which it can deliver to a height of 550 feet. The efficiency of the combination was tested very carefully and found to be between 75 per cent. and 80 per cent. The combination no doubt is one of the most efficient of this character made so far. It is at work in the Poorman Mine, giving excellent satisfaction, being capable of pumping the mine dry within ten hours.

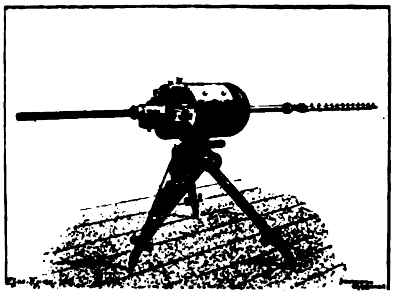

Fig. 12.—Edison Rotary Drill.

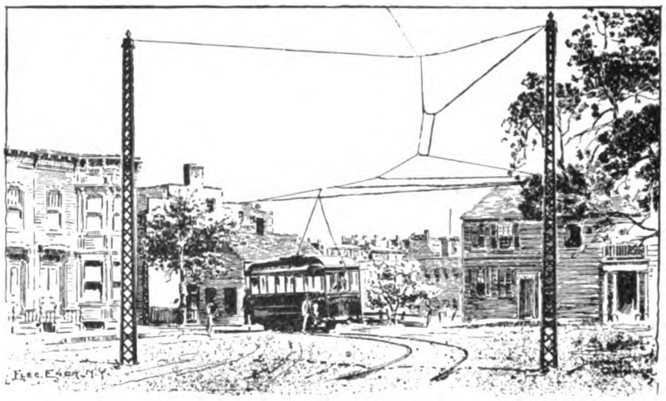

Elec Engr. N.Y.

Fig. 13.—Edison Electric Railway at Schenectady.

XIV.

A special feature of electric mining work is the use of drills, and of these several are usually under test at the Works prior to shipment to their destination in some far-away mining camp. We have shown a couple of them here, Figs. 11 and 12, as seen vigorously demonstrating their ability to "knock the stuffing" out of any obdurate material opposed to their Sullivanesque attack. The Marvin electric percussion drill strikes about 400 to 450 blows a minute, the number of blows being regulated to suit the character of work being done. It is capable of drilling at an average rate of 2 inches per minute in hard granite; and has reached a maximum speed of 4 inches in hard granite. It can drill to a depth of 20 feet, starting with a 3 to 3½ inch starter, and bottoming with a 1⅝ to 1¾ inch drill. It is practically impossible to burn out the coils on account of the incombustible insulation material used. A large number of these drills have been sent out and are doing work in phosphate mines, gold and silver mines, limestone quarries, slate quarries, granite quarries, and a number of them are also used by contractors doing work for railroads in the West.

Regarding the diamond drill, it may be stated that the company are building two sizes: One for deep work up to 650 feet, and the other for lighter work up to 250 feet; the first to be used for outside work principally, and the latter intended more for inside mining work, and such places where a light, portable drill of not too large a capacity is required. These diamond drills embody all the latest improvements that have been made for this kind of apparatus.

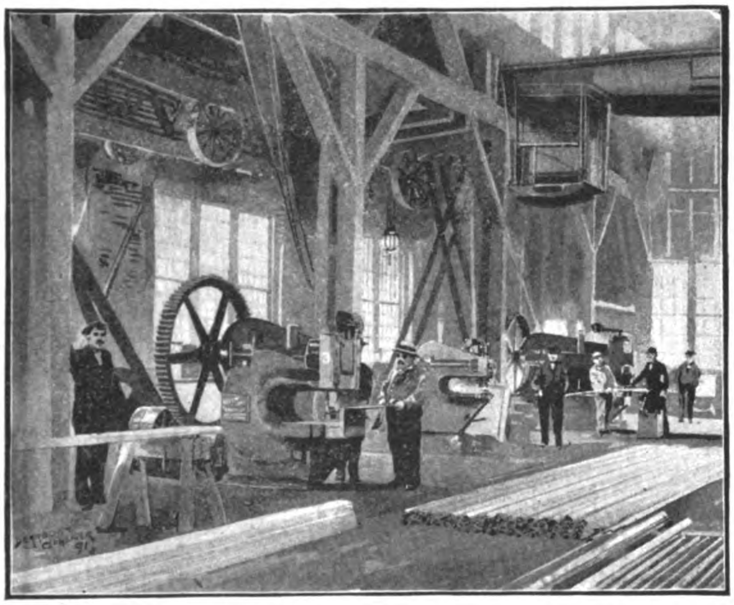

FIG. 15.—BOILER SHOP RUN BY MOTOR.

XV.

Perhaps one of the most interesting features in connection with this power plant is the electric street railway. A modern central station is as universal a basis of supply as a Macy or a Wanamaker store. The want is no sooner created or known than it is met; and it is only natural that where power is so flexible and available new uses should be found for it. It is obvious that in a great many industrial centres, a line of electric railway serving as a bond of union between the residences of the workpeople and the factory in the heart of the town or in a remote suburb, must often be very much of a convenience. In fact it will frequently prove an inestimable boon. At Schenectady, the growth in the population has led to a gradual development of the city away from the low-lying, swampy old sections up to the healthy hills that look down on the Mohawk Valley and the Erie Canal. The new road penetrates on one hand the crowded quarters of the city proper and on the other is cutting its way into the newer residential districts up the hills. Our sketch, Fig. 13, gives a view of the road at one of its sharpest curves. It is evident that under such conditions as have been mentioned above, an electric road can be run very economically, and it is certainly one of the striking proofs of the all-round utility of electricity that the same plant which thus at Schenectady furnishes the workmen and their machines with power, handles freight, swings the cranes, pumps, ventilates and cools, should also be the means of transporting the employees to and from their work.

XVI.

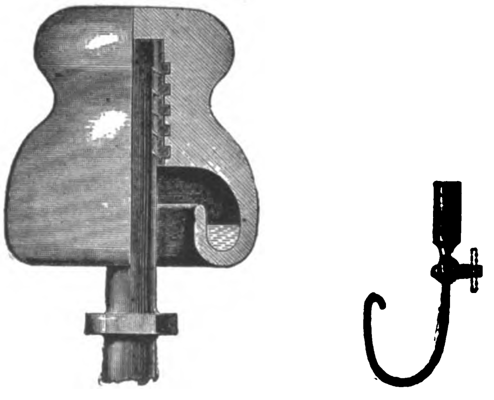
There are of course several applications that can be, and are, made of electric power in and around a factory that even this vast plant at Schenectady does not illustrate. Such, for example, are the special classes of machinery that are to be encountered in shoe factories, printing offices, tailor shops and the like; but it is remarkable how many hundreds of distinct tools in the various lines of wood and metal working belong to the modern electrical factory and are to be seen at Schenectady in full swing and with the utmost success, as evidenced by Figs. 14 and 15. There are, moreover, the peculiar appliances and apparatus necessary in the making of insulated wires and cables, and the manipulation of rubber and cotton or silk. Altogether, the plant justifies many of the claims that are being made so persistently and energetically to-day for the general use of electricity as *the* means of distributing power in mills and factories, and it is very satisfactory to learn that this demonstration at Schenectady is as successful as its scale is generous. So much a matter of fact is it already, that nobody in the Works stops to think about it or comment on it; and any inquiry in any one of the forty or fifty departments elicits the same answer as to complete satisfaction. And yet less than ten years ago, the Comte du Moncel in his book on "Electricity as a Motive Power" said, with the feeling that people would hardly believe him: "When we reflect that now we are enabled to transport to almost any distance a force of several horse power by a wire which could easily be passed through a keyhole without any visible movement or change in its appearance, imagination itself is stupefied, and we ask ourselves if it is not magic!" But it is not magic, it is plain, straightforward engineering.

NOTE ON RESULTS WITH PORCELAIN INSULATORS.

BY

Henry Stott

IN pursuance of the discussion on Porcelain versus Glass Insulators, now being carried on in THE ELECTRICAL ENGINEER, perhaps the experience of the writer some years ago with the particular form of porcelain insulator known as the Johnson & Phillips Fluid Insulator, may be interesting.



THE JOHNSON & PHILLIPS FLUID INSULATOR AND FILLER.

This insulator is made in various forms of brown or white glazed porcelain of the best quality, the mechanical strength being all that could be desired. The groove shown on the inside of the insulator in the figure was filled with a resinous oil, from a siphon, after the insulator was fixed on the pole or roof standard, and the cable then attached. The mains were for the greater part insulated with rubber, but over two of the eight miles were entirely innocent of covering of any description. The 2,000 volt cables were led into the various buildings through porcelain leading-in tubes and then to a high-tension switch, fuse and converter. The fuse bases were made of slate, but this was afterwards discarded and marble substituted on account of the leakage caused by the hygroscopic slate. Tests for insulation were taken every morning, and, as may be imagined, quite a large proportion were taken under the worst atmospheric conditions possible, namely, during that fine penetrating rain so common in England, which no rubber coat could long defy, as the writer remembers without much pleasure. Under this ordeal the insulation test used to give about 60,000 ohms. This, of course, included the leakage from switches, fuses and converters, as well as from the insulators. Deducting 10 per cent. from the leakage for the former, which under the circumstances would be a very conservative estimate, this gives 66,000 ohms as the absolute insulation resistance of about 180 insulators, or 11.8 *megohms each, under the worst climatic conditions imaginable.*

These figures, of course, are approximate only, but no account having been taken of the leakage due to leading-in tubes, this certainly may be looked upon as under, rather than over, the true figure. No breakages occurred except those due to purely mechanical causes which no insulator could be expected to withstand. The cost, including oil, was about 25 cents each. I have no figures at hand, giving tests of glass insulators under similar circumstances, and it would be interesting if Mr. F. W. Jones would kindly give us some information from the test books of the Postal Telegraph Co. for comparison. Mr. Jones' appeal to the porcelain manufacturers should be earnestly backed up by lighting and power companies, especially by the latter, as the day is not far distant when the subject of the transmission of power over long distances at, of necessity, high pressure, will leave the field of speculation and calculation for that of practice and fulfilment, and compel them to look for a higher class insulator than glass.

ON THE LAW OF HYSTERESIS.[1]—II.

BY CHAS. PROTEUS STEINMETZ.

The calculation of the readings was done in the following way:

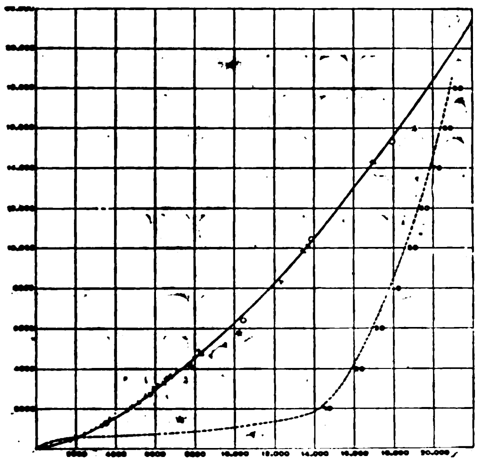


FIG. 1.

After applying the corrections for self-induction of instruments, resistance and speed, the readings were reduced to lines of magnetic force per square centimetre B and consumption of energy by hysteresis per magnetic cycle H, in ergs.

Then the results were plotted on cross-section paper and if any value was found to be very much out of the curve connecting the other values, it was stricken out as evidently erroneous, not considering it worth while to determine whether it was a wrong reading of any one of the instruments or a mistake in the calculation.

Then from the other values of B and H, under the supposition that H were proportional to any power x of B, $H = \eta B^x$, this exponent x was determined.

This value x will be seen always to be so near to 1.6 that 1.6 can be considered at least as first approximation to x.

Then, under the assumption that $x = 1.6$, $H = \eta B^{1.6}$ the coefficient η was calculated, and the equation $H = \eta B^{1.6}$ plotted in a curve, as given in the figures, and the observed values of H drawn in and marked.

From the curve were taken the calculated values of H, corresponding to the observed values of B, the difference $H_{calc} - B_{obs}$ determined, and expressed in per cents. of $H_{calc.}$

These values were given in the tables and shown in the curves.

I.—*Magnetic Circuit of the Westinghouse Converter.* (FIG. 1; TABLE I.)

On this magnetic circuit tests were made with the frequencies of 28, 36, 137 and 205 complete periods per second, and the results found to agree very well with the law of the 1.6 power, as the following table shows:

TABLE I.

Frequency. $N = 205$ complete periods per second.

B	H obs.	H calc.	$H-H$ calc—obs.	%
1790	376	400	+24	+6.0
1990	463	460	− 3	− .7
2380	585	610	+35	+5.7
2620	735	720	−15	−2.1
3060	893	920	+27	+2.9
3390	1054	1100	+46	+4.2
3660	1297	1240	−57	−4.6
3710	1288	1250	−38	−3.0
4620	1822	1800	−22	−1.2
5070	2024	2070	+46	+2.2
4990	2034	2010	−24	−1.2
5910	2698	2620	−78	−2.8
6100	2844	2750	−96	−3.5
6550	3039	3080	+41	+1.3
7290	3673	3640	−33	− .9
8050	4341	4300	−41	−1.0
8320	4410	4530	+120	+2.7
8240	4561	4460	−101	−2.2
		av:	± 47	=±2.7

where B = the maximum magnetization, H the loss of energy by hysteresis.

Exponent of power, derived from tests: $x = 1.6012 \sim 1.6$. Coefficient of Hysteresis: $\eta = .002434$; hence, theoretical curve, $H = .002434 B^{1.6}$.

From these 4 sets of readings, we get the following results:

TABLE II.

	Frequency, in complete periods per second: N	Number of readings.	Exponent of power, found by tests: X:	Coefficient of Hysteresis, found by tests: η:	Magnetization B covered by the observed values: From:	To:	Average difference between observed values of hysteresis H, and values calculated by the law: $H = \eta B^{1.6}$:
1.	28	4	1.6111	.002410	3510	17,940	±2.3%
2.	36	5	1.6476	.002315	7090	19,840	±4.4%
3.	137	10	1.5887	.002438	4000	13,750	±2.0%
4.	205	18	1.6012	.002434	1790	8,240	±2.7%

Therefrom we derive the average, by giving to each value as weight the number of readings, where it is based upon: $x = 1.60513 \sim 1.6$; $\eta_i = .0024164$. Hence: $H = .0024164 B^{1.6}$.

---

[1] Abstract of a paper read at the sixty-third meeting of the American Institute of Electrical Engineers, New York, January 19th, 1892.

Letters to the Editor.

THE LEONARD LAW OF MOTOR EFFICIENCY.

REFERRING to Mr. C. O. Mailloux's article under the above title in the issue of THE ELECTRICAL ENGINEER of January 13, I beg leave to offer the following reply. In his article Mr. Mailloux says: "It was in 1882 that Marcel Deprez first accomplished what Mr. Leonard now claims as his discovery or invention. * * * * * His experiments have been freely quoted, among others, by Kapp (Elect. Transm. 3d ed. p. 89), and also repeated by others." (Thompson Dyn. Elec. Mach. 3d ed. p. 539).

Mr. Mailloux makes a serious mistake in assuming that the contents of such standard works as those he mentions are unknown to others than himself, and does me an injustice (I trust unintentionally) by making it appear to the casual reader that I have put forth the most extravagant claims.

In fact the above references which Mr. Mailloux gives were well-known ones to myself and my patent lawyers before my applications were filed, and were carefully considered along with many others by the Patent Office examiners before they passed favorably upon my applications.

I cannot doubt that Mr. Mailloux's familiarity with the subject made him aware of the fact that the references he cites apply only to a series motor operating under a constant load.

Thompson (p. 539) is extremely careful to limit his statements to a series motor in saying: "With the same load the same current whatever the speed."

Kapp is equally as careful (p. 89) to limit his statement to constant current in saying: "If the current is constant the speed must be proportional to the electromotive force."

When, in considering motors whose torque and speed must both be varied, I stated the law of efficiency as being,

"Vary the voltage as the speed desired,
Vary the amperes as the torque required,"

and said: "In other words, make the speed dependent upon the voltage only and independent of the current, and make the torque dependent on the current only and independent of the voltage," I did not suppose I left any doubt as to my meaning that the volts should be varied *directly* in proportion to the speed desired, and similarly the current as the torque. Yet Mr. Mailloux evidently interprets me incorrectly, for he says:

"The fact is the amperes vary as the torque in all forms of motors *though not in the same way*."

Any number of writers have stated that with a shunt motor on constant E. M. F. the torque varies as the current; also that within a series motor on a constant current the speed varies as the volts.

Yet, evidently with neither of these motors could we vary both the voltage as the speed and the current as the torque; that is, while we could operate efficiently at constant speed with the shunt motor and at constant torque with the series motor we could not with either operate efficiently when both the speed and torque vary. It will be noticed that it is the constant field which we obtain in the shunt motor by constant E. M. F and in the series motor by constant current, which enables us to secure the exact relations between torque and current in the one case, and speed and volts in the other. Evidently this constant field cannot be maintained if we vary the volts on a shunt motor or the current on a series motor.

The use of the separately-excited field, which my method employs, gives perfectly exact relations between current and torque in the general case of performing work—*i. e.*, when both speed and torque are variable.

Thompson, in treating "Magneto motor and separately excited motor" (p. 569) gives one page to the subject, treating it briefly under two cases. Case I, Volts constant; Case II, Current constant; but does not even mention the general case when both are variable. Kapp does not treat the subject of separately-excited constant field motors at all.

That Mr. Mailloux has failed entirely to understand what my method accomplishes is clearly shown by his statement: "I do not regard a constant field as a condition *sine qua non* for accomplishing what Mr. Leonard's method does. A series-wound motor, used in place of his separately-excited motor, would operate quite as satisfactorily in most cases, and more so in many cases."

I realize fully and admit freely that, with the existing system of distributing electricity the series motor is frequently cheaper, simpler and sufficiently satisfactory; but it seems evident that if we can keep the field constant and then supply electric energy, which shall always be exactly proportional to the mechanical power produced and so that every speed will be an automatic one, independent of the load, it will be difficult to secure a more satisfactory result.

The immediate future will bring forth a system of distribution which will make it possible to operate under my method with all the simplicity of a constant-potential system and yet with perfect efficiency and control of speed under any variation of speed or torque.

Regarding the illustration I gave of the three-car train having six motors, Mr. Mailloux pronounces my statament "absurd." Undoubtedly his misstatement of my statement is so, for he makes the mistake of considering the current of the six armatures in connection with the volts of one, which it seems impossible that any reader should do, except with an endeavor to make my statement appear "absurd."

I regret that my method should have been so misunderstood by Mr. Mailloux, and trust that I have made it evident that the law and method I stated are really quite specific and limited and do not claim all the past discoveries of other workers in the field, as Mr. Mailloux mistakenly supposed.

H. WARD LEONARD.

NEW YORK CITY, Jan. 19, 1892.

ANOTHER WAY OF SAVING POWER UPON ELECTRIC RAILWAYS.

IN your issue of January 13th, I notice with interest Mr. Marple's remarks upon the power lost to an electric railway system consequent upon poor rail connections; the additional wear and tear upon machinery, and heating of motor parts due to the unsteady current resulting. Mr. Marple's observations upon the necessity of having good electrical connections between car wheels and rails are, at the present stage of electrical railway history, axiomatic. The suggested remedy is, we believe, good but unnecessarily expensive and troublesome. To keep such a contrivance in good order, to use it frequently and at the proper time requires the whole attention of a number of men. Its effect is not permanent, moreover, and the tracks, soon after the passage of a watering cart, resume the natural condition, dust covered.

What is needed is a device that will thoroughly clean the rails afresh for each car; that will require but little attention and cost but little money. Such a device is found in the strong, durable track brooms now used upon many street car lines and even upon steam roads where the latter accommodates suburban traffic. The brooms are attached to the car trucks so as to rest upon the rails. A properly-constructed broom, well placed, will sweep every particle of dust, sand, stone or dirt of any kind from the track, leaving a clean and perfect electrical connection with the car wheels. It is impossible for dust to settle upon the rails between the times of the passage of the brooms and wheels, and however dirty the rails may have become between cars, they are perfectly clean as the wheels of each car pass over them. Where-ever on the route a car may be, there also is a clean track. Brooms are cheap; they cost little time or money. Once properly adjusted they "fill the bill" as a perfect track cleaner.

W. R. MASON.

CHICAGO, ILL., Jan. 19, 1892.

IRON ROOFS IN THE OIL CITY, PA., STATION.

IN regard to the condensation from iron roofs, I would say that our building is brick, 100 x 60 ft., with a corrugated iron truss roof. Our experience warrants us in saying that they are not a success. Ours only bothers us on very cold nights when the thermometer registers near zero, and to obviate that we have to keep the windows down or rather open at top to prevent any melting of the frost or condensation that adheres to the under side of the roof. As we do not run a daylight circuit, we protect our dynamos with covering during the day and freeze during the night. We are arranging now to have a waterproof covering made that we can swing and hang over our dynamos during the night and drop down on them during the day. Iron roofs may be all right in the torrid zone, but in our latitude they are certainly a failure.

OIL CITY ELECTRIC COMPANY,
J. H. PAYNE,
Manager.

OIL CITY, PA, Jan. 25, 1892.

QUICK RECOVERY OF A BOSTON STATION FROM FIRE.

WE are happy to say that although the fire completely destroyed our Ferdinand street station with a dynamo capacity of 1500 lights, at 3:30 o'clock A. M. on Saturday morning, we were able on Saturday night to burn all but 350 lights out of 3200 arc lights as well as all our incandescent lamps and all our power business. Everything was burning that usually burns on Sundays, and to-night we are happy to say that every light in the City of Boston is burning with the exception of a very few City lights, which instead of starting on time at 5 o'clock, will be started when our day commercial lights are thrown off at 6 o'clock, and practically we are burning to-day every light in the City of Boston that we were burning before the fire on Saturday morning.

We consider this as good as any other fellow could do, but not if he went to bed as people do in other business, though never in the electric light business.

F. A. GILBERT,
President Boston Electric Light Co.

BOSTON, MASS., Jan. 25, 1892.

PLANS FOR HOTEL BELL WORK.

HAVING read Mr. Armstrong's article in your issue of Dec. 23 and also Mr. Miner's criticism on the same, I think Mr. Miner overlooks one very important point, viz.: The voltage on open circuit, by using resistance, remains the same as the street circuit, which I do not think safe to introduce into bell wiring.

Also, an ordinary vibrating bell, used as Mr. Miner suggests, will set up an arc at the contact points without ringing the bell.

Mr. Armstrong's is the best of all plans that I have seen, and I expect to utilize it with one improvement, viz., using only one machine with two windings on the armature and two commutators, making a combined motor-dynamo.

J. CRAWFORD BARTLETT.

PHILADELPHIA, Jan. 26, 1892.

IRON ROOFS IN A NEWARK, DEL., DYNAMO PLANT.

THE trouble with the roof of our church organ factory dynamo plant was caused by condensation of moisture upon the inner surface of the sheets of galvanized iron composing the roof of our engine-room, when the weather was frosty, producing a drip which endangered the dynamos, &c.

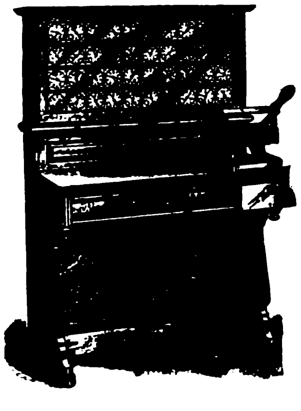
We removed the iron sheets, covered the building with 1 inch hemlock boards and roofing paper, and then replaced the sheet iron as before. This arrangement has given perfect satisfaction. We used tarred roofing paper.

THEO. C. KNAUFF & CO.,
By RUFUS STEWART.

NEWARK, Del., Jan. 26, 1892.

Society and Club Notes.

THE HOLLERITH CENSUS APPARATUS AT THE ELECTRIC CLUB.



A VERY interesting and unusual entertainment was given at the New York Electric Club last week on Thursday, January 28, when Dr. Herman Hollerith, of Washington, member of the club, exhibited his highly ingenious apparatus for counting and tabulating census data. It will be remembered that a description of the system and apparatus was given in these columns on November 11, 1891. Dr. Hollerith brought with him a complete set of appliances, including the "keyboard" and "gang" punches, for stamping holes in the cards, one of which serves for each person; the counting machines, sorting boxes, dials, registering press, tin cases for cards, schedules, tabulation sheets, etc. He also showed one of the old Seaton machines used in the census of 1880. The exhibition was preceded by a brief explanation of the apparatus and the principles involved, after which Dr. Hollerith and his assistant ran a number of cards through the machine. Altogether the exhibit was one of the most interesting that has been made at the club, and it was greatly enjoyed by all. Mr. C. R. Huntley president of the National Electric Light Association, presided, and took occasion to call attention to the use of the machine in tabulating the endless data that Mr. A. R. Foote was wringing out of central station lighting and railway companies.

REMINISCENCES OF LINCOLN.

FEBRUARY 12 is Lincoln's birthday, and in order to celebrate appropriately that interesting occasion, the New York Electric Club has arranged for a special entertainment. Mr. A. B. Chandler, president of the Postal Telegraph Cable Co., who was near Lincoln through the long struggle of the Civil War as a military telegrapher, and who possesses many memorials of the great President, will give a lecture entitled "My Reminiscences of Lincoln," and the lecture will be interspersed by war songs and other melodies given by the well-known Brunswick Quartette.

NATIONAL ELECTRIC LIGHT ASSOCIATION.

MR. C. O. BAKER, JR., the chairman or "master" of transportation for the association, makes the announcement that he has received official notification from the Trunk Line Association, the Central Traffic Association and the Southern Passenger Association, stating that they have granted from points in their territory a fare-and-a-third rate to Buffalo, on the certificate plan, to cover the time of the Convention in February.

Secretary Porter announces that in compliance with the wishes of a majority of the members, in regard to holding an exhibition in connection with the Buffalo meeting, it has been decided that no exhibit will be held under the auspices of the Association. This, however, will not interfere with any arrangements which individual members may wish to make for having a display of goods at the hotel, as has been the custom heretofore.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA.

THE 12th annual meeting of this Society was held in its rooms in Pittsburgh, on January 19th, Mr. T. P. Roberts, the president, in the chair. The secretary's report showed a membership of 370. The following officers were elected for the ensuing year: President, Alfred E. Hunt; vice-presidents, one year, Phineas Barnes; two years, Charles Davis; directors, Robert Munroe, G. W. G. Ferris; secretary, R. N. Clark; treasurer, A. E. Frost.

PHILADELPHIA ELECTRIC CLUB.

SO many have responded to the call for names of those who would interest themselves in an electric club in Philadelphia and the encouragement given those who are soliciting personally, that we feel assured that the club will be a decided succcess. It is proposed that a notice be sent to each person whose name is received, to meet at some hotel to determine on future action.

THE PITTSBURGH ELECTRIC CLUB.

PRESIDENT Morris W. Mead, of the Pittsburgh Electric Club, has appointed the following committee for the government of the club:

House committee, N. H. Byam, chairman, H. Albright and F. H. Ketchum; entertainment committee, E. H. Heinrichs, chairman, W. McC. Ramsey and E. B. Thompson; membership committee, John Campbell, chairman, D. W. Dunn, and H. McL. Harding. At a recent meeting of the board of directors, Mr. Ernest H. Heinrichs, of the Westinghouse Electric and Manufacturing Co., was elected librarian and historian of the club.

Legal Notes.

ELECTRIC LIGHT PLANTS ARE FACTORIES EXEMPT FROM TAX.

AMONG the decisions handed down by the New York Court of Appeals, last week, was one favorable to the relator in the case of the People ex rel. the Brush Electric Illuminating Company, appellant, *vs.* Edward Wemple, Controller. This decision disposes of the interesting legal question whether or not a company which generates and distributes electricity is a manufacturing company within the meaning of the statutes of the State and therefore exempt from the payment of State taxes.

The Controller contended that as the company was not engaged in producing any material thing, it was not a manufacturing corporation within the meaning and intent of the law, and therefore was not exempt from the payment of such taxes. The company appealed from the Controller's order to the General Term, and that court sustained the decision of the Controller. From that decision the company appealed to the highest court, and that court has now by its decision sustained the contention of the company's attorneys.

TELEGRAPH BLANK DECISION—CANADIAN JUDGMENT THAT THE REGULATION PRINTED ON THE BLANKS IS NULL.

THE Court of Appeals has given its opinion of the contract which telegraph companies print on their blanks. The case was that of Lawrence *vs.* the Great Northwestern Company. While Mr. Lionel Lawrence was in New York, one of his employees sent him a dispatch saying: "Writing you to-night." The sentence was made to read: "Waiting you to-night." Consequently Mr. Lawrence made an unnecessary trip from New York to Montreal, and sued the telegraph company for $200 damages. The court in the first instance awarded $30, the actual cost of the trip from New York. The company appealed from this decision. The proof established the fact that the error was due to the negligence of the employees of the company, but the appellant set up the plea that the dispatches were sent under a contract which declared that it would not be liable for damages resulting from errors unless the dispatch was repeated, and then only to the amount of fifty times the price paid for the message. Such a contract the court declared to be contrary to public policy, and any contract by which a party sought to fix the punishment for his faults was illegal. The judgment was confirmed.

A TYPEWRITER SUIT OF INTEREST TO TELEGRAPHERS.

THE Remington Standard Typewriter Manufacturing Company and others have recently filed a bill of complaint in the U. S. Circuit Court, Southern District of New York, against Frank W. Bailey, who is selling the Franklin Typewriter, for infringement of the Crandall Patent which covers a vibrating platen used in combination with type bars carrying multiple type. H. D. Donnelly of this city appears for the complainants.

THE "K. W." VICTORY.

COMMISSIONER SIMONDS, on January 9, rendered a decision in the case of Dillon *vs.* Kimball and Wirt; Electric Cut-Out, in favor of the latter, it being proven that the testimony offered in behalf of Dillon would not stand the scrutiny to which it was subjected. The Commissioner considered that there were enough material faults in the case presented by Dillon to create a reasonable doubt as to its correctness from beginning to end, and the decision of the Examiners-in-Chief awarding absolute priority of invention to Kimball and Wirt was therefore affirmed.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JANUARY 19, 1892.

Alarms and Signals :—

Automatic Fire Alarm, G. S. Tilton, 467,212. Filed Nov. 2, 1891.
An alarm in which the circuit is held open by cords which run through the building and is closed by the burning asunder of such cords.

Electric Railway Signal, W. F. Z. Desant, 467,478. Filed Sept. 26, 1890.
An automatic system of electric block signals for railways.

Dynamos and Motors :—

Commutator, H. P. White, 467 215. Filed Feb. 13, 1891.
An arrangement by which the path of the current is changed during the revolution of the commutator.

Method of and Apparatas for Controlling Electric Motors and Generators, C. T. Hutchinson, 467,230. Filed Nov. 11, 1890.
A method of equalizing the work done by two or more motors.

Commutator for Dynamo-Electric Machines and Motors, E. Thomson, 467,318. Filed Jan. 31, 1891.
A disc commutator having sector shaped contact surfaces with a wedge shaped brush engaging such surfaces.

Regulator for Electric Generators, E. W. Rice, Jr., 467,358. Filed May 2, 1890.
Employs a controller for the electromotive force regulator depending upon the output of the machine, and set in action only at the point of maximum output.

Controlling Apparatus for Electric Motors, C. J. Van Depoele, 467,449. Filed Mar. 19, 1891,
A current regulating and reversing apparatus for vehicles.

Electromagnetic Reciprocating Pumping Engine, C. J. Van Depoele, 467,450. Filed Mar. 19, 1891.
A reciprocating pump electrically operated on the principle of the solenoid.

Reciprocating Electric Engine, C. J. Van Depoele, 467,451. Filed July 10, 1891.

Galvanic and Thermo-Electric Batteries :—

Battery-Zinc, C. B. Schoenmehl, 467,239. Filed Apr. 25, 1891.
A self-amalgamating zinc rod for batteries.

Electric Battery, C. B. Schoenmehl, 467,240. Filed Apr. 25, 1891.

Galvanic Battery, F. Gendron, 467,372. Filed May 14, 1891.
A battery in which the output is automatically regulated according to the work demanded.

Lamps and Appurtenances :—

Filament for Incandescent Electric Lamps, P. Hickley, 467,169. Filed Aug. 21, 1890.
A filament composed of a carbonized root of the rice plant.

Electric Arc Lamp, J. Riedel, 467,199. Filed May 28, 1891.
An arc lamp in which the arc is formed at a point of uniform height and regulated by means of movable carbon holders.

Incandescent Electric Lamp, C. H. Wilkins, 467,270, Filed June 19, 1890.
Employs a helical carbon wound about a conical reflector in the interior of the lamp.

Incandescent Electric Lamp, J. L. Curtiss, 467,276. Filed July 24, 1891.
Claim 1 follows:
An electric motor provided with a socket at one end adapted to receive an incandescent lamp, and electrodes at the other adapted to fit the lamp socket, and electrical conductors from said electrodes to said lamp.

Metal-Working :—

Process of Electric Metal-Working, H. Lemp and W. S. Moody, 467,233. Filed Apr. 23, 1891.
Provides means for correcting the tendency to localization of effects produced by two electric currents flowing at an angle through the same conducting medium.

Miscellaneous :—

Automatic Damper-Controller, F. E. Chatard, 467,153. Filed May 5, 1891.
A thermostatic device for automatically controlling the damper of a heater.

Electric Elevator, N. P. Otis and R. C. Smith, 467,192. Filed July 31, 1891.
Automatic controlling device for the motor operating an elevator.

Rubbing, Polishing and Sandpapering Machine, H. C. Strobel, 467,209. Filed July 10, 1891.
A sandpapering machine operated by an electric motor.

Liquid Rheostat, H. Lemp, 467,255. Filed March 22, 1889.

Automatic Cut-Off for Gas-Burners, J. E. Hogan, 467,287. Filed Apr. 20, 1891.
Provides a supplemental means of cutting off the flow of gas in case the key is accidentally left open.

Rheostat, C. Willms, 467,338. Filed Sept. 30, 1891.
A rheostat in which the collecting sectors are each of the same area as the cross section of the resistance material required at the plane of the sector.

Electrolytical Plant, O. Stalmann, 467,350. Filed June 8, 1891.
Claim 1 follows:
An electrode consisting of a plate of refined material and a plate of crude material with insulating material interposed between said plates and metallic connection between said plates.

Electric Lock, F. S. Holmes, 467,465. Filed Feb. 3, 1891.
A lock which may be electrically controlled at any given point of a station.

Electrolytical Process and Apparatus for Carrying Out Said Process, O. Stalmann, 467,484. Filed Oct. 1, 1890.
Similar to No. 467,350.

Railways and Appliances :—

Trolley for Electric Railways, E. R. Harding, 467,250. Filed Jan. 3, 1891.
A trolley provided with a spring which is automatically relieved of tension in the event of the trolley jumping from the conductor.

Electric Railway-Brake, E. Verstraete, 467,259. Filed Aug. 8, 1890.
An electric brake for steam railways.

Electromagnetic Brake, H. E. Walter, 467,243. Filed Apr. 3, 1891.
A car brake acting by magnetic action upon the rails of the track.

Electric Railway, C. J. Van Depoele, 467,448. Filed June 22, 1885.
An overhead trolley railway system.

Telephones and Apparatus:—

Holder for Telephone Receivers. R. Dent, 467,160. Filed Apr. 13, 1891.

THE ATHENS, GA., ROAD AND ITS YOUNG SUPERINTENDENT.

MR. J. T. VOSS, the general manager of the electric road of the Athens, Ga., Railway Co., has recently written the Detroit Electrical Works the following letter:

> In reply to yours of the 18th inst. regarding the Detroit Electrical Works. "Standard Electric Railway System," which you furnished the Equitable Engineering and Construction Co., of Philadelphia, for our line here, consisting of four 30 h. p. motors and one 80,000 watt dynamo, would say that we are well pleased with the equipments, and are satisfied that we are operating our motors 50 per cent. cheaper than any other system now in use.
>
> We have had very little trouble or expense with the bevel gear, in fact there is no trouble with it when the friction collars are kept well adjusted, which is very simply and easily done. And as to the dynamo, it has not caused us one minute's delay or one cent of expense. As to the whole equipment, we find it to be the simplest and easiest to keep in repair of any of the systems that I have ever inspected.
>
> I have a son 19 years old who has charge of all the cars and motors, and he keeps them in thorough repair; we never have lost as much as a day's service with any one motor, and all the experience he has ever had in electrical work was with your men while here setting up our machinery, while with other systems it is necessary to keep a high salaried expert to keep the machinery in order.
>
> I claim that we have got the best equipped road anywhere, to my knowledge. Our cars make less noise and run smoother than those of any other system that I have ever inspected. I have been in the street railway business for some 12 years, and last year, before we began to make any change in our line here, I made a tour of inspection of the different systems, going to Macon, Ga., from there to Atlanta, Chattanooga, Nashville, Louisville, Pittsburgh, New York, Jersey City, and also Washington, D. C. I became utterly disgusted with two motors to one car, and more especially when I went to the repair shops.
>
> The single motor geared direct to each axle, cannot be beat anywhere, and that is just what we have. We would be glad at any time to show any one our system here.

FRASER & CHALMERS TO USE ELECTRICITY IN THEIR SHOPS.

MESSRS. FRASER & CHALMERS, of Chicago, Ill., the great manufacturers of mining machinery and steam engines, have now shown their readiness to recognize the merits of electricity as a power transmitter and are about to fit up the foundry and boiler shop and the pattern shop in their Twelfth street works with an electric power plant. This plant will consist of two 80 kilowatt generators, one 25 h. p. motor, eight 10 h. p. and eight 5 h. p. motors, distributed throughout the various buildings. The generators and motors will be wound for a pressure of 250 volts. One advantage which is expected to be derived from the use of this potential is that while the electromotive force on the motor circuits will be kept down below any possible danger mark, yet by connecting two dynamos in series a pressure of 500 volts will be obtained, which will permit of testing the various electrical mining machines, the motors for which are usually wound for this higher potential.

Messrs. Fraser & Chalmers have had this plant under consideration for several months, and the competition among the various motor companies has been keen. The "C. & C.," Edison, Thomson-Houston, Eddy, Mather, Brush, Westinghouse and several others, eleven in all, submitted estimates. To the "C. & C." Electric Motor Company was awarded the prize in the shape of the contract for this installation.

It is understood that part of the plant is to be in running order within 60 days and the entire installation is to be completed within 90 days. The plant will be one of the largest as yet installed for general power purposes, and will afford an excellent demonstration of the advantages of electricity under conditions such as exist in Messrs. Fraser & Chalmers' works.

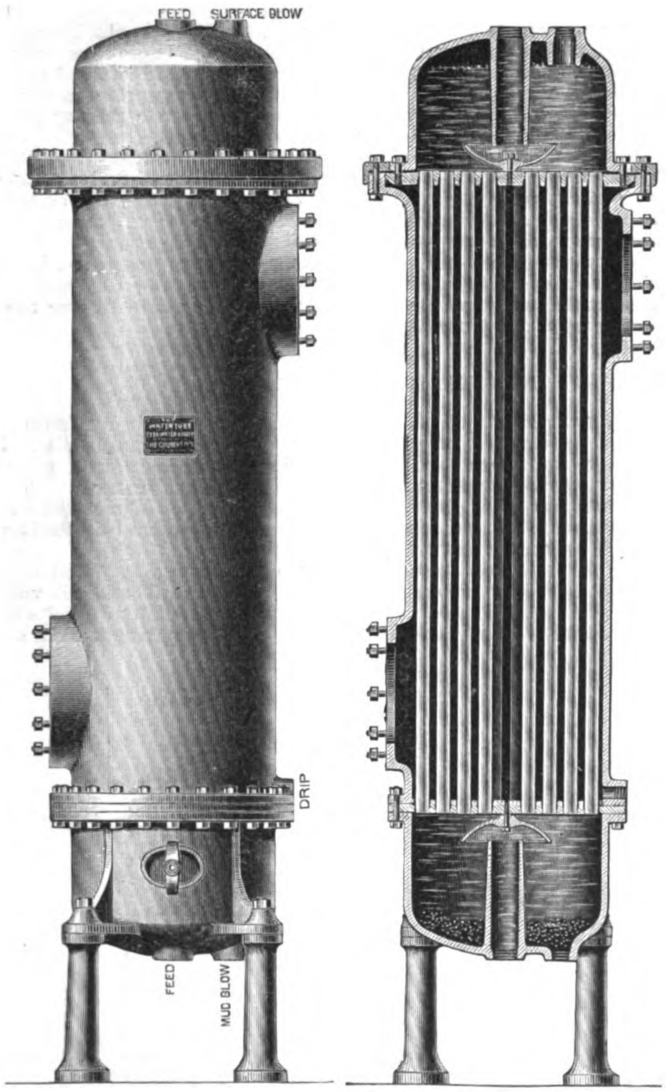
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Advertising is the magnet and trade the armature it draws.

THE GOUBERT "WATER-TUBE" FEED WATER HEATER.

The accompanying illustrations show the latest construction of the Goubert "water-tube" feed water heater. It is essentially composed of two cast iron water chambers connected together by a cluster of seamless drawn brass tubes, rigidly secured at their ends to the tube-plates by means of a roller tube expander in the same manner that boiler tubes are connected to the heads. These are the only parts of the heater under boiler pressure.



Figs. 1 and 2.—Goubert "Water Tube" Feed Water Heater.

The lower water chamber rests on legs on the floor while the upper water chamber is free to move vertically as the tubes expand or contract. The tubes are surrounded by a cast iron shell provided with inlet and outlet nozzles, to which are connected the exhaust pipes. This shell is bolted to the lower water chamber, but is free to expand independently of the tubes, its only connection at the top with the upper tube plate being made by means of a flexible corrugated copper expansion plate. This serves to close up the space between the upper tube-plate and the shell, and has no pressure to withstand but that of the exhaust steam, although it is protected and backed up in such a manner as to easily resist any pressure that may come upon it. At the extremes of temperature this corrugated copper expansion joint never has to spring more than three sixty-fourths of an inch either way, and is practically indestructible.

The water inlet and outlet pipes are made to project inside of the water-chambers, and opposite them are placed dish-shaped deflections to promote the separation of scum and sediment. Surface and mud blows, and also a hand-hole are provided for cleaning.

Among the advantages claimed for this heater are the following: The tubes are of brass, are free to expand; the pressure being from the inside they cannot collapse, neither can they leak at the ends, as the greater the pressure the tighter they become. By simply removing the head all the tubes can be easily cleaned. The area for the passage of steam between the tubes is from eight to sixteen times as large as that of the exhaust pipe, and consequently it cannot cause back pressure. The water, being divided up into small columns and in immediate contact with the heating surface, is quickly heated to the highest point.

This heater is manufactured solely by The Goubert Manufacturing Company, 32 Cortlandt street, New York.

PARTRICK & CARTER CO.'S HOTEL FIRE-ALARM SYSTEM.

The practice of connecting up a large number of electric gongs in series having been found unsatisfactory in a number of instances, on account of the mutual dependence of all parts of the system upon each other, Partrick & Carter Co., of 125 South Second street, Philadelphia, have devised the independent arrangement shown in the accompanying illustration. The apparatus consists of electric bells having gongs of from 6 to 10 inches mounted on a polished base, having a locked box attached for holding two cells of dry battery and an automatic drop. These drops are connected in series to their respective boxes in the halls and pushes in the office. This fire-alarm system has no connection whatever with the working of the annunciator, and does not in any way interfere with the working of the combination return call bells in the rooms. Upon pressing of the fire-alarm buttons, the drops in the various boxes in the series, or floor, operate and close the local circuit to their respective bells and batteries, each bell having its own battery and being entirely independent. The bells will continue to ring until reset. In each hall are placed small alarm boxes containing a push-button and provided with a very thin glass front, while a card of directions is placed in a conspicuous place, reading, "In case of fire break glass and push the button." The pushing of any one button on any floor. will cause all the bells on that floor to ring continuously until stopped by resetting the automatic drop in the bell box, and without the intervention of the office battery.

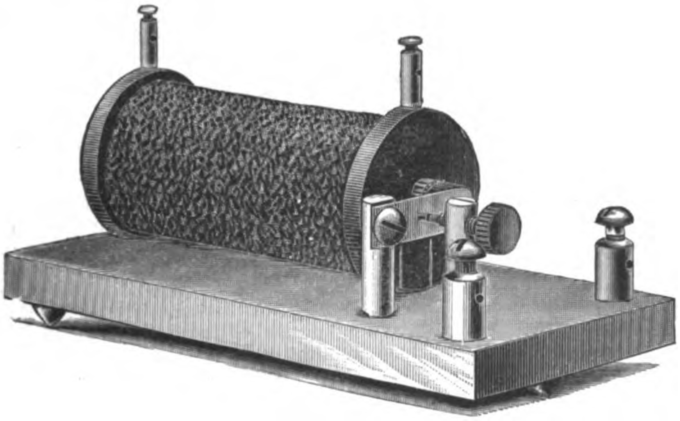
The company guarantee a number of important advantages for their system.

THE TERROR INDUCTION COIL.

NEXT to the galvanic battery as a source of current there is scarcely a single piece of apparatus more valuable and instructive than the induction coil. While permitting of the demonstration of luminous, heat and other effects it brings clearly before the student the great principles involving the action of magneto induction as employed in nearly all modern dynamo electric machinery and especially in alternate current transformers of which it is a special type.

The "Terror" induction coil which is illustrated in the accompanying engraving is constructed on scientific principles, and of materials best suited to secure a high degree of efficiency. The primary coil has a resistance of 0.7 ohm, and the secondary, which consists of many thousand turns of No. 35 wire, has a resistance of about 1,100 ohms. The insulation throughout is carefully attended to, so that the coil will stand a high electric pressure without injury. The automatic break is substantially constructed, and the condenser is made of such size as is found by experiment to give the best results. The coil has nicely polished, hard rubber ends, and is mounted on a polished base of the same material.



THE TERROR INDUCTION COIL.

Among the numerous experiments which can be performed by means of this coil we may mention the following: Divergence of the spark towards a flame; sparking over finely divided metal; ignition of hydrogen gas and explosion of gunpowder, etc. To these must be added the beautiful luminous effects which can be obtained by the aid of vacuum or Geissler tubes, which constitute a never ceasing source of pleasure and instruction. The Blakeney Electric Co., of 431 Broadway, Brooklyn, N. Y., furnish for $5 a "Terror" coil giving a ¼ inch spark, 1 cell of electropoion battery, 1 six-inch Geissler tube, uranium glass, and a full set of accessories.

A NEW BUNNELL CATALOGUE.

J. H. BUNNELL & Co. have just issued a new edition of their catalogue, for 1892, No. 12. It is a fine trade publication of no fewer than 224 pages, and the contents are so numerous that the heads under which they fall make up nearly 700 titles in the index. This fact alone speaks volumes for the scope of the electrical industry as represented by this house, but it must be mentioned that even then the catalogue is not as complete as the firm would like it to be, as many of their lines of electric railway, electric light and other supplies have been omitted. The omissions will be supplied in a special supplement at some future time, but meanwhile the catalogue serves most admirably for any and all of the different branches of supply trade. The articles shown and enumerated range from the famous Bunnell key, which literally swept the country when it made its appearance, down to the Ries incandescent lamp socket, the latest novelty of importance in the lighting field. Altogether the catalogue is a very useful—in fact, indispensable—book of reference for all who have to purchase electrical goods.

PERFORMANCE OF THE JOHNSON SWITCH.

ONE of the most interesting articles in the current issue of THE ELECTRICAL ENGINEER is that by Mr. E. H. Johnson, president of the Interior Conduit & Insulation Co., on his switch for electric light and power work. Mr. Johnson, with wonted force and clearness, describes the principles and features of the device. It may be added here that the switch has been under some very severe tests, with highly satisfactory results. One of these took place last week in the Edison Building, Broad street, where the offices of the Interior Co. are located. The building is connected with the down town Edison station, and has a new plant of its own, and the test was made on the street current. The switch was loaded with 170 amperes at 125 volts, and took the swift changes serenely. The rapid throwing on and off of the load was noticed at the station, which had not been apprised, and thinking it might perhaps be a short circuit on their underground system they immediately raised the voltage to 140 to burn it out. But the switch went through the ordeal very gracefully, and being 'indestructible" is still there for a long career of usefulness. The fact that a 50 or 100 ampere switch can thus be got down to so minute a size shows more than anything else the immense advance that is being made in this important department of station and building appliances.

IMPORTANT SHORT RAILWAY CONTRACTS.

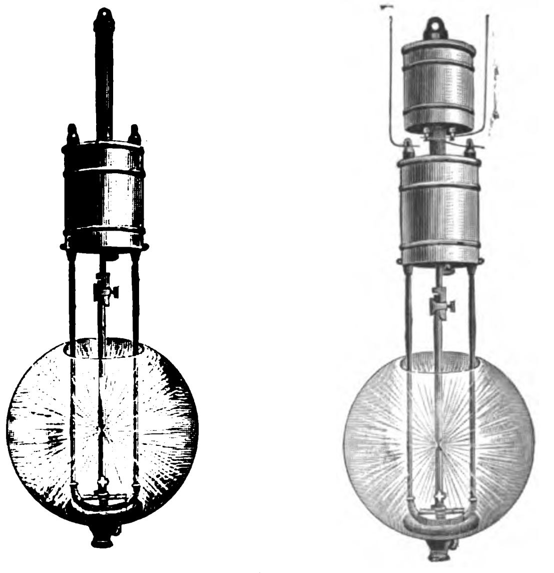
THE Short Electric Railway Company have been fortunate in securing from the Minneapolis Street Railway Co. an order for their entire spring requirements. It will be remembered that this road is one of the largest in the country, operating about an equal number of Thomson-Houston and Sprague equipments. In the extensions to be made this spring, the Minneapolis Company found it necessary to purchase 120 motors, and made a careful investigation of the latest types of motors as made by the leading electrical companies, finally selecting the Short gearless motor as embodying all the best features for modern electric railway practice. The motors are to be in operation by April.

The Consolidated Street Railway Co., of Grand Rapids, Mich., have just placed an order with the Short Electric Railway Company for twenty 40 h. p. gearless equipments to be used on their lines, which are being changed over to electricity. This contract was made after very careful personal investigation of all the leading systems by the general manager of the company, Mr. J. R. Chapman, and is significant as showing in what direction engineers and practical street railway men are looking for the most improved railway practice.

THE MOSHER ARC LAMP.

THE accompanying illustrations show the Mosher arc lamp designed for direct or alternating current incandescent circuits. It is the result of over two years' practical test and use, and, as now constructed, possesses many novel and economic features. In its construction all clockwork is dispensed with. It is provided with a switch and cut-out so that when the carbons burn out, the lamp will be automatically cut out of circuit.

These lamps can be used singly on any voltage of from 50 to 125, or can be run in series of 2, on a circuit of 100 and 125 volts, and 2, 3 or 4, on a 220 volt circuit, or in series of 5 to 10 on a 500 volt circuit. They can be adjusted so as to pass from 8 to 10 amperes each, and to yield from 500 to 2,500 or more candle power. They are made in two sizes; one 42 inches in length, which receives a pair of ordinary length carbons; the other is 52 inches long and will receive 24½ inches of carbon and burn all night. The carbon holders are made to receive carbons varying in sizes from 7/16 to 5/8, and the length of the arc is easily adjusted by means of a regulating screw at the lower end of the spring.



FIGS. 1 AND 2.—MOSHER ARC LAMPS.

The resistance, composed of fine braided wire, is enclosed in the case at the top of the lamp, or may be located at any convenient place away from the lamp, and is also adjustable.

The lamp is so constructed that a weather hood is unnecessary.

NEW SOMOFF LAMPS.

Mr. J. L. Somoff, of No. 1 Ann street, this city, is out with the second part of his lamp catalogue, which contains a number of styles of novel incandescent lamps of low voltage. The demand for such lamps, he says, is steadily growing, and the after-Christmas trade is as brisk as it was in December.

In the accompanying illustrations, Fig. 1 is one of the "Prism" lamps. Mounted upon a chandelier and lighted, they produce the most beautiful display of rainbow colors, the effect being incomparably superior to that of the prisms suspended from a gas chandelier.

A "Torch" lamp, Fig. 2, was designed by Mr. Somoff for purposes of theatrical display, etc. It has four lenses fused on the outside, all the surface around them being frosted. The effect of this combination of a true spheroidal form of the globe with frosting and lenses is to project the light in the form of four condensed beams. During December 450 of these lamps were used upon European stages in the production of the opera "Robert le Diable." They were mounted on torches, containing small storage batteries. Little vanes at the bases of the lamps revolved the lamps with the least motion of the air, the beams of light striking in every direction.

Fig. 3 shows a miniature wall bracket, one-third actual size. Until lately, there have been no brackets on the market suitable for miniature lamps, and it has been found difficult to place them, especially when intended for artistic display, in a way that insures the best effect. This cheap bracket is simple, neat and effective.

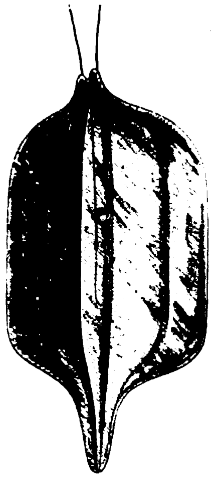


Fig. 1.

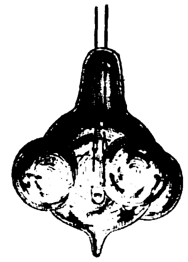

Fig. 2.

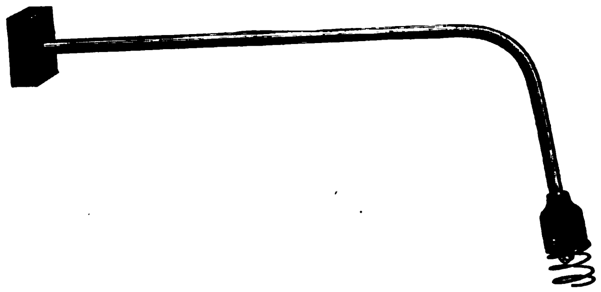

Fig. 3.

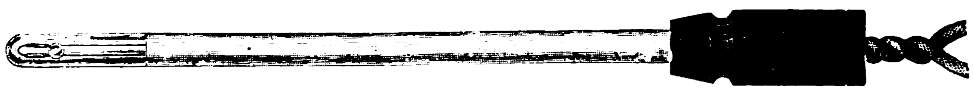

Fig. 4.

Somoff Incandescent Lamps and Socket.

Fig. 4 is an antiseptic surgical lamp which a year ago came into very extensive use by physicians. It is made wholly of glass; the part surrounding the filament of crystal, and the rest, serving as handle, of opaque, milk-white glass. Any uncleanliness can thus easily be seen and readily removed.

Mr. Somoff has also a number of novel and artistic forms of lamps for a variety of purposes.

LONG-DISTANCE ELECTRIC POWER TRANSMISSION—A CORRECTION.

In the article on "Long Distance Transmission of Power by Electricity" by Mr. Francis R. Hart, which appeared in our issue of January 13th, a slight error, due to the engraver, was made in the chart accompanying the paper, on page 43. The percentages marked on the upper left-hand side of this diagram should be made to read in the reverse order from that in which they appear; that is to say, as 20 per cent., 10 per cent. and 5 per cent., beginning from the left.

PELTON WATER WHEELS.

The Pelton Water Wheel Co. report the following recent sales of their water wheels and motors: Four motors to the London Hydraulic Power Co., to operate under 750 lbs, pressure; two motors to the Candelaria Mining Co., Mexico, to run electric generators, under 1100 ft. head, for a Thomson-Van Depoele drilling plant; one 4 ft. wheel and one motor, to run machinery at Hackberry Mines, Arizona, under 1200 ft. head; four 3½ ft. double nozzle wheels and one 6 ft. triple nozzle wheel to run under 24 ft. head, for Limon Electric Plant, Salvador, C. A.; one 4 ft. wheel to Georgia Marble Co.; three 8 ft. wheels for Anaconda Smelting Co.; two motors for Backus & Johnson, Lima, Peru; one 6 ft. wheel for Gold King Electric Plant, Telluride, Colorado; one 8 ft. wheel, for running electric transmission plant, Consolidated Mining Co., Belmont, Telluride, Colo.; two motors to De Beers Mining Co., Transvaal, S. Africa; one 8 foot wheel for running a silver mill, at Lewis, Nevada; one 5 ft. wheel, to Porte Cortez, Honduras; four 5½ ft. double nozzle wheels, for an electric light station, at Santa Anna, San Salvador, C. A., to operate under 60 ft. head; one 6 ft tripple nozzle wheel, for Santa Anna Water Works, San Salvador, C. A.; one motor and one 6 ft. special wheel to Nicaragua, C. A.; one motor to Ricaurate, Salvador, C. A.; one motor for Coffee Plantation, Esperanza, Guatemala; one motor to Callao, Peru; one 6½ ft. special wheel, and one 3¼ ft. special wheel for St. John Del Rey Mining Co., Brazil; two 5½ ft. wheels for running an electric light plant in Japan; one 11 ft. wheel, one 8 ft. wheel, one 1½ ft. wheel, and six 3½ ft. wheels to the Columbia River Paper Mills, La Camas, Washington.

WITH MERCHANT & CO.'S BROWNIES.

Some months ago the metal firm of Merchant & Co., of Philadelphia, issued a most dainty illustrated brochure in which, with the aid of a clever artist, they depicted the Brownies using their various productions in wire, solders, rolled metal, roofing, ventilators, etc. They have now followed that up by a very pretty New Year companion piece, in which they associate their products and the Brownies with the Chicago World's Fair. It is a skillful handling of the subject and some of the pictures are at once humorous and beautiful. At the outset we see the Brownies of all nations heading for the Fair, and all their adventures, misadventures and amusements are mixed up in a Gilbertian manner with cornices, roofing, babbitt, fuse wires and pipe, until one awakes to the enormous possibilities of what we may term industrial comic opera. One is loathe to part with the charming ballerina whose acquaintance is made in the opening pages, she is so altogether gay and graceful, but we live in hopes of meeting her again through the kindly offices of Merchant & Co., to whom and to whose artist we beg to tender the assurance of our most distinguished admiration.

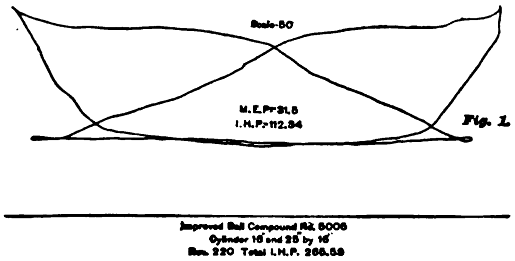
QUICK WORK ON LAVA INSULATORS.

An order was received at Wednesday noon, Jan. 20, by the D. M. Steward Mfg. Co., Chattanooga, Tenn., from the Standard Electric Co., of Chicago, for 5,000 of their lava insulators. By Wednesday night the entire lot was turned out. The pieces were hardened on Thursday, and the whole order was shipped on Friday morning. There is very often a sudden need for insulators such as small bushings, washers, etc., and manufacturers of lamps and other apparatus will certainly find it worth their while to avail themselves of such facilities.

Prof H. T. Bovey, of McGill University, Montreal, has been in New York during January, with Mrs. Bovey, a guest of Prof. Egleston, of Columbia College, at the latter's residence in Washington Square. Many New York electricians who met him during the Electric Light Convention, have been glad of an opportunity thus to see him again. While in this city Prof. Bovey was quite busy on work connected with the new buildings and equipment which will go far to make McGill one of the very first seats of learning on this continent.

IMPROVEMENT IN BALL COMPOUND ENGINES.*

THE accompanying diagrams were taken from a 250 h. p. cross-compound engine just installed in the station of the Edison Electric Illuminating Company of Paterson, N. J. The engine was designed and built by the Ball & Wood Co., at their Elizabethport shops, and embodies some new features in the arrangement of low pressure valves. The steam chest of this cylinder is placed directly underneath, and contains two valves, both of which are double ported, giving large and direct ports with very small clearance. The diagrams speak for themselves as to the efficiency of this arrangement. The dimensions of cylinders are as follows: high pressure 16 in. dia. x 16 in. stroke; low pressure, 25 in. dia. x 16 in. stroke; speed, 220 revolutions.



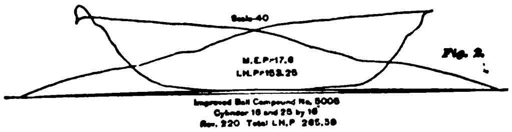


Fig. 1 is a reproduction of cards from high pressure cylinder, and Fig. 2 simultaneous cards from low pressure cylinder. Fig. 3 represents a combination of the cards, showing their relation to each other and the measure of loss between the cylinders up to point of cut-off. In Fig. 4 the cards from both cylinders are referred to the low pressure cylinder in the usual manner, and show the efficiency of the system. The theoretic expansion and compression curves are shown in dotted lines. No tests of economy have yet been made, but the very small losses between the cylinders and in back pressure promise an excellent showing.

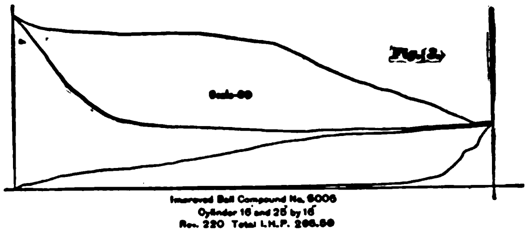
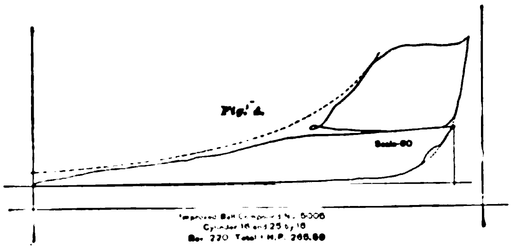




This engine being the first of its kind, and not having been tested at the works for lack of time, considerable interest was manifested in its start, and quite a number of people assembled to witness its first move.

THE AMERICAN ELECTRICAL WORKS, of Providence, and the Eugene F. Phillips Electrical Works, of Montreal, have just issued a very pretty calendar for 1892. It has an ornamental design of the world enveloped in lightning clouds, with a pole line reaching out into the distant background. At the bottom is a large-number pad.

THE SOUTHERN ELECTRIC COMPANY.

THE Southern Electric Company of Baltimore, Md., is nearly ready to place on the market a number of specialties which bid fair to make great changes in the method of wiring buildings for incandescent lighting and also in the apparatus for handling them. These devices have been carefully worked out by the electrician of the company, Mr. Painter, under the direction of Mr. J. F. Morrison, the president of the company, and when the details are made known as to how 10 chandeliers of 14 lights can be controlled from a little plate of less than one foot square (which is only a small part of what has been accomplished) the market may well consider itself treated to something entirely new.

The Southern Electric Company has been somewhat delayed in getting out these new specialties through being pushed with contract work. Besides these features the company is doing an enormous business in wire, of which it claims to have sold during the past few months more than any other one electrical supply house in the United States. This is a pretty big claim, but the Southern is ready to back it by showing its hand.

NEW ENGLAND NOTES.

TELEPHONES AND THE NEW RECIPROCITY TREATIES.—Owing to the favorable nature of the new trade reciprocity treaties, the outlook for the introduction of electrical goods in the West Indian Islands, and various countries of the Spanish Main is excellent. Mr. James H. Howard, general manager of the Tropical American Telephone Co. has, with his usual vigilance, prepared for the situation and now has agencies and supply depots established in Barbadoes, Jamaica, Cuba, Porto Rico, &c. He is also making arrangements, it is said, to represent the Hunning long distance transmitter, Bell & Blake sets and Gower-Bell sets, of the Consolidated Telephone Maintenance & Construction Co. of London, for the tropical field. Mr. Howard in a recent conversation said that "he had been allowed three more patents on telephone transmitters and magneto call bells, which will enable the company in March, 1893, to offer the public a complete set of private line telephone instruments, the transmitters of which will be entirely different from present forms and will be free from any interference with Blake, Berliner or Hunning." He says that the expired claims on Edison's, Blake's and other telephones open the field in a variety of ways, especially Edison's English patent 2909 of 1877 which expired July 30, 1891. Mr. Howard furnishes the following suggestive little list, from which he seems to derive considerable comfort: Bell's original patent of 1876 expires March 7, 1893; Blake's English patent 229 of 1879 expires Jan. 20, 1893; Hunning's 3647 of 1878 expires Sept. 16, 1892 and Crossley's, 412 of 1879, expires Feby. 1, 1893.

THE EDDY ELECTRIC MANUFACTURING COMPANY, of Windsor, Conn., have such a great demand for their automatic motors and other electrical apparatus, in the vicinity of Boston, that they have decided to open a branch office in that city. They have accordingly secured convenient quarters at 39 Oliver street, and have appointed Mr. Edwin R. Gilbert as manager, who will be pleased to furnish all information regarding dynamos and motors. Mr. Gilbert has had an excellent experience both in the factory and in the selling department, and celebrated his appointment to the Boston office by selling a motor within fifteen minutes after his arrival in the city. Doubtless Eddy motors will become more popular than ever in the East, and Mr. Gilbert gives every promise of being a keen competitor for business.

THE DOW ADJUSTABLE LIGHT COMPANY, of 309 Washington street, Boston, are kept busy supplying the demand for their new adjustable incandescent light balls. This is a device by which lamps hung on cord can be raised or lowered to any desired height by coiling up the cord inside of a hollow ball. The device works perfectly, and there are no complicated parts to get out of order. The ball is made of metal, and contains a spring cylinder upon which runs the cord, allowing the light to be raised or lowered to the desired position, being operated in the same way as a curtain fixture.

THE MATHER ELECTRIC COMPANY, of Manchester, Conn., have recently contracted with the Val. Blatz Brewing Company, of Milwaukee, Wis., to equip their new works with electrical power apparatus consisting of about 350 h. p. of generators and 400 h. p. of motors, the generators being 175 h. p. each, and the motors ranging in size from 10 to 50 h. p. This is probably the largest isolated electric power plant ever contracted for, and Mr. F. A. Baux, the Chicago manager of the Mather Company, has the honor of sharing the triumph with Mr. Julius Andrae of Milwaukee.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

THE
Electrical Engineer.

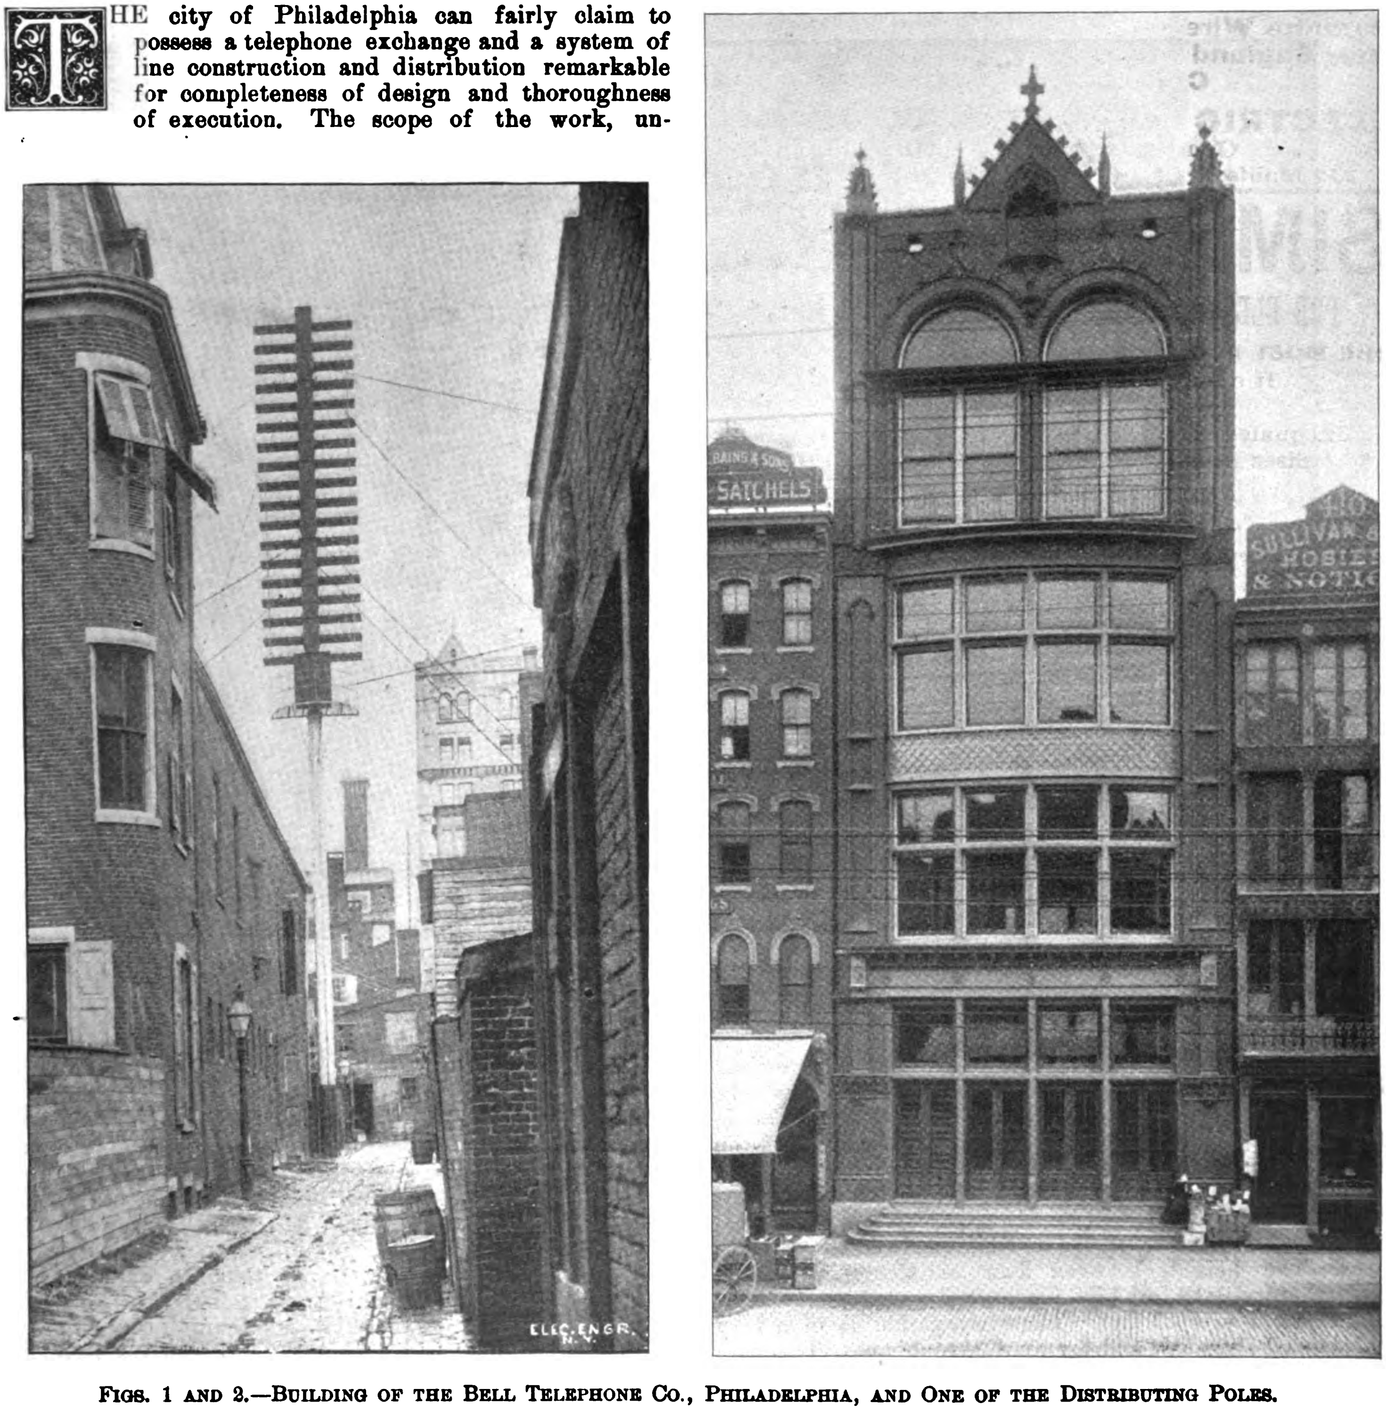
Vol. XIII. FEBRUARY 10, 1892. No. 197.

THE BELL TELEPHONE CO., OF PHILADELPHIA—ITS NEW PLANT.

BY

Geo. M. Phelps

THE city of Philadelphia can fairly claim to possess a telephone exchange and a system of line construction and distribution remarkable for completeness of design and thoroughness of execution. The scope of the work, undertaken, some four years ago by the telephone company, included not only a central station building—to be wholly occupied by the telephone service—an entire new outfit of station apparatus and a system of underground conductors; but included also an amplification of the whole plan sufficient to provide for the growth of twenty years to come. No less a sum than $750,000 has been expended in the new work. The directors and officers of the company went about their plans and work in a large-minded way, and upon specifications and estimates thoroughgoing, and ample enough to secure a plant that should not



Figs. 1 and 2.—Building of the Bell Telephone Co., Philadelphia, and One of the Distributing Poles.

only be permanent but should embrace such devices and methods as had proved their value in the past as well as newer features adapted to promote convenience, safety and efficiency in the operations of the service.

THE NEW BUILDING.

Some readers will recall the former exchange and offices in the Wood Building, at Fourth and Chestnut streets, with roof fixtures and the usual mass of overhead wires, like cobwebs across the sky. At 406 Market street, extending through to Merchant street in the rear, and but a short distance away, may now be seen the new building, with no external indication of the entrance of any wires. It is a handsome structure, of iron, brick and terra-cotta, and has been carefully planned for commodiousness and the admission of ample light. The view given herewith, Fig. 1, is of the Market street facade, which is precisely similar to that on Merchant street. The ground space is 117 feet by 35 feet and 6 inches. The total height of the building is upwards of 80 feet. Unusually high ceilings are therefore afforded for the four floors above ground. In our illustration it will be observed how far the telephone building towers above its four and five-story neighbors. The height, between floor and ceiling, of the ground story is 18 feet; of the second and third 16 feet, and of the fourth 23 feet. The construction is of a very substantial character and fireproof throughout. The cost of the lot and building, including boilers and steam-heating plant, ready for the introduction of cables and electrical apparatus was $175,000. The basement is occupied for the entrance of cables from the street conduits, by the steam plant and a workshop. On the first floor, about 3 feet above the ground level, are located the connecting board and protectors, offices for the superintendent, chief inspector, chief of construction, and chief of reconstruction, the supply department, and a public pay station, with long-distance service. The executive offices are assigned to the second floor, together with accommodations for the clerical and accounting departments. Here are found the rooms of the general manager, treasurer and cashier. Part of the third floor is given to the technical department—electricians and draughtsmen. The remaining portion will include the meeting-room of the Board of Directors of the Bell Telephone Company of Philadelphia, and the executive and clerical offices of the Delaware and Atlantic Telegraph and Telephone Company. The top floor is devoted wholly to the operating department.

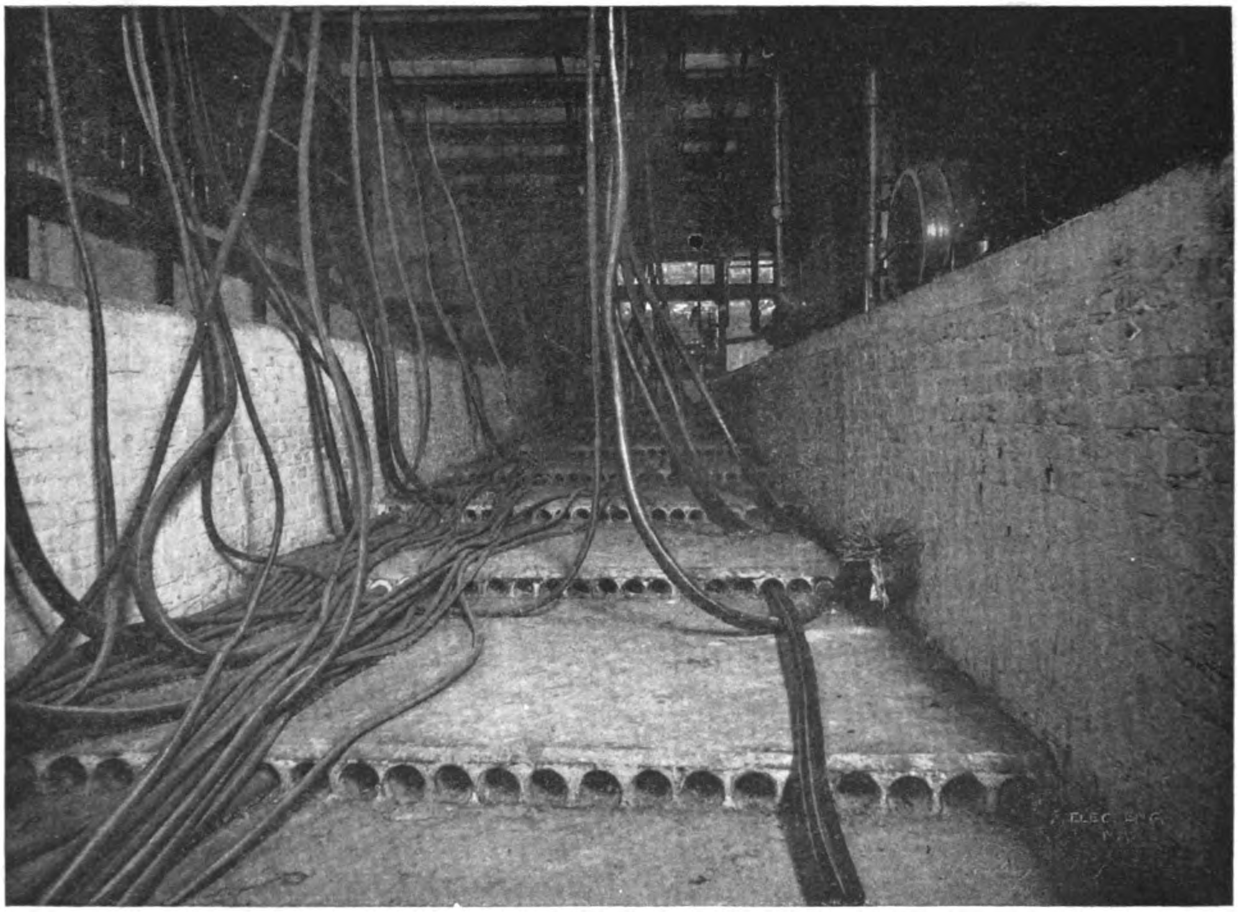


FIG. 3.—CABLE VAULT.

UNDERGROUND CABLES.

All of the 3,500 subscribers' lines now in use are in underground cables to a considerable distance from the Exchange, some of the cables extending two miles. The conduits and cables now cover practically all points within the city proper, that is, from Vine to South streets and from the Delaware to the Schuylkill rivers; beyond which district pole lines continue circuits to more distant subscribers. The cables are, uniformly, 2 inches in diameter and contain each 110 No. 18 (B. & S. gauge) copper wires twisted in pairs and laid up spirally. The wires have an insulating covering of dry paper. The covering pipe is of lead, with three per cent. of tin, and weighs 3.5 pounds per foot. These cables have all been made by the Electric Cable Construction and Maintenance Co., of Philadelphia.

Their adoption for the entire system has been the result of prolonged and satisfactory trial by the Telephone Company. Their low inductive capacity is noteworthy, namely: .07 to .08 microfarads per mile, as shown by many and oft-repeated tests. They are drawn into ducts 2½ inches in diameter. The ducts are first filled with a plastic composition impervious to water and gases. Through devices employed in drawing in the cable the plastic material is partially drawn out of the duct, the portion remaining thus forming a complete envelope for the cable and entirely filling the space between the lead pipe and the duct. Iron, indurated fibre and creosoted wood have each been used as material for the ducts; the latter, however, has been found most satisfactory and is chiefly employed in all the more recent work. The ducts are made of square timber—preferably of white pine—in lengths of eight feet, and are thoroughly "creosoted," 12 pounds of dead oil of coal-tar being absorbed to the cubic foot. Manholes are located at street intersections, usually about 500 feet apart—in some instances much closer—for convenience in drawing in cables, making splices, etc., and vary greatly in size, according to circumstances. The largest, on Market street, where the number of ducts ranges from 90 to 130, are 10 feet square and from 8 to 10 feet deep, affording space equal to a moderate-sized room. The smallest of these manholes are 3 by 4 feet and from 4 to 6 feet deep, located in small streets or alleys, near the bases of the distributing poles.

The street plan of Philadelphia—almost entirely rectangular and including a series of narrow streets, lanes or alleys, running midway between the principal streets east and west—affords special facility for the distributing system adopted. From a manhole adjacent to a distributing point, a smaller cable, having smaller conductors but of precisely the same type and construction as the main cable to which it is jointed, is led a short distance through a conduit to a distributing pole set at the curb and about midway of a street block in one of the intermediate alleys. By overhead wires from the pole, convenient access is had to the roofs or windows of all buildings in the block. One of these poles is shown in Fig. 2, page 129. They are about 90 feet high. The cable is run up the pole to the platform and terminal box, as shown in the illustration, protected for some twelve feet above the ground by an iron pipe. The particular pole shown provides for twelve wires from each cross-arm—216 in all, or for 108 metallic circuits.

As before stated the conduit system occupies the territory embraced in the old city proper, between the Delaware and Schuylkill rivers and Vine and South streets, in which portion of the city are located about five-sixths of all the subscribers to the Exchange. The plan of the system somewhat resembles in outline a tree, the trunk being on Market street, the principal limbs on each alternate street north and south, and the branches leading from there east and west, through small streets, to reach the poles located near the centres of the blocks.

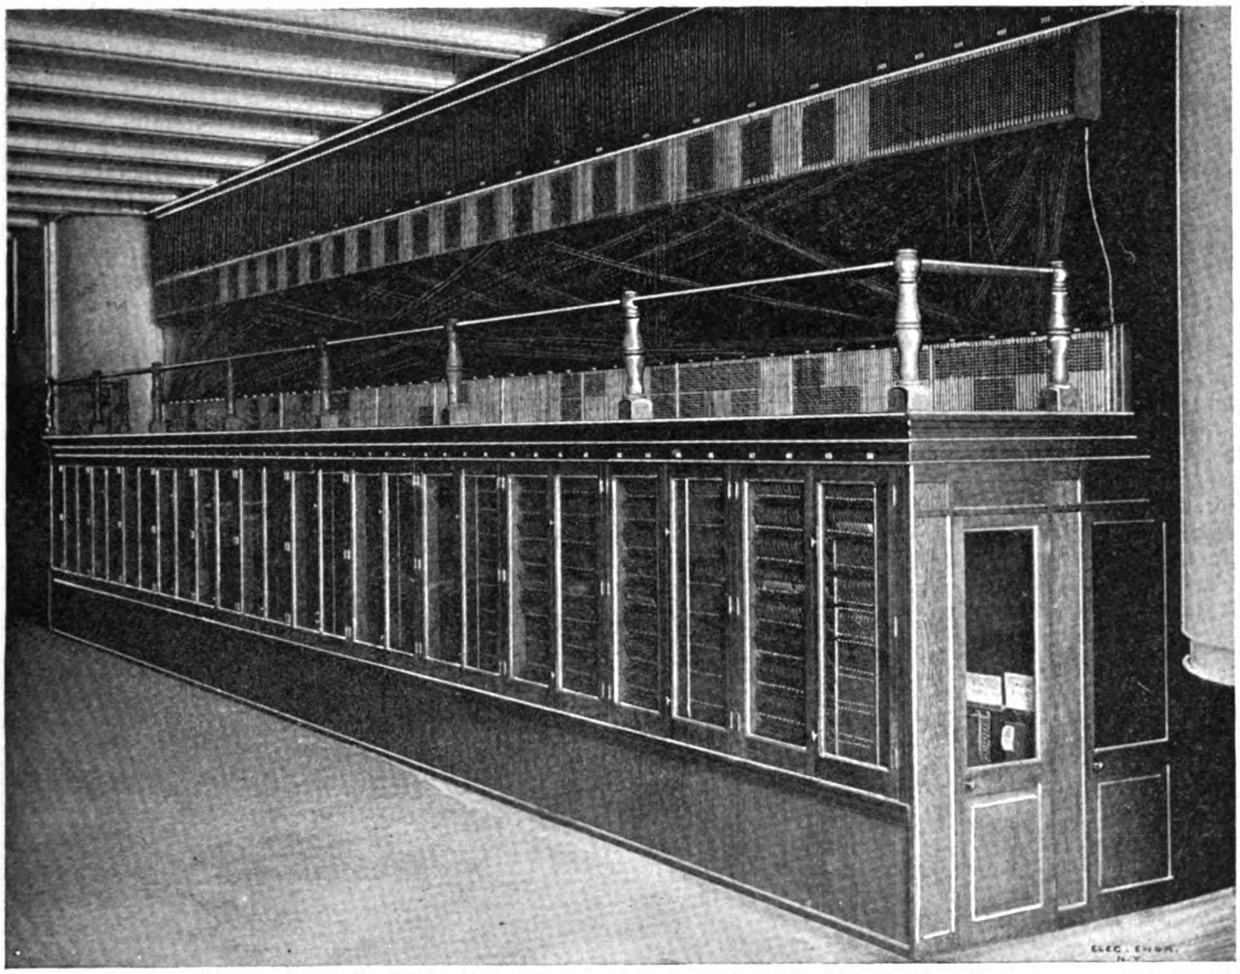

FIG. 4.—CONNECTING AND PROTECTOR BOARD.

The extent of the underground work accomplished up to January 13, 1892, is shown by the following table:

	Feet.	Miles.
Conduit laid	91,148	17.26
Duct laid	1,130,864	214.18
Cable drawn in	113,932	21.57
Single conductor	12,410,171	2,350.41
" " in use	7,034,020	1,332.18

There are 199 large manholes and 124 smaller ones. The line construction has cost $492,000, something more than half of which sum was for the cables alone.

The cables are all brought into the building through a vault under the sidewalk on Market street whence they are led through conduits into a trench-like pit running lengthwise of the basement and immediately under the position of the connecting board on the floor above. The illustration herewith Fig. 3, page 130, shows this arrangement so clearly that no further description is required.

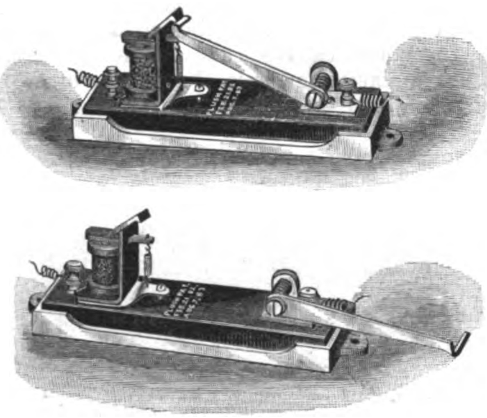

FIG. 5.—PLUSH ELECTRIC PROTECTOR, CLOSED AND OPEN.

INTERIOR OF THE EXCHANGE.

The principal apparatus on the first floor is the protector and connecting board, a view of which is given in Fig. 4, showing the long cabinet with glass doors, containing the protectors; and above it the arrangements for connecting, and for changing connections, between the protectors and the conductors leading to the switchboard on the top floor. A Plush electric protector is here interposed in the circuit of every line running into the Exchange. They are exposed to view and readily accessible to attendants. These very efficient protectors against heavy currents accidentally entering will be recognized as familiar acquaintances by many readers who have seen them in use. The latest form in which they are now made by the Electric Protection Co., of Philadelphia, is seen in Fig. 5, closed and open. When actuated by an electric light or other too powerful current they make an absolute break of three inches in the circuit. The protector cabinet (Fig. 4) is arranged to receive no less than 20,000 of these protectors; nearly 4,000 being already in position.

From the bars of the connecting board, near the ceiling of the first floor, connections are run to the fourth floor in lead-covered cables through iron pipes concealed from view between a wainscotting and the wall of the building. Between the ceiling of the third story and the floor of the fourth a space of several feet, sufficient to permit the entrance of workmen, is provided, through which the cables are carried across the building, terminating immediately beneath the switchboard. Fig. 6 exhibits the operating room, with the switchboard—or table—on the right, looking toward Market street, and the circuit board on the left; an enlarged view of the latter being shown in Fig. 7. with Manager U. H. Balsley at his post. The switchboard is of a new and improved type, combining features never successfully attempted before—whereby 10,000 subscribers with metallic circuits can be brought within easy reach of each operator.

The system is the same as that employed in the old exchange, adopted some 10 years ago, having two wires to each subscriber's station; one for calling on and calling off and the other for conversation. The apparatus, while improved in the main, embraces the general features of the system familiar to most of our readers as the "Law" system. That system was very successfully employed in the telephone exchange operated by the Law Telephone Co. in New York, until a few years ago, and is used now in many other exchanges, particularly in those of the Southern Bell Telephone Co., which adopted it twelve years ago. When the telephone company determined to undertake the extensive building and construction described in this article, a careful consideration led them to refit with the same system. Much weight was given to the advantage that a subscriber, having both his independent line and constant access to a calling circuit, cannot be wholly shut off from "Central" by failure of an operator to disconnect.

The switchboard in the Philadelphia Exchange is remarkable for its compactness. Its length is 85 feet, and in that space it will serve until the number of subscribers lines reaches 6,000; each of its thirty sections contains 6,000 sockets for subscribers' connections. The sockets are constructed for metallic circuits, double cords and plugs being provided for the subscribers' lines. A similar board or table of 20 sections, when added, will provide for an increase to ten thousand lines. The subscribers' lines are not yet actually worked on metallic circuits, but the switchboard is connected up and used precisely as if they were: that is to say, the return connections from the double cords of the switchboard are all bunched and connected to a common ground. Complete metallic circuits, through the twisted pairs of conductors in the underground cables, can be established at any time for any number of subscribers without changing or interfering with the switchboard. The compactness of the arrangement of the double contact sockets is a very striking feature; each of the half-sections of the cable containing 3,000 of them, arranged in blocks of 100 each—each block occupying a space on the table of but 3⅛ by 2⅝ inches. The brass strips in each socket are firmly imbedded in hard rubber, vulcanized after the insertion of the strips. The operation of vulcanizing the rubber sections with the metallic strips in position is regarded as a feat of some difficulty, and was said to be impracticable by rubber manufacturers.

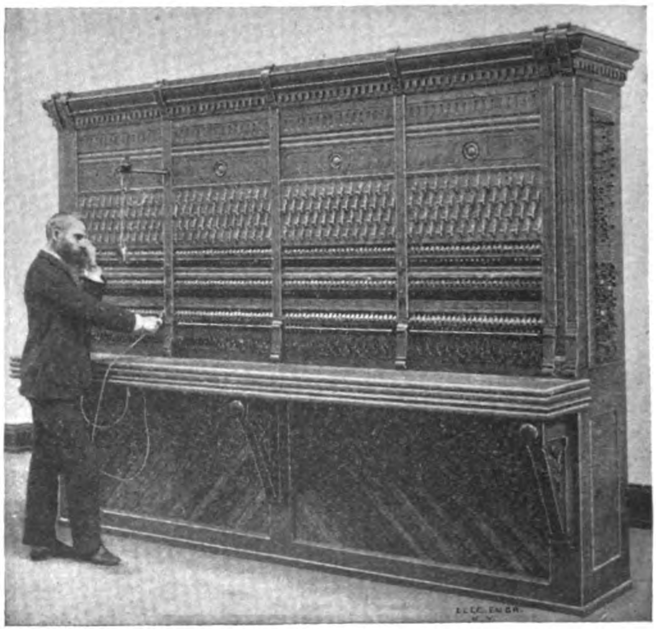

FIG. 7.—CIRCUIT BOARD.

The circuit board, Fig. 7, is fitted with testing keys, for trying the continuity and electrical condition of circuits, spring jacks, with cords and double plugs for looping calling circuits, and with strap and pin switches for connecting the several sections of the operating table to calling circuits as desired. On one end, at the right in the figure, is a strap and pin switch for battery or dynamo connections for the call-bells.

The manufacture and the setting up of the switchboard, protector board and other electrical apparatus have involved an expenditure of not less than $75,000.

The switchboard and other electrical apparatus were practically completed some months ago, when the operating department was transferred to the new building. The executive offices have now been removed from the old quarters at Fourth and Chestnut streets, the entire service and administration being established under one roof again.

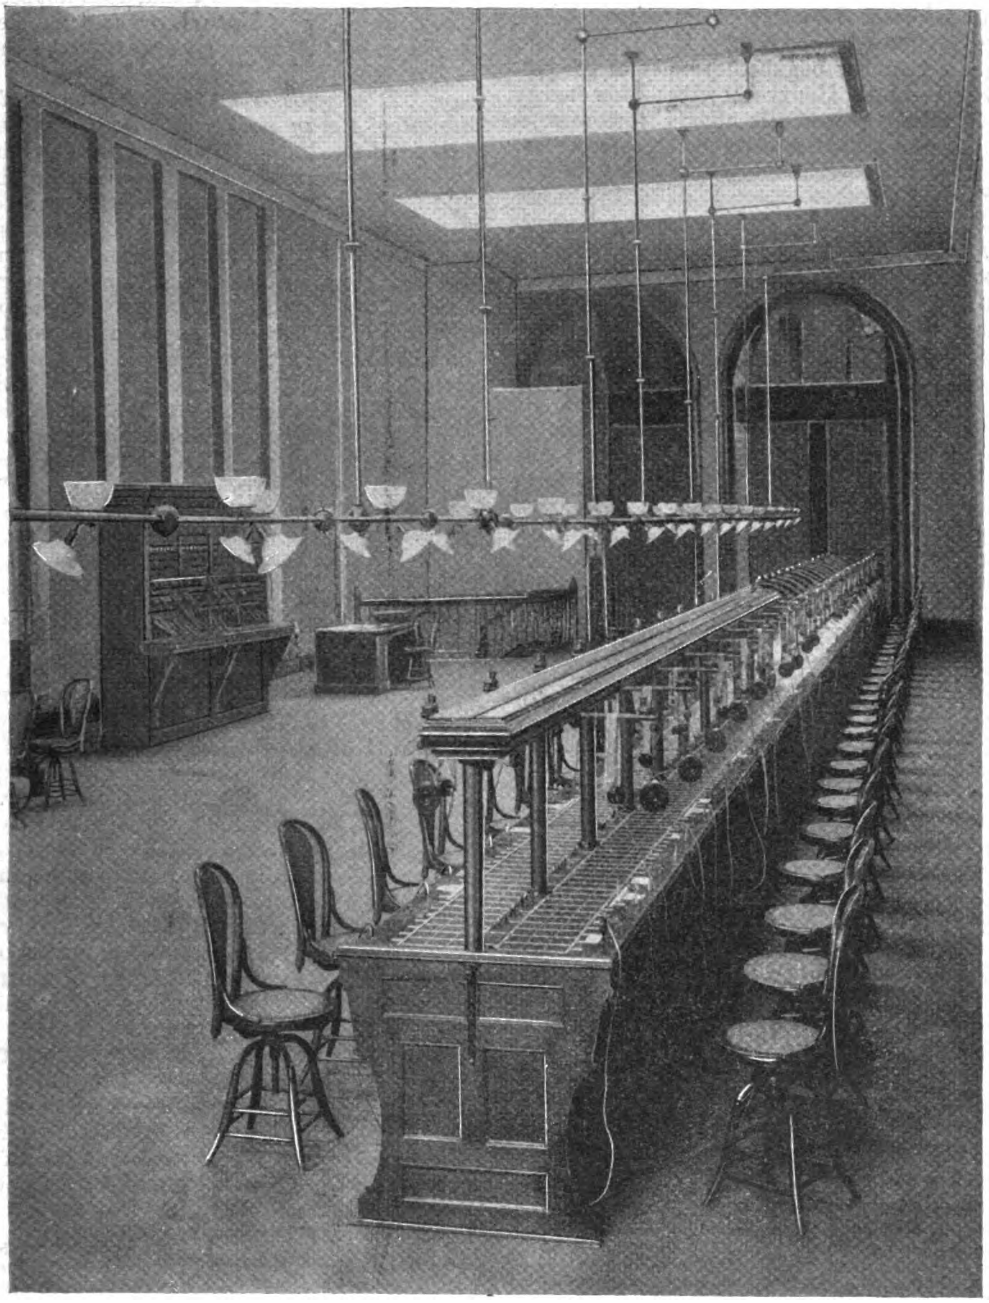

FIG. 6.—OPERATING ROOM.

The completion of this broadly planned work by the Bell Telephone Company of Philadelphia reflects great credit upon the directors and officers of the company.

If there still exist in Philadelphia any of that diminishing class of people who, perceiving that telephones are relatively simple and inexpensive instruments to manufacture, are under an impression that the construction, operation and management of a telephone exchange in a great city are also simple and inexpensive, they would discover much to modify or remove that impression through a visit to the new headquarters in Market street, and an inspection of the system now centering there.

LIGHTING THE WORLD'S FAIR.

PLANS adopted for lighting the buildings and grounds provide for 138,218 electric lamps, of which 6,766 are to be arc lamps of 2,000 c. p. each, and 131,452 incandescent, 16 c. p. each. The electric lighting will cost something like $1,500,000 and will be ten times as extensive as was employed at the Paris Exposition. The light and motive plant at the Exposition, it is estimated, will require 26,000 h. p., of which 22,000 will be required for the electric plant.

PROF. JAMES B. DE MOTTE, of the De Pauw University, Greencastle, Ind., lectured recently before the Montauk Club, Brooklyn, on "Electricity, the Wizard of the Nineteenth Century."

AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—IV.

BY

Mary A. Henry

IV.

And now let us go over the ocean to Faraday, and see how he asks the great question. Bence Jones tells us that as far back as 1824, Faraday began the study of the subject. "He believed"—as did Henry—"with all his energy, that as voltaic electricity powerfully affects a magnet, so the magnet ought to exert a reaction upon the electric current,"[1] and he makes an experiment which nearly makes the discovery.[2] He again makes experiments in November, 1825, December, 1825, and April, 1828, but without result. "*The momentary existence of the phenomena escaped him.*" "The good time was now come."[3]

In the beginning of the year 1831 comes over the sea Henry's paper in *Silliman's Journal.* It describes the magnets that have sprung up under Henry's hands, and the rules of their construction. Faraday, with quick philosophic instinct, sees in these powerful instruments for producing magnetism; means for a new trial of the old experiments, and again he goes to work. "He began his experiments on August 29, 1831."[4] Let us look at his apparatus. We see at a glance it is Henry's magnet, with its poles elongated, and the whole bent into the form of a ring. On the side B are wound the wires to convey the electric current for magnetizing the ring; there are "three lengths of wire, each about 20 feet long," insulated and wound as Henry taught Faraday to do in his paper in *Silliman's Journal.* These "three lengths" may be "connected as one," when the ring will be an "intensity" magnet, a long single wire; or, each of the three strands may be independently connected with the battery, when it will be a "quantity" magnet. Connected as one, the three strands are used by Faraday, and for the intensity magnet thus formed, if Henry's instructions are followed properly, there must be an "intensity" battery—a battery of many pairs of plates, and we find there is "*a battery of* 10 *pairs of plates, four inches square.*" On the A side of the ring is a wire, corresponding exactly to the wire surrounding the armature in Henry's experiment, and it is carried to a distance, and brought so near to a magnetic needle that upon the passage of the current it will oscillate, as did the needle in Henry's galvanometer. The essential apparatus; the means of the discovery used by the two men, like the discovery itself, is identical. Faraday saw his needle "oscillate," as Henry saw his "swerve" at the making and the breaking of the galvanic current. There is, however, a marked difference in the immediate mental attitude of the two men in regard to the observed phenomenon. Henry sees instantly that the question is answered. He says:

> "This experiment illustrates most strikingly the reciprocal action of electricity and magnetism, if it does not indeed prove their absolute identity. In the first place magnetism is developed in the soft iron of the galvanic magnet by the action of the currents of electricity from the battery, and secondly the armature, rendered magnetic by contact with the poles of the magnet induces in its turn currents of electricity in the helix which surrounds it. We have thus as it were *electricity converted into magnetism and this magnetism into electricity.*"

He immediately recognizes the condition essential to the production of electricity by magnetism—that is, *motion* or *change*. He tries other ways of producing the effect: "*slipping off the armature by degrees until the contact was entirely broken,*" dipping the battery plates but a little way into the acid at first, and afterwards immersing them by degrees, etc., all detailed in his paper, and then again he emphatically repeats his clear statement of the phenomenon:

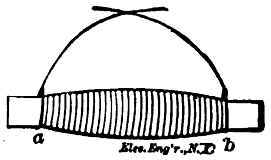
> "A current of electricity is produced for an instant in a helix of copper wire surrounding a piece of iron, whenever magnetism is produced in the iron. An instantaneous current, in one or the other direction, accompanies every change in the magnetic intensity of the iron."

Faraday, on the other hand, does not seem to have understood the reply of Nature, or at least he seems far from confident of it. He writes to a friend the 23d of September, "*I think that I have hold of a good thing; I cannot say. It may be a weed instead of a fish that after all my labor I may pull up.*" On the next day, September 24th, the third day of his experiments, he is again trying the effect of a helix of wire conveying the voltaic current of 10 pairs of plates, upon another wire connected with a galvanometer, and other like experiments, but "*no induction sensible.*" Had Faraday at this time discovered the essential nature of the phenomenon, experiments like these could not have failed, in his hands, to give conclusive results. "He gave up experiments for that day with the electromagnet and tried instead the effect of bar (permanent) magnets." An iron cylinder had a helix wound around it. The ends of the helix were placed between the poles of the magnet, arranged as in the accompanying figure. Every time the magnetic contact was made or broken there was motion in the galvanometer." Now, but not until now, he reaches a positive conclusion: "Hence here distinct *conversion of magnetism into electricity.*"

This constitutes his first distinct annunciation of the phenomenon, so that his discovery can scarcely, in justice, be said to have been made until this day, September, 24, 1831.

Not until the ninth day of experiment, October 17, does he produce the deflection of the needle by thrusting a bar magnet into a helix of wire; the experiment which came over to Henry in that brief paragraph of April, 1832, and which incited him to repeat his own experiments in the last two weeks of June of the same year. With no other knowledge of Faraday's work than this particular mode of producing the effect, it is curious to see Henry in these June days bending the armature of his magnet into a ring (see page 104 of this article), while on the other hand, Faraday, equally unconscious of Henry's efforts, in his paper of November, 1831, makes the important observation that "a soft iron bar, in the form of a lifter to a horseshoe magnet, when supplied with a coil of this wire, becomes, by juxtaposition with a magnet, a ready source of a brief but determinate current of electricity," thus adopting the precise method which had been employed by Henry.

Faraday, as Henry, desired that the electricity he could produce through magnetism might be manifested by a spark. An entry in his note-book of February 8, says:



Faraday's Apparatus for Producing a Spark from an Electromagnet.

> "This evening at Woolwich, experimented with magnet, and for the first time got the magnetic spark myself. Connected ends of a helix into two general ends, and then crossed the wires in such a way that a blow at *a b* would open them a little. Then bringing *a b* against the poles of a magnet, the ends were disjoined and bright sparks resulted."

It may be well to give in full Bence Jones's account of Faraday's work up to the 24th of September, so that the reader may be enabled to judge for himself whether we have interpreted it correctly. We break its thread, here and there, for comment, as we have already done with Henry's paper.

> "On August 29th, 1831, Faraday began his Electrical Researches."

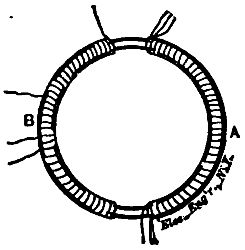
---

1. *Life of Faraday*, ii., 1.
2. Quarterly Jour. Science, July, 1825, p. 338.
3. *Life of Faraday*, ii., 2.
4. *Ibid*, ii., 2.

> "In December, 1824, he believed with all his energy that as voltaic electricity powerfully affects a magnet, so the magnet ought to exert a reaction upon the electric current. Guided by this idea he made an experiment, of which one part (the passage of a magnet through a metallic helix connected with a galvanometer), if separated from the rest of the experiment, would then have made the great discovery of magneto-electricity. This experiment he published in the *Quarterly Journal of Science*, July, 1825, p. 338."

The phenomenon, it will be noticed, was here actually produced under Faraday's hands, although unperceived by him. To use our former simile, he had failed to catch the moment when the gnome was at work.

> "In November, 1825, also, he had failed to discover voltaic induction. He passed a current through a wire, which was lying close to another wire, which communicated with a galvanometer, and found 'no result.' *The momentary existence of the phenomena of induction then escaped him.*
>
> "Again, Dec. 2, 1825, and April 22, 1828, he made experiments which gave 'no result.' These experiments were not published.
>
> "The good time was now come. The first paragraph in the laboratory note-book is 'Experiments on the production of electricity from magnetism.' His first experiment detailed in the second paragraph records the discovery by which he will be forever known.



Faraday's Inductive Ring.

> "'I have had an iron ring made (soft iron), iron round and ⅞ of an inch thick, and ring six inches in external diameter. Wound many coils of copper round, one half of the coils being separated by twine and calico: there were three lengths of wire, each about twenty-four feet long, and they could be connected as one length, or used as separate lengths. By trials with a trough each was insulated from the other. Will call this side of the ring *A*. On the other side, but separated by an interval, was wound wire in two pieces, together amounting to about sixty feet in length, the direction being as with the former coils. This side call *B*.'"

We here find Faraday working with an electromagnet made exactly in accordance with Henry's plan as given in his paper in *Silliman's Journal* of January of the same year. It is immaterial that Faraday's iron core is in the form of an endless ring instead of a horseshoe. That Faraday had carefully studied Henry's paper is shown not only by this use of Henry's system of construction, but in the publication of his results in the *Experimental Researches*, Nov. 31, 1831, he says:

> "'There is no doubt that the arrangements like the magnets of Moll, Henry and Ten-Eyck and others, in which as many as *two thousand pounds* have been lifted, may be used for these experiments.'"

Henry had introduced Moll's results, very much inferior to his own, with his paper in *Silliman's Journal;* and Ten-Eyck had been mentioned in Henry's paper as his assistant who had been engaged in constructing magnets under his personal direction. There were no others at work upon the subject. It was Henry's little giants Faraday saw in Henry's paper lifting the enormous weight of 2,000 lbs., and the notice, although couched in undiscriminating language, nevertheless makes it certain that the paper had come under Faraday's notice, and that he had learned the lesson it had to teach. Before the paper of Henry had reached his hands, the only electromagnet available for Faraday's use was Sturgeon's horseshoe bar, with its single loosely wound uninsulated helix of wire.

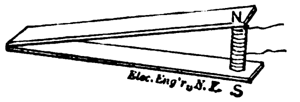
> "'Charged a battery of ten pairs of plates four inches square. Made the coil on *B* side one coil, and connected its extremities by a copper wire passing to a distance, and just over a magnetic needle (three feet from wire ring), then connected the ends of one of the pieces on *A* side with the battery: immediately a sensible effect on needle. It oscillated and settled at last in original position. On breaking connection *A* side with battery, again a disturbance of needle.'"
>
> "In the 17th paragraph, written on the 30th, he says: 'May not these transient effects be connected by causes of difference between power of the metals at rest and in motion in Arago's experiments?'"

The requisition of change or motion obviously occurs here, in a certain sense, to Faraday's mind, but only as a question. As the children say, Faraday is at this point "very warm" in this curious game of hide-and-seek, but the gnome is not yet caught, as we plainly see from the experiment next described. Faraday is even not absolutely sure that his ring produced the phenomenon, as the next paragraph unmistakably indicates:

> 'After this he prepared apparatus. Writing to his friend R. Phillips, September 23, he says: 'I am busy just now again on electromagnetism, and I think that I have hold of a good thing, but I can't say. It may be a weed instead of a fish that, after all my labor, I may at last pull up.'
>
> "September 24 was the third day of his experiments. He began paragraph 21 by trying to find the effect of one helix of wire, carrying the voltaic current of ten pairs of plates, upon another wire connected with a galvanometer. 'No induction sensible.'"

Faraday is here repeating the ring experiment; this time, to him, without apparent result.

"Longer and different metallic helices show also no effect." These experiments are essentially the same. In them, although unperceived by Faraday, magnetism must necessarily have produced electricity. With a conception of the necessary condition of change or motion (which, considering the failure of these experiments, could apparently have been but a passing thought) he has laid, as it were, his very fingers upon the result, yet it continues to elude him. Not sure of the glimpse he has had of it with his ring—that experiment repeated is apparently denying its former assertion while those other experiments fail. He is here evidently still baffled by the transitory nature of the effect and so is still failing to catch the moment when it is produced. Not yet can the discovery be said to have been made; since the very existence of the phenomenon was to this date still unproven. He gives up experiments for that day, and tries the effects of a bar magnet instead of the ring magnet that he had used on the first day. In paragraph 33 he says:



Faraday's Conversion of Magnetism into Electricity.

> "'An iron cylinder had a helix wound on it. The ends of the wires of the helix were connected with the indicating helix at a distance by copper wire. Then the iron placed between the poles of bar magnets as in accompanying figure. Every time the magnet contact at *N* or *S* was made or broken, there was magnetic motion at the indicating helix—the effect being, as in former cases, not permanent, but a mere momentary push or pull. But if the electric communication (*i. e.*, by the copper wire,) was broken, then the disjunction and contacts produced no effect whatever. *Hence here distinct conversion of magnetism into electricity.*'"

In this sentence we find the first positive recognition of the phenomenon; of its necessary condition of change or motion. Faraday has at last caught the moment when the gnome is at work; the discovery is made—but not in justice can it be said until this day, September 24, 1831.

Two or three other experiments follow, with helices of wire around a core of wood instead of iron, and, as we may conjecture, are successful, since the essential condition of the phenomenon is no longer a mystery. Then follows the experiment usually given in the text-books, as the one by which Faraday made the discovery.

> "'The fifth day of experiment was October 17. Paragraph 57 describes the discovery of the production of electricity by the approximation of a magnet to a wire.
>
> "'A cylindrical bar magnet, three-quarters of an inch in diameter and eight inches and a half in length, had one end just inserted into the end of the helix cylinder (220 feet long); then it was quickly thrust in the whole length, and the *galvanometer* needle moved; then pulled out, and again the *needle moved*, but in the opposite direction. This effect was repeated every time the magnet was put in and out, and therefore a wave of electricity was so produced from *mere approximation of a magnet;* and not from its formation *in situ.*'
>
> "The ninth day of his experiments was October 28, and this time he 'made a copper disc turn around between the poles of the great horseshoe magnet of the Royal Society. The axis and the edge of the disc were connected with a galvanometer. The needle moved as the disc turned.' The next day, November 4, he found

'that a copper wire, one-eighth of an inch, drawn between the poles and the conductors produced the effect.' * * *

"In ten days of experiment these splendid results were obtained. He collected the facts into the first series of *Experimental Researches in Electricity.* It was read Nov. 24th, at the Royal Society. Then he went to Brighton."

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—IV.

BY

Francis B. Crocker and S. S. Wheeler.

CHAP. III.—*Continued.*

Series Dynamo on Constant-Current Circuit.—The connections in this case (Fig. 8) are extremely simple, the armature, field-coils, amperemeter, main circuit and lamps, all being connected in one series.

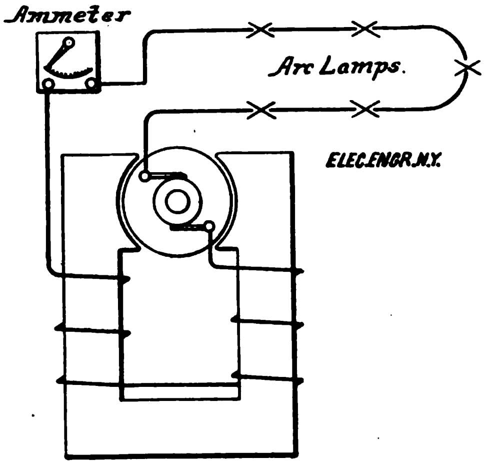


FIG. 8.—SERIES DYNAMO ON CONSTANT CURRENT CIRCUIT WITH LAMPS IN SERIES.

Alternating-Current Plant.—The proper connections in this case are shown in Fig. 9, in which the names of the different parts of the plant are given and which therefore requires no explanation.

The diagrams of connections of all cases of *dynamos coupled together* and of *electric motors* are given in the chapter on Starting where they are required to explain the proper steps.

CHAPTER IV.

DIRECTIONS FOR STARTING DYNAMOS AND MOTORS.

General.—Make sure that the machine is clean throughout, especially the commutator, brushes, electrical connections, etc. Remove any metal dust, as it is very likely to make a ground or short circuit.

Examine the entire machine carefully and see that there are no screws or other parts that are loose or out of place. See that the oil cups have a sufficient supply of oil, and that the passages for the oil are clean and the feed is at the proper rate. In the case of self-oiling bearings see that the rings or other means for carrying the oil work freely. See that the belt is in place and has the proper tension. If it is the first time the machine is started it should be turned a few times by hand, or very slowly, in order to see if the shaft revolves easily and belt runs in centres of pulleys.

The brushes should now be carefully examined and adjusted to make good contact with the commutator and at the proper point, the switches connecting the machine to the circuit being left open. The machine should then be started with care and brought up to full speed gradually if possible, and in any case the person who starts either a dynamo or motor should closely watch the machine and everything connected with it and be ready to instantly shut down and stop it (and throw it out of circuit if it is connected) if the least thing seems to be wrong, and should then be sure to find out and correct the trouble before starting again. (See "Locating and Remedying Troubles.")

Starting a Dynamo.—In the case of a dynamo it is usually brought up to speed either by starting up a steam engine or by connecting the dynamo to a source of power already in motion. The former should of course only be attempted by a person competent to manage steam engines and familiar with the particular type in question. This requires special knowledge acquired by experience, as there are many points to appreciate and attend to, the neglect of any of which might cause serious trouble. For example, the presence of water in the cylinder might knock out the cylinder head; the failure to properly set the feed of the oil cups might cause the piston rod, shaft or other part to cut, or other great or small damage might be done by ignorance or carelessness. The mere mechanical connecting of a dynamo to a source of power is usually not very difficult; nevertheless, it should be done carefully and intelligently, even if it only requires throwing in a friction clutch or shifting a belt from a loose pulley. To put a belt on a pulley in motion is difficult and dangerous, particularly if the belt is large or the speed is high, and should not be tried except by a person who knows just how to do it. Even if a stick is used for this purpose it is apt to be caught and thrown around by the machinery unless it is used in exactly the right way.

It has been customary to bring dynamos to full speed before the brushes are lowered into contact with the commutator, but there is no particular reason for this practice, provided the dynamo is not allowed to turn backwards, which sometimes occurs from carelessness in starting, and might injure copper brushes by causing them to catch in the commutator. If the brushes are put in contact before starting they can be more easily and perfectly adjusted, and the E. M. F. comes up slowly so that any fault or difficulty will develop gradually and can be corrected, or the machine stopped, before any injury is done to it or to the system. In fact, if the machine is working alone on a system and is absolutely free from any danger of short-circuiting any other machine or storage battery on the same circuit, it may be started up connected to the circuit, in which case the E. M. F. and current feel their way, so to speak, through the whole system, and any trouble manifests itself so slowly that it can be taken care of before serious injury results.

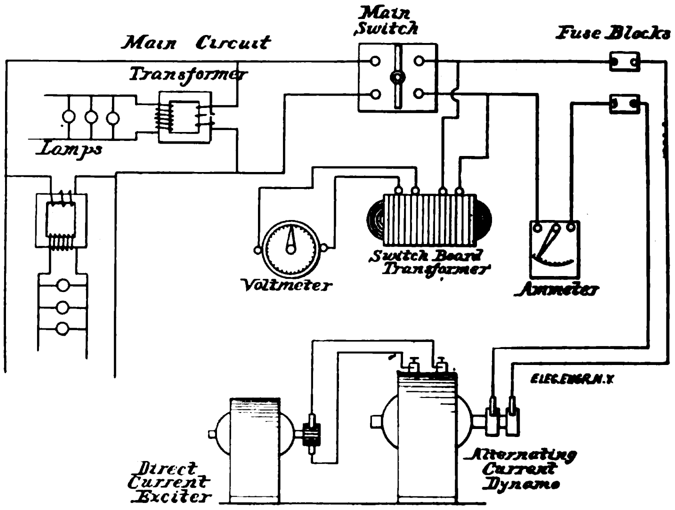

FIG. 9.—ALTERNATING CURRENT PLANT.

If, however, a dynamo is to be connected to another or to a circuit having other dynamos or a storage battery working upon it, the greatest care should be taken. In fact, this coupling together of dynamos can be done perfectly if exactly the correct method is followed, but is likely to cause serious trouble if any mistake is made.

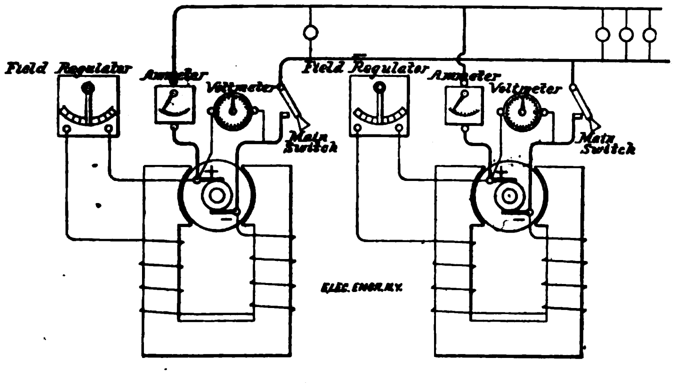

FIG. 10.—SHUNT DYNAMOS IN PARALLEL.

Coupling Dynamos.—Two or more machines are often connected to a common circuit. This is especially the case in electric lighting where the number of lamps required to be fed varies so much that one dynamo may be sufficient for certain hours, but two, three or more machines may be required at other times.

Dynamos may be connected together either in parallel (multiple arc) or in series.

Dynamos in Parallel.—In this case the + terminals are connected together or to the same line and the — terminals are connected together or to the other line. The currents (*i. e.*, amperes) of the machines are thereby added but the E. M. F. (volts) are not increased. The chief condition for the running of dynamos in parallel is that their voltages should be equal but their current capacities may be different. For example: A dynamo producing 10 amperes may be connected to another generating 100 amperes, provided the voltages agree. Parallel working is therefore suited to constant potential circuits. A dynamo to be connected in parallel with others or with a storage battery must first be brought up to its proper E. M F., speed and other working conditions, otherwise it will short circuit the system, and probably burn out its armature. Its field magnetism must also be at full strength owing to the fact that it generates no E. M. F. with no field magnetism. Hence it is well to find whether the pole pieces are strongly magnetized by testing them with a piece of iron, and make sure of the proper working of the machine in all other respects before connecting the armature to the circuit. It is quite common for the field circuit to be open at some point and thus cause very serious results. In fact, a dynamo should not be connected to a circuit in parallel with others until its voltage has been tested and found to be equal to or slightly (not over 1 or 2 per cent.) greater than that of the circuit. This test may be made by first measuring the E. M. F. of the circuit and then of the machine by one voltmeter; or voltmeters connected to each may be compared. Another method is to connect the dynamo to the circuit through a high resistance and a galvanometer, and when the latter indicates no current it shows that the voltage of the dynamo is equal to that of the circuit. A rougher and simpler way to do this is to raise the voltage of the dynamo until its "pilot lamp," or other lamp fed by it, is fully as bright as the lamps on the circuit, and then connect the dynamo to the circuit. Of course the lamps compared should be intended for the same voltage and in normal condition. Be sure to connect the + terminal of the dynamo to the + wire and the — terminal to the — wire, otherwise there will be a very bad short circuit.

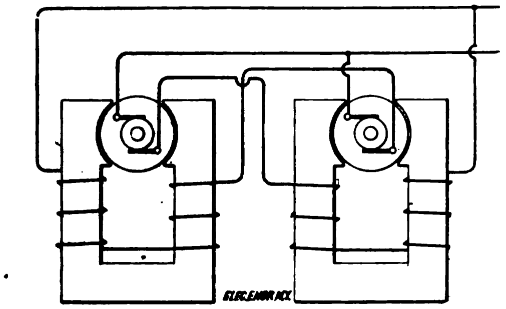

FIG. 11.—SERIES DYNAMOS IN PARALLEL.—MUTUAL ACTION.

When the dynamo is first connected in this way it should only supply a small amount of current to the circuit (as indicated by its ammeter) and its voltage should then be gradually raised until it generates its proper share of the total current.

If the voltage of the dynamo is less than that of the circuit, the current will flow back into the dynamo and cause it to be run as a motor. If it is shunt wound the direction of rotation is the same, however, and no great harm results with a slight difference in voltage. Shunt machines are therefore particularly suited to being run in parallel, Fig. 10.

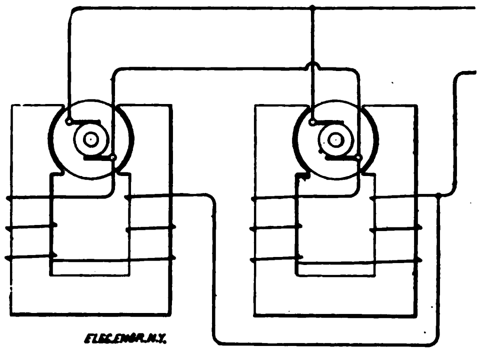

FIG. 12.—SERIES DYNAMOS IN PARALLEL.—EQUALIZING WIRE.

Series Wound Dynamos in Parallel.—If the machine is series wound, this back current would cause a reversal of field magnetism and motion which is very objectionable. In fact, series dynamos in parallel are in very unstable equilibrium, because if either tends to generate too little current that very fact weakens its own field which is in series, and thus still further reduces its current and probably reverses it. One way to run series dynamos in parallel is to cause each to excite the other's field magnet, as shown in Fig. 11, whereby if one generates too much current it strengthens the field of the other and counteracts itself, so to speak.

The other way, Fig. 12, to run series dynamos in parallel, is to connect together the two + brushes by what is called an "equalizer," as well as the two — brushes. By this means the electrical pressure at the terminals of the two armatures is made the same, and the currents in the two fields are also made equal. Series machines are not often run in parallel, but the principles just explained help the understanding of the next case, which is important.

ELECTRIC HEATING IN SWITZERLAND.

THE Maloja Kursaal on the Engadine is to be heated electrically during the winter by power derived from the Mera river in Aseima. There is no doubt that considerable use will be made of electric heaters in those cases where natural power is abundant, and it is probable that this department of electrical engineering will become exceedingly important in such cases.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, FEBRUARY 10, 1892. No. 197.

The philosopher who discovered the scientific principles upon which the electromagnet is founded, and who invented the form of apparatus best adapted to demonstrate these principles, must be regarded by the whole world as having made the chief contribution towards the application of electromagnetism to the various wants of man.—Scientific American.

THE EDISON AND THOMSON-HOUSTON CONSOLIDATION.

FOR several years past rumors have been current from time to time of impending consolidations or coalitions of leading electrical companies. Several such reports have been verified by the absorption or control of several companies by others of more commanding position; but the most striking and significant event of the kind, so far, is the proposed consolidation of the Thomson-Houston Electric Company and the Edison General Electric Company. A stockholders' agreement for such a consolidation was drawn up a few days since, by prominent officials of the two companies and was printed in full in some of the daily papers of Saturday, February 6. The agreement, to be effectual, requires the assent of a majority of the stockholders of both companies on or before May 1, 1892. The terms of the agreement involve the surrender of stock in the present companies to be replaced by stock in the proposed new company on the following basis (quoted from the agreement as published):

(*a*) Shares of the stock of the Edison Company shall be exchanged in full payment for shares of common stock in the new corporation, share for share.

(*b*) Shares of preferred stock of the Thomson-Houston Company shall be exchanged in full payment for shares of preferred stock of the new corporation, at the rate of four shares of the old stock (par $25 each) for one share of the new (par $100 each).

(*c*) Shares of common stock of the Thomson-Houston Company shall be exchanged in full payment of common stock of the new corporation at the rate of five shares of the old stock for three of the new.

The new corporation is to have a capital stock of $50,000,000, in 500,000 shares of $100 each, of which not more than 20 per cent., may be preferred stock, entitled to receive dividends of 7 per cent. per annum, cumulative, but without preference as to principal. The corporation is to have the right to acquire stock, property and rights of other corporations or individuals. It is provided in the agreement that after the issue of stock to holders of shares in the present companies "further issues of stock shall be made only for the general purposes of the company." A committee is appointed to carry out the project, consisting of the following gentlemen:—J. Pierpont Morgan, D. O. Mills, H. McK Twombly, Fred. L. Ames, T. Jefferson Coolidge and H. L. Higginson. The agreement also contains the following:—

> Instead of a new corporation, any existing corporation may, in the discretion of the Committee, be selected and reorganized so as to provide for the substantial accomplishment of the purposes of this agreement.

The figures of the last annual reports of the Edison and Thomson-Houston companies give the capital stocks issued, respectively, as follows:

THOMSON-HOUSTON.		
Common stock	$6,000,000.00	
Preferred stock	4,000,000.00	
		$10,000,000.00
EDISON.		
Stock (1,000,000.00 in treasury)		15,000,000.00
		$25,000.000.00

The issue of stock in the proposed new company, according to the published agreement, would result as follows:—

To Edison shareholders—and the treasury.		
Common, share for share		$15,000,000.00
To Thomson-Houston shareholders—		
Preferred, four (@ $25) for one (@ $100)		4,000,000.00
Common, five (@ $25) for three (@ $100)		14,400,000 00
Total capitalization for the existing companies merged		$33,400,000.00
Making preferred	$ 4,000,000 00	
Common	29,400,000.00	
and leaving in the treasury:—		
Preferred stock	$ 6,000,000.00	
Common stock	10,600,000.00	
		$16,600,000.00

The agreement if carried into effect by the assent of a majority of shareholders of both companies will thus result in an increase in capitalization of $8,400,000.00 over that of the two companies as they stand, and will leave the way open to a further increase of $16,600,000.00.

The primary object of such consolidations is, of course, to increase the profits of shareholders through the reduction of the expense of administration and management, as well as the abatement of onerous competition in selling. The former of these means of increased revenue can doubtless be accomplished by the proposed amalgamation of the Thomson-Houston and the Edison Companies—but there is much room for doubt in respect to the latter. To say nothing of several less conspicuous companies actively competing for business, the Westinghouse Company would seem to be in a good position to contest the ground with the proposed new combination. If, as is confidently asserted, the Westinghouse Company has satisfactorily completed its reorganization and can, with adequate capital, keep the field against the Edison and Thomson-Houston Companies, combined, the element of strenuous competition in prices will be likely to continue to be an important factor in the situation for an indefinite period.

The proposed capitalization of the new company will doubtless be deemed excessive by conservative financiers. The combined earnings of the two companies, as per their last reports, would seem to justify the proposed capitalization; but investors appear to have a deeply rooted desire for dividends rather than for the accumulation of a surplus expended in the building up of a great corporation. It is understood that during the past year, the Edison General Co. earned net \$1,650,000 (it paid out about \$1,200,000 in dividends), while report has even placed the Thomson-Houston net earnings at about \$2,500,000, though it does not appear that anything like such a sum has yet been available for dividends.

We do not regard the projected combination as likely to be injurious to the many smaller companies and individuals engaged in electrical manufacturing or dealing. Competition in prices can hardly be more severe than at present, and should the new company, as seems not unlikely, seek to maintain and strengthen prices, rather than to reduce them further, that policy could not fail to result in benefit to well-established concerns which have meritorious products to offer to the public.

THE PHILADELPHIA TELEPHONE EXCHANGE.

One after another, in close succession, the telephone exchanges in the large cities are being reconstructed to meet the requirements of larger and better service, and upon plans embracing both improved and new devices evolved from the experience of the past fifteen years. The introduction of the telephone to public service, like that of electric lighting, was so rapid and extensive that the accessories of an exchange, both as to housing and apparatus, were, perforce, extemporized for the most part as they best might be. Nowhere can the contrast between an early crude "central," with its maze of overhead wires, as well as its ponderous signaling and connecting machinery and a well-equipped exchange of the present day be better exemplified to an observer than in the new building apparatus and underground lines of the Bell Telephone Co. of Philadelphia, which we have the pleasure to describe in other columns of this issue. The complete system, planned by Dr. Samuel M. Plush, general manager of the company, and carried out under his supervision, includes interesting features of novelty in devices and arrangement. Especially noteworthy is the extreme condensation effected in the operating apparatus. Another impressive fact is the magnitude of investment in entire reconstruction. There are many features that have to be taken into account in a modern exchange of which little was thought in the earlier days. The underground system alone is a new element of enormous costliness, especially when taken in conjunction with the use of metallic circuits. Altogether we can but congratulate our telephonic friends in Philadelphia on the largeness and liberality with which they have laid their plans and carried them out.

MR. TESLA BEFORE THE LONDON INSTITUTION OF ELECTRICAL ENGINEERS—AND THE ROYAL INSTITUTION.

(*Special Cablegram to* The Electrical Engineer.)

On the evening of February 3, Mr. Nikola Tesla, by special invitation, delivered a lecture on the results of his latest investigations before the London Institution of Electrical Engineers.

After a short introductory as to the theory which led him up to his new line of work, involving the application of enormously high potentials and frequencies far exceeding those heretofore employed, Mr. Tesla began his experimental demonstrations with the exhibition of various forms of discharges. He showed first an induction coil operated by condenser discharge. With this coil he produced various remarkable discharge phenomena. Among others he imitated the spark of a Holtz machine and showed a brush discharge covering an area of something like 4 or 5 square feet, and also a luminous wire outlining the name of William Thomson. Mr. Tesla then took up some very novel and exceedingly interesting phenomena discovered by him some time ago consisting of a brush rotating in an exhausted globe. He showed that the brush was affected electrostatically, magnetically (even by the earth's magnetism), and that the study of these phenomena might lead to important discoveries as to the nature of electrostatic or electromagnetic fields.

Mr. Tesla showed how Crookes' well-known radiometer is set in motion *at ordinary atmospheric* pressures with alternating high potentials, thus affording another link in the chain of evidence which is gradually establishing the truth of modern views.

The subject of obtaining motive power was next taken up by Mr. Tesla, who exhibited a motor running on one wire and also without any connection with the generator, and the lecturer also dwelt on the possibility of running motors without wires.

Mr. Tesla next spoke of the construction of light-giving bulbs and the manner in which the dissipation of the energy supplied is prevented in the bulb by screening and allowing it to be dissipated only from the point at which it is wanted. In this connection he brought before his audience the results obtained with "carborundum," the new diamond-like substance recently produced by Mr. E. G. Acheson, of Monongahela, Pa.

Mr. Tesla then proceeded to show an interesting experiment which consisted in bringing a button to incandescence in a tube, holding the latter in the hand, and with another tube he repeated the experiment of Prof. Crookes by bringing a small platinum wire in the tube to incandescence and rotating a small fan.

Mr. Tesla also dwelt on phosphorescence and concluded his address with a demonstration of the luminous effects produced upon tubes in an electrostatic field.

On the following evening Mr. Tesla repeated his lecture before the Royal Institution by invitation.

Some idea of the interest aroused by Mr. Tesla's lecture may be formed from the fact that the London *Times* went to the unusual length of devoting a column editorial to it and publishing a very full report of it, with a description of his more striking demonstrations.

TESTS OF GLASS AND PORCELAIN INSULATORS.

BY

F. W. Jones

I CHEERFULLY comply with the wish expressed by Mr. Henry Stott, in THE ELECTRICAL ENGINEER of February 3, and the accompanying tables give some measurements I have made on insulators.

On March 1, 1891, I placed two new ten-pin cross-arms side by side on a fixture about 8 feet above the roof of Nos. 5 and 7 Dey street, New York, exposed to the weather on all sides, besides chimney smoke and condensed steam from exhaust pipes. On one arm I placed 8 English-made porcelain insulators and two brownstone earthenware, of a pattern very similar to our American double petticoat screw glass. On the other arm I placed 10 new glass insulators of the latter style. The porcelain insulators were kindly loaned to me by Mr. I. W. Gladstone of Mr. Edison's laboratory.

After a lapse of over nine months I connected the insulators on each arm, respectively, together by a copper wire in the same manner as they would be connected in actual use, and from each set I conducted an okonite wire highly insulated down through the building to my testing-room. The leakage of the leading wires was nearly negligible.

Feby. 3.			
3:30 P. M.	38,750,000	155 000,000	Rained last night. Overcast, wind moderate

NOTE: Persons desiring the temperature and moisture of atmosphere on above dates can secure them at the U. S. Signal Office.

The results, I think, are entirely in accord with those in the very exhaustive paper read before the Society of Telegraph Engineers in London in March, 1878, by Mr. John Gavey. It will be noticed that the porcelain insulators do not rise so quickly nor so high in insulation after the atmosphere dries up, and this, strangely enough, is a virtue, rather than a vice, as our long circuits work clearer and quicker when their electro-static charges have a chance to become dissipated along the route, instead of emptying themselves at either end of the wire to the earth. It has been the case on long overland circuits through a dry country, that artificial leaks have had to be employed, as is well known. Our multiplex circuits work better in damp than in clear, frosty weather; but the hygroscopic peculiarities of glass cause such a leakage of the signaling current that it readily falls below an efficient margin in the relays of the receiving station, so that the quicker working of the wire can lend no aid. Of course it will be seen that a loss of 50 per cent. of the received current will decrease the working force on the armatures of the relays more than 50 per cent., but not quite as the squares as shown by Prof. Silvanus Thompson in his splendid book on electromagnets.

It is strongly contended by some well-informed electricians in this country that electricity not only escapes to earth by the points at which the telegraph wire is supported on the poles, but also directly from the wire through the mist or fog enveloping such wire, and some have gone so far as to apply an insulating paint to the wire to cut off this leakage. I have made tests in heavy fogs with large galvanized plates in close proximity to earth plates, and have failed to detect the slightest variation of a Thomson astatic mirror galvanometer of 7,758 ohms resistance unshunted with 100 volts, the surface exposed to fog being equal to nearly half a mile of galvanized iron wire. Perhaps some of your readers may have had opportunities to test this matter more thoroughly and can throw light on the subject.

THE IRON ROOFS OF THE EDISON STATION, HAZLETON, PA.

BY

J. Edwin Giles.

It is remarkable that among the splendid class of men who constitute the close student and the practical engineer so little should be known of the iron roof as a covering for electric stations. At the rebuilding of this station about two years ago it became the duty of the writer to decide between iron and other material as a protection against fire, for the double reason, first, to remove the expensive insurance and, second, to give confidence to our customers in the matter of reliability. I corresponded with a number of persons throughout the country with the hope of obtaining information that would be of value to me, but the information received was so contradictory that it proved of no value whatever. I determined, however, to adopt iron trusses and corrugated iron roof, holding open a good road, however, for retreat, should disaster overtake us. Mr. Braddell's article in THE ELECTRICAL ENGINEER of Jan. 6, calling attention to the good and bad features of iron roofs is timely. I believe Mr. Braddell visited this station one bright morning following a cold night close upon the completion of the roof, and had the editor of THE ENGINEER been present on this or other like occasions he never would have gotten off the classic phrase "dropping from their iron roofs like a heavy dew," as the dropping was of the magnitude of a veritable rain-storm. The entire cement floor was thoroughly wet from this dropping. The dynamos covered with canopies and the belts with pouches made the dynamo-room look like a Japanese bazar. The letter by the Milliken Bros., in the issue of January 13, has but one reasoning, to wit, that an iron roof is only fit to be used on a barn or other building where the temperature of the interior can be kept about the same as the exterior. The roof builder and company manager must not forget that the men who live under these roofs are as sensitive to atmospheric changes as are the gentlemen who spend their busy hours in steam-heated offices. The experience of Mr. Robt. Amory, manager of the Brookline Gas Light Co., is interesting and valuable. But would not a little further experiment at the hands of Mr. Amory with the material in his roof be further instructive? What would have been the result had the slate been removed from his roof, leaving the cork to take care of condensation within a room such as he depicts, with temperature of the outside ten degrees below zero, as it has been here for the last three nights? Again had the cork been left off the iron, and the slate and iron been separated by a few inches, what would have been the result? In my opinion there would have been no condensation on the inner iron, as I can see no reason why the outer slate should act differently from an outer iron roof. Our engine and dynamo room is 40x60 feet, the walls are of brick, side walls 19 feet high and gables 30 feet to apex, trusses and purlins iron, and No. 26 corrugated roof, the latter having five coats of paint on the inside. Central on this roof is a ventilator 15x38x4 feet, the sashes of which are manipulated from the floor of the room. No moisture could penetrate this roof except by condensation, as every crevice was carefully closed, and yet I have seen icicles hanging from the inside of this roof eight inches long. As an experiment I had a small section of lining or interior roof put in just under and close to the truss rafter, leaving about five inches of air space between this and the corrugated roof. The lining is galvanized iron with standing seams tied to purlins and rafters. The visible side is without projections, except along the inside of walls, which is worked into a neat cornice forming a trough which conveys water either from condensation or leakage to a conductor and the sewer. This proved a splendid success. On occasions when the outer roof would send down a shower of dewdrops this lining was perfectly dry; not the least moisture could be discovered on close examination. We have lined the entire roof, and even on our coldest nights there has never been a particle of sweating on this iron lining, although we have positive evidence that the under surface of the outer roof still acts as a condenser. This remedy is comparatively cheap, light, handsome and effective, and not the least—is fireproof.

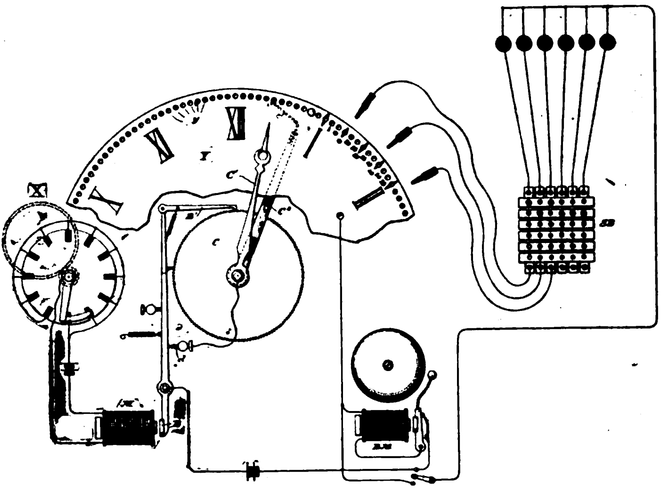
DELANY ELECTRICAL REMINDER OR SIGNALING APPARATUS.

We illustrate on this page a recent invention by Mr. Patrick B. Delany, which should prove an important addition to the numerous electrical appliances which have become so useful and convenient as to render them almost indispensable. Mr. Delany's device is, broadly, an electrical reminder, or alarm, intended for use in offices, stores, factories, residences or hotels.

The twelve hours on the dial are divided up into five-minute sections, so that by the use of plugs an alarm may be set in advance for any time during the day or night, and as many alarms may be set as there are holes in the dial, twelve to each hour.

By the use of the switchboard calls may be set for any time for any room in a house, factory or hotel. On reaching his office in the morning the business man may provide against any lapse of memory and insure all his engagements for the day by sticking plugs in the holes corresponding to the time for which his appointments were made; and at his home at night before retiring he may, with the same facility, arrange to wake up his cook, coachman, guests and himself at whatever hour of the morning that may be predetermined.

The operation of the reminder is very simple. A clockwork X causes a trailing contact maker to make a complete revolution hourly. In its path are twelve segments corresponding to intervals of five minutes. When the trailing finger makes contact with a segment the magnet M is energized and the hand C is pushed forward five minutes at a time. On the same arbor with the hand, and back of the dial, is another contact arm, flexible at its end. This contact arm partly overlaps the holes in the dial. If there be a plug in its path the circuit of magnet B M is closed and the trembling bell rung, so long as the armature lever B of M remains in contact with *d*, or while the trailing finger of X is passing over a segment. This duration may be regulated to any length desired, depending as it does on the size of the segment.



Delany Electrical Reminder.

The plugs for connecting distant calls are so insulated as to prevent contact with the dial, making contact with the contact arm only.

FLY-WHEEL ACCIDENTS IN ELECTRIC LIGHT STATIONS.

In an admirable address on "Centrifugal Force and Resulting Phenomena," delivered by the eminent engineer, Mr. Chas. E. Emery, before the students of Sibley College, Cornell University, the speaker dwelt upon the comparative frequency of fly-wheel accidents, which he showed could in part be traced to the comparatively high speeds at which engines are now being operated, but more especially to the higher strains on material now found desirable under the spur of competition to produce increased work in engines of a given size by the use of higher steam pressures.

Mr. Emery then proceeded to deduce a number of valuable formulæ for calculating the strength of fly-wheels, and then described several accidents due to the bursting of fly-wheels. The description of an accident of this nature which occurred at the station of the Lynn, (Mass.) Electric Light & Gas Co. will prove of more than ordinary interest to electrical engineers and station managers, as it involves questions not only of a mechanical but of an electrical nature as well, and which were brought out in the suit instituted against the insurance company for the non-payment of the loss sustained. We quote from Mr Emery's address as follows:

The engine was provided with cylinders 20 and 30 inches in diameter each with 48 inches stroke of piston and connected to a crank at one end of the fly-wheel shaft. The surface condenser was of the Wheeler independent form with independent circulating and air pump, the station being near an arm of the sea. The fly-wheel was 20 feet in diameter with 40 inches face, and was said to weigh 38,000 pounds. It was belted directly to a jack pulley on a shaft near the centre of the building, a little way in front of the cylinders. The passage in front of the cylinders was under the slack side of the belt and over the tight side which ran underneath the floor at that point. The jack shaft was continued by several lengths of line shafting connected by friction clutches and carried pulleys belting directly to the dynamos.

The accident occurred in October, 1890, in connection with a small fire in the tower of the building from which the conductors for arc lamps were carried out to the pole lines. A swath was cut through the roof and both sides of the building, and at least one piece of the fly-wheel was carried fully 150 feet horizontally across a vacant lot and a railroad track, wrecking the corner of a house and falling alongside the cabin of the watchman at the railroad crossing. Fortunately no deaths resulted from this accident, though two men were temporarily injured by flying pieces.

Interest in the case has been renewed by a suit brought by the electric company against the insurance companies for reimbursement for all the damages that occurred, not only from the fire directly, but those due to the wrecking of the engine. In connection with Mr. Manning, of the Amoskeag Mills, and Mr. C. J. H. Woodbury, vice-president of the Boston Manufacturers' Mutual Fire Insurance Co., the speaker was engaged as an expert by the insurance companies. It is thought that it will be of interest to briefly state the points claimed by each side in this very interesting litigation, for the reason that all were dependent on electrical and mechanical engineering principles combined in an unusual way.

The insurance law in Massachetts is understood to be that insurance companies are responsible not only for the fire but for all damage directly occasioned by the fire. The burden of proof is, however, on the insured to show that the losses other than those from the fire itself were actually occasioned by the fire. The plaintiffs in this case did not, therefore, attempt to account for the fire in the first instance, but endeavored to show that such fire caused all the damage, they claiming that the fire caused a short circuit in the tower by enveloping the plates of the lightning arresters in flame and possibly expanding them so that they came in contact. They claimed that this short circuit was brought on so suddenly that it broke the pulley operating the dynamos then in use, that pieces of this pulley flew and hit others, and, according to one phase of the theory, one of the pieces broke off one ball of the governor so that the engine ran away and caused the damage; and according to another phase, providing for the fact that the loss of one ball would not disable the governor, it was assumed that the jar due to breaking the first pulley caused the next pulley to break, and that the next, and so on from pulley to pulley across several undisturbed bearings and a friction clutch attachment, a distance of about 30 feet, until the jack pulley was thus broken, and that then pieces of this were carried by the belt under the fly-wheel and broke that, causing the wreck.

On the part of the defendants it was only necessary to disprove the probability of the assumptions, but in addition affirmative proof was presented to show that the conditions indicated a defect in the governor belt and that the damage to the machinery was simply due to the running away of the engine. The disaster occurred between 1:30 and 2 A. M. when current was being supplied for only 95 arc lights and for incandescent lights in the station. The arc lights were operated by two 50-light Thomson-Houston dynamos, such lights being distributed in four circuits from the station, which were, however, coupled two and two in series so as to form one circuit for each machine. Both dynamos were operated by one pulley on line shaft, the belt to the pulley of the farther dynamo running over the driving pulley on the top of the belt from the other dynamo. A similar pair of dynamos were running on open circuit at the time, and in addition an alternating dynamo and exciter for the same were in operation to light the station. There were at the time only two men in the engine and dynamo room and a third man in the fire-room adjoining. The testimony of all was to the effect that one discovered the fire in the tower and that another who was busy wiping shafting came and inspected it. The statements were to the effect that up to that time everything was working smoothly. It was stated that one called out to the fireman to blow the whistle and then turned on the fire alarm near another entrance to the building, and that the watchman after inspecting the fire went to the throttle valve of the engine. It was claimed that suddenly there was a tremendous roar indicating a short circuit. The evidence of the firemen would imply that the roar continued for some time, but the testimony of the engineer was to the effect that coincidentally therewith the pulley driving the two dynamos went to pieces and that immediately other pulleys commenced to fly and that he left the building. The watchman claimed that he had started to shut steam off the engine, for a reason not clearly explained, but that the pulleys commenced to fly and he, though struck by a flying fragment, bounded over a gate out of another entrance.

All the experts agreed that the first effect of short circuiting a Thomson-Houston arc dynamo is to materially increase the load due to the increase of current, but that such load is very soon brought back to the normal by the action of the current regulator. The efforts of the plaintiffs were to show that the short circuit, being an electrical phenomena, brought an instantaneous shock on the dynamo, which was transmitted through the belt from the dynamo to the operating pulley on the main shaft. Instances were cited showing that a belt operating a dynamo had in several cases been run off in this way, and in one instance the belt became foul with the operating pulley in such a way as to crush it. An important point arose as to the time it required the dynamo regulator to act and reduce the current; several of the witnesses claiming that it required 10 to 15 seconds, and all agreeing that this time would vary with the condition of the apparatus and the amount of damping afforded by the fluid in the cylinder attached to the regulator.

As a method of accounting for the short circuiting, the plaintiffs presented a diagram of the lightning arresters in the tower. There was one connected in each outgoing and each incoming conductor of each circuit, and as there were four circuits in use there were, therefore, eight lightning arresters involved. The four circuits were, however, as stated, coupled up at the time to make two, one for each machine; that is, the current going out from one terminal of the dynamo came back to the switchboard instead of to the dynamo, and was directed out on another circuit and brought back to the dynamo through the second terminal of the second circuit. To account for the short circuiting it was claimed that the fire filled the whole tower with flame, which, as it contained carbon, was a conductor and short circuited the dynamos by enveloping the segments of the lightning arresters. It was also claimed that in due time such segments became sufficiently expanded by heat to be brought in actual contact and thereby make a metallic short circuit. It was further claimed that fragments of carbon from the burning woodwork dropped between the horns of the lightning arresters and thus short circuited them, and that in one or more of these several ways the several lighting arresters were connected to form a short circuit.

In response, the defendants urged the improbability of any such action. Such a short circuit could only take place by grounding both branches of each circuit through two lightning arresters at the same time. The fire was localized in the vicinity of two of the arresters which were on the same circuit, but such circuit was connected in series with another, so that if short circuited it would only cut out about half the lights in the double circuit; or one-fourth of the whole. Two other lightning arresters of the four circuits were near and two more were on the opposite side of the tower where there were few signs of fire. It was clearly shown that to short circuit all the lights through the lighting arresters the segments of at least four widely separated must be in contact or the space bridged by flame or dropping sparks at exactly the same instant; and if this were done by flame it was necessary that the flames, which would naturally roll around and show alternately flame and smoke as in any fire, should form forks of conducting flame sufficient to form a short circuit at four to eight different points in the tower at exactly the same instant. Any less mysterious coincidence would only short circuit one pair of lightning arresters, and cut out about half the lights on one dynamo, or, roughly, one-quarter of the whole, and if this operation were repeated shortly after, another quarter would follow, and so on, and instead of a sudden shock it would be a series of small shocks quite insufficient, even on the theory of the plaintiffs, to cause the damage. It was shown that the quadrants of the lightning arresters would be expanded at a temperature of 1,200 degrees, sufficient to be brought in contact, but it was difficult to suppose that the flame was at a sufficiently high temperature to expand all at the same time when the fire was confined to one corner of the tower. Ordinary flame has a temperature, according to the books, of 790 degrees, for the reason that currents of air are commingled with it in order to carry on the combustion with a material developing so much hydrocarbon gas in the process of combustion. Brass melts at about 1,950 degrees, and it is well known that brass cannot be melted in an ordinary wood fire, but requires a blast with charcoal or other solid combustible. The brass was not melted, so the highest temperature obtained in the hottest corner of the tower was therefore less than 1,950 degrees, and much less elsewhere.

It was further claimed on the part of the defendants that the fracture of one pulley would not necessarily fracture the next one on the line, and that of the next and so on, and produce the train of breakages in the order claimed by the plaintiffs. The plaintiffs showed that one of the piers of the line shaft alongside the first pulley that broke was fractured, and claimed that this was done by that pulley fouling at the time of the short circuit, bringing a jar on the pillow block, which caused the disruption of the next pulley and that in turn the next, but this was answered by the fact that no other pier was injured and that no great shock could be transmitted beyond the next journal. There were two journals before reaching the two on either side of the jack pulley, neither one of the four being disturbed, and a friction clutch intervened. The defendants claimed that the pieces of the first pulley which it was in testimony flew up and struck the ceiling and the switchboard could not in the limited height available spread very greatly, and that therefore no piece of the first pulley could fly off at an angle of 40 to 45 degrees for a distance of about 40 feet and break the governor of the engine at the outset, and it was stated that if it did the engine would still be under control.

Mr. Walter C. McKinlock, secretary and treasurer of the Southern Electric Supply Co., is contemplating a trip to the cities of Mexico and Florida, combining business with pleasure.

ON THE LAW OF HYSTERESIS.—III.

BY CHARLES PROTEUS STEINMETZ.

II.—MAGNETIC CIRCUIT BUILT UP OF WELL INSULATED LAYERS OF VERY THIN SHEET-IRON. (FIG. 2, TABLE III.)

With this magnetic circuit tests were made for the frequencies 85, 138 and 205, and on *open* magnetic circuit for the frequency 138, and gave the following results:

TABLE III.

	Frequency in complete periods per second: N:	Number of readings:	Exponent of power, found by tests: X:	Coefficient of Hysteresis, found by tests: η:	Magnetization B covered by the observed values: from:	to:	Average difference between the observed values of hysteresis H, and the values calculated by the law: $H = \eta B^{1.6}$:
Closed magnetic circuit:							
1.	85	9	1.6041	.00285	5910	17,940	±4.4%
2.	138	14	1.6044	.00335	5220	19,320	±2.8%
3.	205	9	1 6970	.00373	6360	16,700	±3.4%
Open magnetic circuit:							
4.	138	8	1.6040	.00393	3150	12,280	±3.4%

Herefrom it seems that the consumption of energy by hysteresis per magnetic cycle increases with increasing frequency—that is, with increasing velocity of the magnetic change.

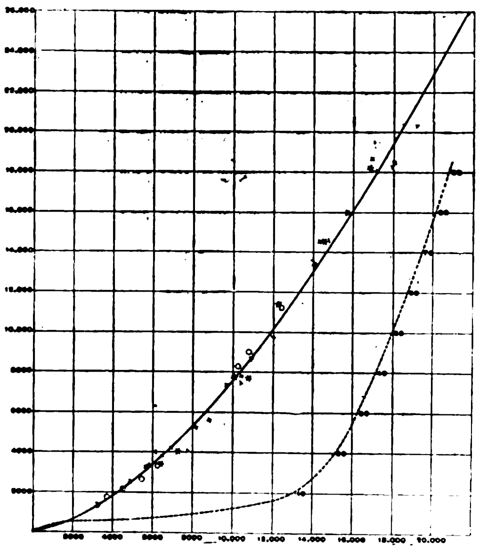

FIG. 2.

The three values of three coefficients of hysteresis for closed circuit in their dependence upon the frequency N, can be expressed by the *empirical* formula:

$$\eta = (.0017 + .000016\,N - .00000003\,N^2)$$

To compare the values of hysteretic loss for different frequencies, in Fig. 2 the curve of hysteretic loss for $N = 100$ complete periods per second is plotted, giving:

$$\eta_{100} = .003\text{; hence } H = .003\,B^{1.6}.$$

and the observed values of H are not directly drawn in, but the observed values of H multiplied with the factor: $\frac{\eta_{100}}{\eta_{\text{obs.}}}$ to compare the different frequencies with each other.

These values are plotted for:

$N = 85$ with the mark Y } closed magnetic circuit.
138 " " +
205 " " *
$N = 138$ with the mark o; open magnetic circuit.

Especially noteworthy is the last set of readings, on open magnetic circuit, in so far as it proves the fallacy of the general opinion that the hysteretic loss of energy in the iron is smaller in the open magnetic circuit than in the closed circuit.

For the coefficient of hysteresis observed on open magnetic circuit $\eta = .00393$ is even greater than that for closed magnetic circuit, $\eta = .00335$

But this discrepancy is easily explained by the fact that in the closed magnetic circuit the magnetization is nearly uniform throughout the whole iron. But in the open magnetic circuit the magnetic field intensity differs considerably from point to point, being a maximum in the middle of the magnetizing coils, a minimum at the ends of the iron sheets. Now, the values of B given in the table, are the average values of the magnetization, and the values H, the average values of hysteretic loss. But the average value of the 1.6th powers of different qualities B is larger than the 1.6th power of the average value of B.

Taking this into account, it seems that the loss of energy due to hysteresis depends only upon the intensity of magnetization and perhaps upon the frequency, but is independent of open or closed magnetic circuit, as is to be expected.

A third set of determinations of the hysteretic loss of energy was made on a magnetic circuit built up in the same way as in the tests, Table II, but of pieces of sheet-iron .0686 cm. in thickness.

Here with this thicker kind of iron, evident proof of the induction of eddy-currents in the iron was found.

The method of determination, the apparatus, etc., were essentially the same as in the other set of tests. In calculating these tests, the law of the 1.6th power was assumed as true, and the loss of energy in the iron expressed by the equation,

$H = \eta B^{1.6} + \varepsilon N B^2$, where $H_1 = \eta B^{1.6}$ is the true hysteretic loss per cycle and cm³., which is independent of the frequency, and $H_2 = \varepsilon N B^2$ is the loss of energy by eddy-current, per cycle which is proportional to the frequency N.

From this expression $H = H_1 + H_2$ the coefficients η and ε were calculated and the agreement or disagreement of these coefficients η and ε allow us now to check the correctness or incorrectness of the law of the 1.6th power, Table IV.

TABLE IV.

No.	Frequency, in complete periods per second: N.	Number of readings.	Coefficient of hysteresis, found by tests; η.	Coefficient of eddies, found by tests; ε.	Magnetization B, covered by the observed values. From:	To:	Average difference between the observed values of loss of energy in the iron, and the calculated values.
1.	78	6	.00331	$.751 \times 10^{-6}$	4171	16,050	±1.9%
2.	140	6	.00331	$.730 \times 10^{-6}$	4880	17,200	±2.2%
3.	207	5	.00336	$.757 \times 10^{-6}$	2710	18,200	±1.6%

The values found for η are so nearly alike that we can consider them as constant, and take their mean value $\eta = .00333$ as the coefficient of hysteresis.

Even the values found for ε are not much different from each other, not more than was to be expected from the unavoidable differences in the temperature of the iron, which because of the high electric temperature-coefficient of iron makes ε rather variable.

Taking the average of ε, we derive $\varepsilon = .746 \times 10^{-6}$ and as the formula of iron loss, $H = .00333\,B^{1.6} + .746 \times 10^{-6}\,N B^2$.

Two other sets of determinations of the hysteretic loss of energy, for the frequency 170 complete periods per second, were made on two laminated horse shoe magnets, with laminated keeper or armature, each of 2660 cm.³ of iron, of 70 cm.² cross-section, the thickness of the iron sheets being .0405 cm.

The method of observation and of calculation was the same as in Table III., and the same precautions were taken. In the first set of readings, considerable eddy-currents were found; in the second set only a small amount of eddies. In the first set of tests, the number of readings was 14;

as coefficient of hysteresis found: $\eta = .0045$
" " " eddies " $\varepsilon = 1.16 \times 10^{-6}$,

while the range of magnetization was from 842 to 2,600 lines of magnetic force per cm², the average difference between observed and calculated values = ± 2.8%.

WHAT THE WORLD IS WAITING FOR.

IT is reported that a new electric motor is now on exhibition in San Francisco which is expected to supersede all the present motors now used for transportation purposes. The electricity is said to be generated in batteries which can be made of any size and shape required, and that all the chemicals used can be recovered and worked over again indefinitely. This motor is said to be very cheap, easily managed, and capable of doing almost anything that can be required of it. In fact, it seems to be the very thing for which the world is waiting.—*San José Herald.*

Letters to the Editor.

CLAUSIUS' LAW OF ENTROPY.

In your editorial on Mr. Steinmetz's paper an erroneous statemen is made of Clausius' Law of Entropy. The law should be stated as follows: A number of physical processes which form a complete cycle never diminishes the total entropy of the bodies which are involved in these processes. If the cycle is not reversible then the total entropy is increased and heat is developed at the expense of some other form of energy. *Vice versa*, if heat is necessarily developed at the expense of some other form of energy then the cycle is non-reversible. By such a cycle the entropy is increased. Hysteresis of iron is only a special case of non-reversibility. It is therefore easily seen that Clausius' Law of Entropy does not represent all processes of nature as irreversible as your statement of it seems to imply.

M. I. Pupin.

New York City.

We are very glad to take notice of Dr. Pupin's letter and willingly accept his suggestion, that Clausius' Law of Entropy be expressed in its negative form, that is, "The change of entropy cannot be negative," instead of stating it in the positive form, namely, "The change of entropy must be positive," so as to include the ideal case in which the entropy equals zero, though they practically amount to the same in the end.

Theoretically the Law of Entropy is expressed thus,

$$\int \frac{d\,Q}{T} \geqq 0$$

where T is the absolute temperature, and Q the quantity of heat, and the sign of equality corresponds to the completely reversible, and that of inequality, to the non-reversible, cyclic process.

Nevertheless the completely reversible process, that is, the complete conversion of one form of energy into another and back again, with an efficiency of 100 per cent., has only an ideal or theoretical existence, since nature's cyclic processes seem to be all non-reversible If a reversible cyclic process existed, we could complete it over and over again without either gaining or losing energy, and therefore have perpetual motion, which experience shows us we can never attain.—Eds. E. E.

THE SPREADING OF FIRE IN CENTRAL STATIONS.

Is there an element about an electric generating station or about any building where electric light or power wires are used, that makes them burn more *rapidly* than other buildings? That is the question that is now agitating the minds of fire underwriters. The belief has been suggested many times in the past on account of the reported rapid spread of fires and the extensive damage done before they were subdued. I call to mind several instances during the past few years, notably, the burning of the Providence Narragansett Co.'s station, the Boston Edison station, the New York Manhattan station and more recently the Chicago Arc Light & Power station. In December last the large fire in the wholesale shoe stores on Federal St., Boston, is believed by some to owe its origin, rapid spread and great destructiveness to the presence of "electric wires" in the building. Last month a one story brick electric car house 100 x 150 feet in Toledo, Ohio, was entirely consumed with a large number of electric cars, and a fortnight later the Ferdinand St. station of the Boston Electric Light Co. was nearly destroyed. I have seen a sensational and interesting account of the Toledo fire in which the particulars were stated about as follows: The fire was discovered about 3 o'clock in the morning by the car cleaners. It was described by a colored man, I think, who first saw it, as a "small blue flame" burning on the seat of one of the cars. He endeavored to extinguish it with "buckets of snow" (a most effective piece of fire apparatus). There was a howling snowstorm raging outside. In an incredibly short time the fire spread from this car and seemed to instantaneously extend over the whole car house with a "strange hissing noise" and the occupants of the building had to beat a precipitate flight for life. The rapid spread with the strange hissing noise are the mysterious characteristics of this fire and they are supposed to have been due to the presence of the trolley wires and incandescent lights in the building. It is plain to my mind that the rapid spread after the fire had burned out of the car where it was first seen, and where they must have tried for some minutes at least to extinguish it, is precisely what would have taken place if the same building had contained the same number and kind of horse cars or even *mule* cars, with the same raging storm outside, and *inside* of course, and that if the wires had not been there the strange hissing noise would not have been suggested, although the same noise would have been there. It has also been insinuated that the embarrassed financial condition of the company aided the spread of the fire. That theory of course would explode the mysterious electrical hypothesis. Knowing nothing about either I should think one about as probable as the other. It is more than probable, however, that the presence of a reliable system of automatic sprinklers covering the entire inside of the building, together with available hose and water and a few level heads and hands to use them, would have stopped the fire or confined it to one car, electric wires and financial condition notwithstanding.

Now to come to the Boston Ferdinand St. fire. This started in the early morning and certainly did spread rapidly and most completely to every part of the building which is about 100 x 60 feet and 3 stories high. There was evidently a needless delay in calling the fire department but still, with all that, it seems improbable that the fire could so completely have communicated to, and burned with such fierceness, in all parts of the building without some unusual aid or uncommon conditions. The inside construction was heavy, rough, spruce timbers and joists with double 2 inch wood floors. The ceiling of this first floor (engine room) was sheathed with soft wood and the brick walls bare. The walls and ceiling both in the second floor (dynamo room) were similarly sheathed, while the walls and ceiling of the third floor (supply room) were both bare. Not only is the sheathing almost entirely consumed but the joists and floor boards underneath, in every room, and even under the engine room floor next the ground, are burned and charred an inch or more in depth, and no part of the building seems particularly more burnt than another.

It cannot be denied that this thin, soft wood sheathing, dried and seasoned by the heat of a large station for over two years, was terribly inflammable and would "burn like tinder" (as it really was), and that the spread would be accelerated by the excessive air currents caused by engines, fly-wheels, belts and dynamos of a 1400 arc light station; but still, is that all there is to the question? With all conditions of building the same, with the same engines, fly wheels, belts and speed operating the same number of machines for producing mechanical instead of electrical power would the results of the fire have been the same?

Here were 25 arc machines (24 Brush, 1 T-H.) We know that arc dynamos spark and that the electric spark liberates ozone, because our olfactories tell us of the ozonic presence. We know that it permeates all parts of such a station as this and that it affords several times more support for combustion than does oxygen. Is then the fierceness and rapid spread of these fires due to the disintegration of oxygen and consequent increased support for combustion? Admitting for the sake of argument that there is a greater fierceness and more rapid spread, are the causes those above suggested? And if not, what are they?

Without expressing any further opinion I would like to see the subject analyzed and treated by some of our many eminent scientists engaged in the electrical business.

The presence of unusually dangerous conditions not only in electric generating stations but *wherever electric wires are installed* is fast taking root in the fire insurance mind, and it certainly behooves the electrical interests to demonstrate that there is no foundation for such beliefs, if indeed there is none, else there is trouble ahead in the increased cost and difficulty of procuring fire insurance.

If there is foundation for the belief, the remedy must be applied in the way of appropriate construction and fire protection, or the fiddler must be paid.

Stephen E. Barton.

Boston, Mass, Feb. 2, 1892.

EFFECT OF THE VAN DEPOELE vs. DAFT DECISION.

Your interest in patent practice and the welfare of inventors has doubtless drawn your attention to the decision in *Van Depoele* vs. *Daft*, on page 520 of the Official Gazette, Jan. 26, '92.

The decision speaks for itself and very plainly too. It is matter of history that for many years the most glaring frauds were perpetrated through the agency of a perverted application of the law in the matter of reissued patents. This, however, was finally exploded by the Supreme Court of the United States and then it was that the divisional application began to flourish.

Several decisions of the Commissioners of Patents have been aimed at divisional applications, beginning with *ex parte Holt*, most of them being for the protection of the public and to prevent inventors from practically extending the *term* of their patent beyond seventeen years by hatching out a divisional application every few years.

The present decision, however, disposes of the practice under which an applicant was allowed to take a rib from the parent case, complete the skeleton, and then clothe it with a mantle of claims sufficiently broad to cover the subsequent growth of the art, claiming the date of the *filing* of the original, or parent, application as the age of his new creation. Under these circumstances an old application which has been skilfully kept alive in the Office year after year, in defiance of the law, was worth its weight in gold, as no subsequent *actual* inventor could, by any possibility, overcome the so-called "record date" of this buried treasure, which thereby became an invincible weapon by which further progress in the art was practically prevented.

Frankland Jannus.

Washington, D. C., Jan. 30, 1892.

CARBON STUBS AS FUEL.

In visiting the various arc light stations throughout the country, one notices barrels and boxes filled with carbon stubs which have been carefully saved and stacked up for no apparent reason and occupying valuable space. It has not been my fortune to find a station superintendent who could give any reason for their preservation, except possibly that some carbon manufacturer would some day call them in, and finding some way of utilizing them, allow a difference in trade.

As no such offer has yet been made, this saving process still continues. It may be of interest to know that they make a very slow, even, hot and smokeless fire when burned in a grate, stove or under a boiler, and that Mr. Hill Williams of the Upper Appomattox Co., of Petersburg, Va , has toasted his shins in his office for some time by this kind of a fire. When his water wheels do not get sufficient water, he burns them under his boiler, and a few shovels full of them make it very difficult to keep his safety valves from deafening the neighborhood.

NEW YORK CITY, Feb. 2, 1892. JEAN A. WETMORE.

PRACTICAL FORMULÆ FOR STREET CAR MOTORS

In your issue of Dec. 23, Mr. Thorburn Reid concludes his article thus : "Having found *w*, ... we may substitute ...... *E*. We are thus enabled to determine the size of wires ...... for feeders. Will you kindly inform me (1) if *E* is not a fixed E. M. F. (500 volts), and (2) how the E. M. F., *E* determines the size of the feeder wires ; (3) in equation (1) if n = revs. per *minute* why the equation does not read $E = \frac{S_2 N n}{60}$? Should it not be n = No. of revolutions per second?

SUBSCRIBER.

BALTIMORE, MD.

NOTE BY MR. THORBURN REID.

I HOPE the following explanations will make clear to "Subscriber" the difficulties he has found in my article.

(1) The E. M. F. in the formula is that which is impressed on the terminals of the motor. It is therefore the E. M. F. of the line at the point where the car is running. The standard E. M. F. for street railways is 500 volts *at the station*, but if it is 500 volts at the station, it must be less than that at any point on the line where current is being taken off, on account of the $C R$ drop on the line.

(2) Having determined by means of the formulæ in my article the E impressed on the motor terminals required to drive the car at a fixed speed, we subtract this value from the fixed E at the station which may be somewhat more or less than 500 volts, and thus obtain the value of the $C R$ drop on the line. Then, having determined the current flowing along the line to the different cars supplied by it, we may determine the resistance of the line and hence, knowing its length, the diameter of the wire required to give this resistance.

(3) Writing n as revolutions per minute was an oversight either on my part or the printer's. Equation (6) gives the value of n in revolutions per second. This oversight however would not affect the results obtained from equations (4) and (8), since all constants in equations (1) or (2) are included in a in equations (8) and (4).

In the ENGINEER of January 20, Mr. Arner finds an apparent discrepancy between formula (4) of my article and that given by Kapp. Kapp's formula is an approximation, as is mine. He gives, a little before the page cited by Mr. Arner, the formula:

Electrical efficiency of motor $= \frac{e}{E}$ and says very truly that that formula is not exact enough for his purpose. which is to obtain a formula for the *commercial* efficiency of on electric railway, including generator, line and motor. Kapp's formula is not exact and, under certain conditions, would not give as accurate results as the formula $\frac{e}{E}$.

It would take more space than the limits of this communication would permit to go thoroughly into the question of the losses in transmission from generator to car axle, but I think I can briefly reconcile the apparent discrepancies Mr. Arner has found. w, as stated in my article is the work done by the motor. This work is partly expended in overcoming the friction of the motor bearings and gears. The remainder may be called the useful work, since it is expended only in driving the car. It is the ratio of this useful work to that supplied to the generator that Kapp intends to obtain by his formula. His formula would give that value exactly, however, under only one particular set of conditions. w in my article includes all the work done by the motor, whether in its own bearings and gears or on the car axle. It also includes the magnetic, or hysteresis and eddy current loss in the core of the armature. This fact does not affect the accuracy of equations (3) and (4) for the reason that equation (9) $w_1 = b n$ is as nearly correct for these internal losses as for the external, except the magnetic loss, which is so small a proportion of the total as to be entirely negligible, especially in such rough calculations as these must be.

THORBURN REID.

SCHENECTADY, N. Y.

CONCERNING ELECTRICAL WRANGLES.

On behalf of all the readers of electrical matter in the daily papers I beg to interpose a respectful but firm objection to the trial at the present time, of the Morse—Vail telegraph controversy in the columns of the *Evening Post*. If we have got to sit as judges in this sort of thing, we want to do the work decently and thoroughly and regularly and in order; and we do not see therefore why, when the calendar of like cases already before us is so great, why when our judicial faculties are already over burdened, this particular row should be advanced out of its proper succession and suddenly sprung on us. Both sides have been hard at work evolving pleasing and suitable testimony for the last fifty years and we submit that plainly, and in no possible circumstance, can this be regarded as a "short cause." Look at this list of merely some of the more important cases which choke our calendar in the electrical field alone. I put the names of the parties first and the issue adjacent:

(1) John Doe (unknown Chinaman,) *vs.* Flavio de Gioja, Mariner's Compass. (2) Vieta *vs* Gilbert, The Earth's Magnetism. (3) Wall *vs.* Von Guericke, The Electric Light. (4) Hauksbee *vs.* Davy, Electric Illumination. (5) Musschenbroeck *vs.* Cunæus, *vs.* Von Kleist, The Leyden Jar. (6) Franklin *vs.* Dahliard, *vs.* De Romas, Identity of Lightning and Electricity. (7) Galvani *vs.* Sulzer *vs.* Volta *et al.*, Galvanic Cell. (8) Ritter *vs.* Nicholson and Carlisle, Electro-decomposition. (9) Ritter *vs.* Erman *vs.* Planté, Secondary Battery. (10) Romagnesi *vs.* Oersted, Magnetic Action of Current. (11) Sturgeon *vs.* Arago, Electro Magnet. (12) Henry *vs.* Faraday, Magneto Induction. (13 Watson *vs.* Ronalds *vs.* Wheatstone *vs.* Cooke *et al.*, Electric Telegraph. (14) Dal Negro *vs.* Davenport *vs.* McGawley *et al.*, Electric Motor. (15) Davidson *vs* Jacobi *vs.* Page *vs.* Hall *vs.* Lilly, Electric Railway. (16) De Moleyns *vs.* Starr, Incandescent Lamp. (17) Hjorth *vs.* Varley *vs.* Siemens *vs.* Wheatstone, Self-Exciting Dynamo. (18) Pacinotti *vs.* Gramme, Ring Armature. (19) Michell *vs.* Coulomb, Laws of Magnetism. (20) Jordan *vs.* Spenser *et al.*, Electro-Metallurgy. All of these far outdate the Morse-Vail dispute. Since then we have added and quite recently: Brush *vs.* Faure, Storage Cell. Bell *vs.* Reis *vs.* Gray *vs.* Drawbaugh, Telephone; and Edison *vs.* Everybody, Everything.

Of course when we go into other fields there are the fights over the telescope, (Galileo *vs.* Jansen); the locomotive, (Stevenson *vs.* Evans); the steamboat, (Fulton *vs.* Hulls, *et al.*); the screw-propeller. (Smith *vs.* Stevens, *et al.*); the monitor turret, (Timby *vs.* Ericsson) and plenty of others.

The Chinaman *vs.* Gioja discussion has been going on now for about 700 years and it has not been reached and formally submitted to us for decision even yet. At the same rate the Morse-Vail question ought not to come up regularly until some time in the latter half of the twenty-sixth century. Let us leave it to the readers of the papers of that date.

PARK BENJAMIN.

32 PARK PLACE, NEW YORK, 15th January, 1892.

WASHING AND SCRUBBING ELECTRIC CAR TRACKS.

In your last issue Mr. W. R. Mason says in regard to my article on the effect of a clean track that a well-adjusted broom will "fill the bill" equally as well.

I must take exceptions to this, because in certain cases the track broom (which, by the way, I had considered as part of the necessary equipment of every car, and did not mention on that account) does considerably *more* than fill the bill.

If Mr. Mason should ever be so unfortunate as to ride over some of the country roads where the cars run at a speed of ten or twelve miles an hour and find the track broom turning the car into an amateur cyclone of dust, I am sure he would be convinced of the wisdom of watering the track, for comfort if not for economy.

Besides, it is almost impossible to run a car thus without getting the journals hot and delaying traffic, to say nothing of injuring the vital parts of the motor. The actual cost of spreading the water is slight compared with the benefit got from it, and with its use the track broom is made much more effectual.

LUCIUS E. MARPLE.

NEW YORK CITY, February 4, 1892.

UNREASONING PREJUDICE AGAINST ELECTRIC LIGHT AND POWER.

I DESIRE to call your attention to the two enclosed clippings both taken from the Springfield *Daily Republican*, of Springfield, Mass. The one referring to the fire in the Holyoke Street R. R. Co.'s car shed shows the entire trend of the paper and that it is prejudiced against the electric industries. This is not the first time that it has thrown discredit upon the electric light by claiming that the wires were the cause of the fire. In two distinct cases where it claimed that the electric light wires were the causes of the fires the morning after they occurred, it has been proved that such was not the case. In the case of the fire in the Holyoke Street R. R. car shed the treasurer of the Company told the writer that he had never for a moment any suspicion that the fire was caused by electric light wires. Regarding the second slip referring to the "Rise in Insurance Rates," the writer is not aware whether the statement made in the last paragraph correctly represents the sentiment of the insurance people, yet judging from the facts, it does not seem possible that it could. According to the "Chronicle Fire Table," out of 22,412 fires in 1890, only 121 were caused by electric wire and lights, while 1,239 resulted from defective flues, 697 from explosions (of lamps, lantern, etc.), 223 from cigars, cigarettes and tobacco pipes, 269 from gas jets and 691 from matches.

It does not seem from the above facts that it is fair to assume that electric apparatus is to blame for the great increase of fires during the last year, and the daily press should be more careful in making statements that are detrimental to the great industries which have grown out of the use of electric apparatus. It would also be well to keep in mind the important aid rendered the firemen by electric apparatus in giving prompt notice when fire occurs.

ARTHUR J. NEWELL.

HOLYOKE, MASS., Jan. 26, 1892.

Personal.

MR. FRANK B. RAE.

THE well-known electrical engineer above named has recently made such arrangements that he is now free to engage in engineering and consultation work, as announced in our advertising pages. Mr. Rae, of whose interesting career we gave a sketch some months ago, was one of the very first electrical engineers in this country to give attention to electric traction; and the result is that both his work and his name are now familiar to all. Mr. Rae will, hereafter, as before, make a specialty of electric railway work, and he will also be ready to take up any questions in the electrical transmission of power and in the design of new electrical machinery for power transmission purposes. Plans and specifications will be fully drawn out by Mr. Rae, and supervision of work given by him. Mr. Rae has taken offices in the Hammond Building, Detroit. It is interesting to know that Mr. Rae is already engaged on some new and important railway work that promises well.

Obituary.

GEORGE WORTHINGTON.

NEWS reaches us from Buffalo of the death there of Mr. George Worthington, at the residence of his brother, after a lingering illness of about two years. It is seldom that any industry loses a man so active and prominent as the electrical industries lose in Mr. Worthington, who deserves the title of the pioneer of weekly electrical journalism in America. He was born in East Bethany, Genesee County, New York, March 18, 1844, of good stock, his family having been prominent in the interior of the State for years. He attended school at the Genesee and Wyoming Academy, at Alexander. N. Y. In 1862, he went to Milwaukee, Wis., and engaged in the hardware business until April, 1864, when he enlisted in the Fourth United States Infantry and served until the close of the war. He returned to Owego, N. Y., and then again to Milwaukee, Wis., where he again entered the hardware business, under the firm name of Worthington & Meek. Subsequently Worthington was appointed Consul to Ghent, Belgium. He soon resigned that position, returning home, went to Pittsburgh, Pa., where he was in the employ of the Pennsylvania Railroad Company for a short time. He then came to New York and entered the employ of W. H. Eldred, of the Gold and Stock Exchange Telegraph Company, and remained there until he founded *The Electrical Review*, in February, 1882. He never married and is survived by his father and by his brother, Mr. C. G. Worthington, of the insurance firm of Worthington & Sill, Buffalo, N. Y.

At the time Mr. Worthington founded his paper, there was no other weekly electrical journal in America. THE ELECTRICAL ENGINEER, then a monthly, had preceded it by but a few weeks, and the only other paper in the field was *The Operator*, a telegraphic journal, which did not drop that title and come out as *The Electrical World* until about the middle of 1883. Mr. Worthington had many bright newspaper ideas, and a wonderful talent for making friends, and the *Review* was soon on a very prosperous footing. Its work in aiding the development of the telephone, the electric light and all the later industries is known to all. To Mr. Worthington as editor of the *Review*, and in association with Mr. Charles W. Price, belongs a large part of the credit of establishing the National Electric Light Association and the New York Electric Club—a forerunner of many like organizations all over the country. Mr. Worthington was also a charter member of the American Institute of Electrical Engineers, but was never active at all in its affairs, his tastes and sympathies inclining him more to social and commercial, rather than technical, activities and pursuits. It may well be doubted whether any man in electrical work during the last ten years had a wider circle of acquaintances or was held in more affectionate esteem by them all. Yet he was a good fighter withal, and as to his qualities in active work it is enough to say that during all the heat and hurly burly of the last decade—certainly the most important that electrical applications have seen—he more than held his own.

GEORGE E. MUMFORD.

GEORGE E. MUMFORD, of Rochester, N. Y., died last week in Florida, aged sixty years. Mr. Mumford was born in the central part of the State and was the son of William Mumford, one of the pioneers of central New York. George E. Mumford was a graduate of Williams College, and was a lawyer by profession. He practised law for many years in Rochester in association with George H. Mumford, who was largely interested in the Western Union Telegraph Company in its earlier history when it had its headquarters in Rochester. In the latter years of his life Mr. Mumford abandoned the practice of law, confining his attention to many business enterprises with which he was connected. He was president of the Brush Electric Light Company of Rochester, which purchased the Genesee Falls and used the water-power to furnish Rochester with electric light, a plan that has proved to be very successful.

HENRY CHURCH.

IT is with much regret we announce the death from la grippe of Mr. Henry Church, of the Phœnix Iron Works, Meadville, Pa., builders of engines, etc., for electric lighting and power. Mr. Church was the son of Judge Gaylord Church, and was born in Meadville in 1842. He began as a civil engineer, and about 20 years ago consolidated the business interests of Dick & Church and the Phœnix Iron Works Co., of which concern he remained active manager down to the time of his death, witnessing the gradual and solid expansion of the industry he himself did so much to develop. Mr. Church was a high Mason, and took a keen interest in Masonic matters. His death was rather sudden, and came as a shock to the community that had known him from childhood and in all the honored relationships of life.

Society and Club Notes.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

THE 61th meeting will be held at the headquarters of the institute, 12 West 31st street., near 5th Ave., on Tuesday evening, February 16th, at 8 o'clock. A paper will be read by Lieut. F. Jarvis Patten, on "A Proposed New System of Alternating-Direct Current Transformation." Members who are especially interested in this subject may secure advance copies upon application to the secretary, which will be forwarded at the earliest possible moment. Distant members are invited to contribute their remarks in writing, in case they are unable to be present.

PAPERS TO BE READ AT THE N. E. L. A., BUFFALO CONVENTION.

Below we give a list of the papers to be read at the Buffalo Convention of the National Electric Light Association :

How to Fire a Steam Boiler	Richard Hammond.
The Allied Powers	Daniel Ashworth.
Switchboards: Their Safety and Operation	M. C. Sullivan.
Aerial Wires	E. F. Peck.
The Alternating Motor	Wm. Stanley, Jr. L. B. Stilwell.
From the Tannery to the Dynamo	Chas. A. Schieren.
Underground Wiring	E. A. Leslie.
Underground Systems	J. B. Craven.
Municipal Franchises for Quasi-Public Works	Allen R. Foote.
Electric Lighting from a Financial Standpoint	Erastus Wiman.

A SPECIAL TRAIN FOR THE BUFFALO CONVENTION.

ARRANGEMENTS have been perfected for a special vestibule train, composed of parlor, dining, and buffet cars, which will leave the Grand Central station, New York City, via. N. Y. C. & H. R. R. R., at 11:00 A. M., on Monday Febuary 22, (Washington's Birthday), and will connect with the Boston party at Albany. Seat checks for this train can be procured from C. O. Baker, Jr., master of transportation, room 505, 136 Liberty street, at the rate of two dollars each. Railroad tickets can be procured at the various ticket offices. It will, however, be necessary for the purchaser to request the ticket agent to furnish him with a certificate, which will entitle him to rebate fare on his return passage. These certificates are made absolutely non-transferable.

The following gentlemen have charge of transportation matters for their respective localities:

H. A. Cleverly........1018 Chestnut street, Philadelphia.
Fred W. Royce..1408 Pennsylvania avenue, Washington.
A. C. Shaw................620 Atlantic avenue, Boston.
John L. Martin..........146 Michigan avenue, Chicago.
Morris W. Mead..........................Pittsburgh, Pa.
S. D. Nesmith......... ...T.-H. Electric Co., Cleveland, O.
C. F. Hesser........Cincinnati Electric Light Co. Cin. O.
H. D. Stanley........................Bridgeport, Conn.
Prof. Henry T. Bovey..McGill University, Montreal, Can.
N. J. Hart..............................New Orleans, La.
James I. Ayer............322 Pine street, St. Louis, Mo.
Frederic Nicholls........................Toronto, Canada.
John I. Sabin........................San Francisco, Cal.
E. W. Rollins.....Denver Consol. Elec. Co., Denver, Col.

Reports of Companies.

STANDARD UNDERGROUND CABLE CO.

THE new board of directors of the Standard Underground Cable Co. met in the company's office January 28, 1892, for the purpose of organizing. Mr. Joseph W. Marsh was re-elected as vice president and general manger; Mr. Frank A. Rinehart as secretary and treasurer, and Mr. O. R. Ebel as auditor, and John N. Dalzell, Mark W. Watson and James H. Willock were chosen as the executive committee for the ensuing year.

The company declared a dividend of 1½ per cent., and made a strong showing of business despite the prolonged depression in trade.

A WESTINGHOUSE DIVIDEND.

C. A. TERRY, secretary of the Westinghouse Electric and Manufacturing Co., has announced that the Board of Directors has declared an interim dividend of 1 per cent. on the preferred stock of the company for the fractional part of the quarter ending Dec. 31, 1891, payable Feb. 1.

A POLICE SIGNAL SYSTEM FOR NEW YORK.

THE Board of Police Commissioners have invited proposals from the various electric fire-alarm and police-signal companies who wish to equip the police department.

The board want some system by which the attention of the patrolman on the beat can be attracted that he might know that he was wanted by the officer in charge of the station. This is just as essential as that the policeman should be able to call up the station house.

Among the companies represented are the Municipal Signal Company of Boston, the Metropolitan Duplex Fire and Police Signal Company, the Pierce & Jones Company, the Gamewell Company, the National Electric Manufacturing Company, United Fire Alarm and Police Signal Company, the Porter Teletype Company, the Electric Patrol Indicator Company, the Non-Interference Successive System, and the Herzog Teleseme Company.

DRY BATTERY PATENTS.

A SPECIAL circular in regard to dry battery patents has been issued by J. H. Bunnell & Co., who claim that serious infringement has been made of the Burnley patents. A hearing is now proceeding before Mr. H. C. Andrews, referee, appointed by the U. S. District Court, for evidence in a suit against the Manhattan Electric Supply Co., on account of alleged violation of the Burnley patents. The Manhattan Co. make what is known as the "Mesco" dry battery.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JANUARY 26, 1892.

Accumulators:—

Apparatus for Charging Secondary Batteries, C. O. Mailloux, 467,543. Filed April 24, 1891.
Provides means for charging a large number of batteries of the same or a different number of cells in series at the same time.

Apparatus for Charging Secondary Batteries, C. O. Mailloux, 467,544. Filed Apr. 24, 1891.
Similar to No. 467,543.

Charging Secondary Batteries, C. O. Mailloux, 467,545. Filed Apr. 24, 1891.
Preserves automatically the rate of flow of current through the battery without using cumbrous resistance coils or the like.

Apparatus for Charging Secondary Batteries, C. O. Mailloux, 467,546. Filed Apr. 24, 1891.
Similar to No. 467,545.

Apparatus for Charging Secondary Batteries, C. O. Mailloux, 467,547. Filed Apr. 24, 1891.
Similar to 467,545.

Secondary Battery, J. B. Entz & W. A. Phillips, 467,573. Filed Jan. 7, 1891.
Provides means of rendering the electrolytic action uniform.

Alarms and Signals:—

Electric Railway Signaling Apparatus, F. I. Myers, 467,581. Filed Mar. 16, 1891.
An improvement upon the existing "Sykes system" of semi-automatic signaling.

Electrical Signaling Apparatus, P. B. Delaney, 467,651. Filed Sept. 19, 1890.
An electrical alarm clock by means of which any number of alarms may be given within the compass of 24 hours.

Test-Circuit for Multiple Switchboards, C. E. Scribner, 467,901. Filed May 29, 1891.
An audible test signal of a character distinct from any sound which might be produced by any accidental cause.

Test Circuit for Multiple Switchboards, C. E. Scribner, 467,902. Filed May 29, 1891.
Provides means for ascertaining whether or no any line is in use at some other board.

Clocks:—

Electric Clock, F. A. Ellis, 467,748. Filed June 13, 1891.

Conductors, Conduits and Insulators:—

Composition of Matter for Insulating Purposes, D. H. Piffard, 467,520. Filed May 26, 1891.
A combination of rubber, resin and plaster of paris in the proper proportions.

Apparatus for Laying Underground Conduits for Electric Wires, H. B. Camp, 467,650. Filed Oct. 13, 1891.
A mandrel arranged to slide through an electric conduit as it is being laid for the purpose of cleaning.

Distribution:—

System of Electric Distribution, N. W. Perry, 467,897. Filed Apr. 13, 1891.
Has for its object to automatically disconnect conductors from a high tension main circuit when they become idle and to automatically reconnect them when called into use.

Dynamos and Motors:—

Alternating-Current Motor, L. Gutmann, 467,537. Filed Nov. 29, 1889.
Consists in producing relative motion of the armature and field-magnets by giving multiple poles to the armature, permanently forming local closed circuits in the armature by induction and increasing the induced currents in the closed circuits by an independent current.

Carbon Brush-holder, C. O. Mailloux, 467,542. Filed Mar. 18, 1891.

Heating:—

Electric Heater, L. Gutmann, 467,538. Filed Nov. 12, 1890.
An electric heater for cooking, etc.

Lamps and Appurtenances:—

Hanger for Electric Lamps, D. B. Matson, 467,511. Filed Nov. 24, 1890.
An arrangement whereby the lamp circuit is broken automatically when the lamp is lowered for trimming or repairs.

Incandescent Electric Lamp, E. P. Roberts, 467,623. Filed July 15, 1891.
Provides means for the protection of the wires passing through the socket piece and connecting with the electrodes.

Incandescent Electric Lamp, H. J. Gutman, 467,576. Filed April 10, 1891.
Has for its object to provide in an incandescent lamp the maximum area of shading and reflecting surface.

Electric Arc Lamp, J. A. Mosher, 467,610. Filed Jan. 24, 1891.
Relates to a novel method of feeding by reversing the movement of the magnet core.

Electric Arc Lamp, C. E. Scribner, 467,656. Filed July 3, 1888.
Contains two sets of carbons with clutch levers supported a short distance above the lifting lever and a cut-out carried by the lifting lever by means of which said lever may be raised a short distance without being obstructed by the weight of the clutch lever.

Incandescent Lamp Socket, P. Dunn, 467,716. Filed March 12, 1891.
A simple socket switch for incandescent lamps.

Measurement:—

Meter for Electric Translating Devices, H. H. Cutler, 467,669. Filed Jan. 2, 1889.
An arrangement by means of which the meter gives the highest indication when affected by the smallest current.

Metal-Working:—

Arc Metal-Working Apparatus, H. Howard, 467,752. Filed July 6, 1891.
Relates to improved methods of electric heating and welding.

Miscellaneous:—

Electric-Drill System, H. N. Marvin, 467,509. Filed Aug. 15, 1891.
A reciprocating drill operated without commutators.

Electric Drill System, H. N. Marvin, 467,510. Filed Aug. 21, 1891.

Has for its object to direct alternately into the two magnetizing coils rising and falling impulses of current.

Phonograph, J. H. White, 467,530. Filed June 4, 1891.

Automatic Electric Controller for Air Pumps, A. Bergmann, dec'd., B. Bergmann, administratrix, 467,551. Filed Sept. 18, 1890.

Relates to means for maintaining air or gas pressure in a receptacle connected with casks containing malt liquor, the air pump being driven by an electric motor provided with an automatic controlling device.

Rheostat, J. A. Mosher, 467,611. Filed Apr. 4, 1891.

Claim 1 follows:

A rheostat composed of heads, a cylinder held thereon, and strips surrounded by asbestos held to such heads and wrapped with braided wire.

Contact Board for Rheostats, S. H. Short, 467,613. Filed March 18, 1891.

A contact board for connecting in the resistances on an electric motor car.

Magnetic Separator, F. H. Richards, 467,645. Filed Oct 12, 1891.

A separator for paper pulp employing a trough having a depressed, transverse, magnetic floor section and a deflector extending into such trough over said section.

Electric Conductor Support, E. M. Boynton, 467,679. Filed March 19, 1891.

A bifurcated beam having blocks of insulating material inserted within it from which one or more conductors are suspended.

Door Opener, C. H. Grebenstein, 467,684. Filed June 26. 1891.

Adjustable Electrode for Dental Purposes, W. P. Horton, Jr., 467,738. Filed June 10, 1891.

Regulation of Electric Circuits, F. B. Rae. 467,773. Filed May 1, 1889.

Consists in an adjustable circuit-controlling and current-regulating switch so operated that the current admitted to the field magnet circuit will pass through the field magnet windings either wholly in series, partly in series, and partly in parallel, or wholly in parallel.

Electric Tell-Tale for Tanks, C. Reuter & G. Bollman, 467,774. Filed June 19, 1891.

Lineman's Wire Grip, C. A. Kent, 467,815. Filed May 22, 1891.

Magnetic Separator. F. H. Richards, 467,833. Filed Sept. 29, 1891.

A separator for removing particles of iron from paper pulp, etc.

Push Button, A. Lungen, 467,875. Filed Mar. 4, 1891.

Electric Wire Tapper, G. S. Neu, 467,891. Filed Sept. 17, 1891.

Railways and Appliances:—

Trolley Wheel for Electric Cars, L. A. Simons & G. R. Roof, 467,583. Filed Jan. 22, 1891.

Employs cutting edged corrugations on the surface of the wheel.

Station Indicator, R. B. Ayres, 467,678. Filed July 27, 1891,

Motor Mechanism for Street Cars, R. W. Thickins, 467,693. Filed Apr. 20, 1891.

Means of communicating the motion of a motor to the wheels of the street car.

Station Indicator, R. B. Ayres, 467,884. Filed Feb. 16, 1891.

Electric Railway, W. B. Hutchinson, 467,699. Filed Apr. 14, 1891.

Claim 1 follows:

In an electric railway a hollow carrier for the main conductor, said carrier having a longitudinal slot in one side and having its rear wall inclined downward to the slot.

Switches and Cut-Outs:—

Electric Switch, H. J. Haight, 467,504. Filed Dec. 24, 1890.

Has for its object to cut out one or more groups of local circuits without affecting the continuity of the line circuit.

Electric Switch, C. J. Klein, 467,540. Filed Apr. 6, 1891.

Employs a pair of tangential contact pieces one outside of the other, so arranged as to complete the circuit between themselves.

Telegraphs:—

Electric Indicating Instrument, H. J. Haight, 467,505. Filed Feb. 7, 1891.

An indicating instrument for use in dial telegraphy exhibiting meteorological data, stock quotations, etc.

NOTES ON THE CRYSTAL PALACE ELECTRICAL EXHIBITION, 1892.

THE Electrical Exhibition at the Crystal Palace, like its predecessor of 1881, has been taken up most enthusiastically, and difficulty was experienced by the Palace authorities in finding sufficient space for the requirements of exhibitors. Messrs. Siemens Bros. show dynamos of their make in combination with Willans and Tangye engines, as used on P. & O. steamers.

The Brush Electrical Engineering Co. show a large number of Brush dynamos, and engines for driving them. Crompton & Co. show a Crompton dynamo combined with a Willans engine of 200 h. p. This machine is capable of running nearly 4,000 8 c. p. incandescent lamps, and is of the same pattern as the machines employed in the Kensington & Knightsbridge Co., Notting Hill E. L. Co., and Westminster E. L. Co. This company also shows Otto gas engine driving a smaller dynamo, which charges a large number of accumulators. Crompton mains are to be seen in section on this stand.

Messrs. Crossley Brothers, the original owners of the Otto patent, show a number of engines of their well-known type, driving various electrical machinery. The British Gas Engine Co. show their patent cycle engines. Messrs. J. F. Andrew & Co. show the Stockport gas engine. Dick, Kerr & Co. with the Griffin gas engine. Messrs. Day & Co., of Bath, a new form of gas engine, all driving dynamos of various makes.

In the nave a number of very important exhibits are to be seen, among which the Postmaster-General exhibits a complete set of apparatus, showing the instruments used from the introduction of the telegraph in 1887 to the present time.

The Edison Swan Co. show 10,000 incandescent lamps in one group making a most magnificent display. About 200 h. p. will be required to light these at one time.

The National Telephone Co. have established an exchange in connection with their London head-quarters, and rooms have been arranged where visitors may, by paying a small fee, hear the London opera transmitted by telephone.

The Consolidated Telephone Company, have two stands, one in the nave and one in the gallery, connected by telephone, and showing various kinds of instruments.

Messrs. Croggon & Co. show a model of a church with lightning conductors of the latest form. This church also has bells, rung by electricity from a keyboard below.

Messrs. Rashleigh, Phipps & Dawson have arranged their stand in the shape of an Egyptian mosque, introducing various designs as used by the ancient Assyrians. It is handsomely decorated and well lighted by electricity.

Crompton & Co., Limited, show various types of the Crompton dynamo, together with a large projector or search light, as supplied to the navy. This is erected on a conning tower as on board ship, the lights being thrown from one end of the Palace to the other. They also show the Crompton electric crane, which is made to travel, hoist, and slew at the same time. A new feature shown in connection with this exhibit is a new form of automatic lamp, which has only just been perfected. On this stand a complete testing station is shown, using Crompton Howell cells.

Messrs. Siemens Brothers show an important exhibit of large arc lights and poles, hand-regulating holophote, city posts, iron brackets of various shapes and sizes, samples of submarine cable, etc.

The Brush Electrical Engineering Company show various sizes of their well-known dynamos, arc lamps, Mordey alternators, and other machinery. They also show a full-sized electric car made at their Falcon Works.

Woodhouse & Rawson show a model of an electric launch built for the Thames, a patent winch, electro-hydraulic riveters, etc.; also different forms of electric lighting.

Messrs. Johnson & Phillips show buoys and other marine apparatus, together with dynamos and arc lamps as manufactured by them, an electric capstan for winding, and an electric pumping plant as used in collieries. This firm is making a speciality of electrical transmission. Among the other exhibitors in the nave may be mentioned Messrs. Osler & Co.; Messrs. Appleton, Burbey & Williamson; Messrs. Day & Co.

The galleries can be reached by means of Messrs. Waygood's electric passenger elevator driven by a Siemens single magnetic circuit motor.

Messrs. Rashleigh, Phipps & Dawson also show a dining-room fitted in Italian style to illustrate the adaptation of electric lighting. The lights are made to represent the solar system, the large light the sun, and the smaller lights the planets. Various wrought iron fittings represent fruits, such as the pomegranate, orange, lemon, etc. Various emblematic figures are used, among which is the figure of youth with a torch representing light. The decoration and furniture are by Messrs. Godfrey, Giles & Co., beautifully executed with a deep embossed frieze, etc. The conservatory is fitted up by D. Radcliffe, Ltd., showing rocky cliffs, dripping wells, etc., combined with electric light, and giving a very pleasing effect.

At night the Palace will be very powerfully illuminated, and a number of search lights are used. The catalogue has had added to it an interesting descriptive article at the commencement of each section, explaining the kind of machinery exhibited under that heading, and its uses. This is quite an innovation, and should make the book far more interesting than catalogues generally are.

KERITE.

MR. F. W. CUSHING who has just taken the general Western agency for "Kerite" insulated wires and cables, is too well known in electrical circles both East and West to require any lengthy introduction. His experience during the last five or six years in the construction of underground conduits, management of electric light companies and the general supply business eminently fits him for the line he has taken hold of and predicts an assured success for his new venture. No one in the electrical business is better adapted to increase the large business and retain the enviable reputation enjoyed by "Kerite" and in wishing him full measure of success we can say that Kerite is in the best of hands. We understand that the manufacturers of this wire have decided to place it in the prominent position which its merits deserve and have made recent improvements in its manufacture which render it second to none. The wire has been favorably known by the leading telegraph companies for the past 25 years and we have no doubt that before another year it will be just as well known and largely used by the electric lighting, power transmission and electric railway companies.

HAGERSTOWN, MD.—Notice is given that the firm of Benham & Schindel has been dissolved by mutual consent, Mr. A. D. Benham retiring. His interest has been purchased by Mr. Joseph E. Schindel. The style of the firm name hereafter will be Schindel & Schindel. The business will be carried on in all its branches as heretofore. With increased facilities the firm will be able to fill all orders for electrical wood supplies promptly and satisfactorily at lowest possible prices.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Both "alternating" and "continuous" advertisements are effective.

SPEEDY HORSE POWER CALCULATORS.

THE accompanying illustration shows a convenient means whereby the average pressure of steam in an engine cylinder may be instantly found. This average steam pressure and horse-power indicator consists of a square foundation plate with a circular disc about 8 inches in diameter, both being graduated in accordance with the factors of the formulæ whose solution they give.

In order to obtain the average pressure of steam with any ratio of cut-off, the zero of the cut-off scale on the disc is set to the initial pressure on the plate, then opposite any given cut-off will be found the average pressure in pounds per square inch for the whole stroke.

This indicator serves, however, a further and more important purpose. With it the horse-power of a steam engine can be found almost instantaneously, whatever the ratio of cut-off. By means of the radial edges of the movable arm shown on the right, the various factors of the formula

A SPEEDY STEAM PRESSURE AND HORSE POWER CALCULATOR.

$$\frac{D^2 \times .7854 \times 2S \times R \times P}{33000} = \frac{D^2 \times S \times R \times P}{21008}$$

$= D^2 \times S \times R \times P \times .0000476$ are alternately brought into contact with each other, and the resulting horse-power is then found opposite the zero of the cut-off scale; the horse-power with the given cut-off being found, as already explained in the case of the average pressure of steam, on the top outer scale opposite the ratio of cut-off.

Another indicator, similarly constructed, gives the horse-power of a fall of water or of a turbine, when the height of the fall and the volume or discharge of water are known; or with the scales slightly modified, it gives the horse-power of a turbine or water wheel when the head of water, number of square inches of water vented, or diameter of nozzle are known, as well as the percentage of efficiency at which the turbine or water wheel is rated. It also shows at a glance the combinations of head and volume of water, etc., required to produce a given horse-power at a given rate of efficiency.

These instruments are manufactured by Messrs. Keuffel & Esser of this city.

MR. CHARLES A. TUCKER, president of the Tucker Electric Construction Co., has resigned, and disposed of his entire interest in the company.

WESTERN SPEED FOR WESTERN TRAVEL.

RUMOR says that an extraordinary fast mail train will shortly be run between New York and Chicago, making the entire trip in 17½ hours. This arrangement would lessen the time consumed between these points about 7½ hours. It is said that Third Vice-President H. Walter Webb of the New York Central and H. R. R. R. has informed Assistant Postmaster General Bell of his willingness to run a train over their lines as above. All Western mails would be greatly expedited by this arrangement, a difference of 12 hours being made to some points West of Chicago. By this arrangement mails leaving New York one day can be delivered in Chicago the next. The Central is evidently very much alive and on its mettle.

THE SCHOENBERG PNEUMATIC RESET FOR ELECTRIC ANNUNCIATORS.

THE simple and effective device for pneumatically resetting annunciator drops, shown in the accompanying illustrations, is due to the ingenuity of Mr. Ralph Schoenberg, of 129 East Sixty-second street. As will be seen, Fig. 1 shows the arrangement in normal position, in which the drops are free to fall, while Fig. 2 shows the act of resetting. But little explanation is required. The cross rods are all connected to a vertical bar, the lower end resting upon a small bellows, which is inflated by means of a bulb at the end of a tube of any reasonable length. The combined weight of bar and rods is sufficient to quickly contract this bellows when the pressure is relieved. This arrangement, aside from its convenience is claimed to increase the life of the annunciator, as the racking incident to the use of a mechanical reset is obviated.

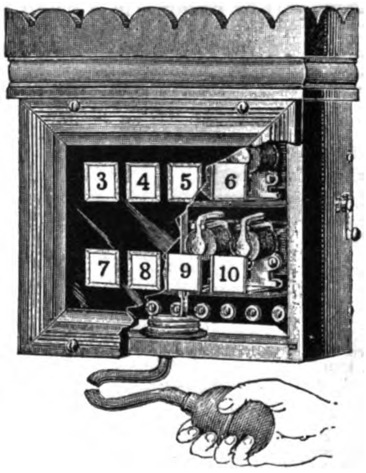

FIG. 1.—THE SCHOENBERG RESET.

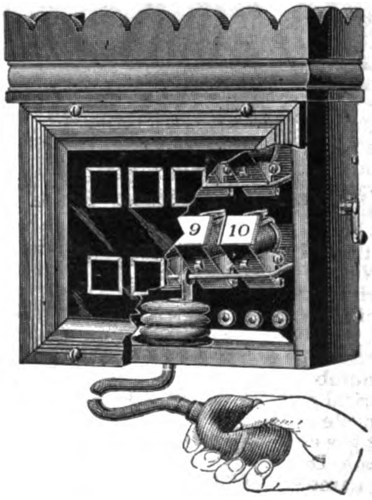

FIG. 2.—THE SCHOENBERG RESET.

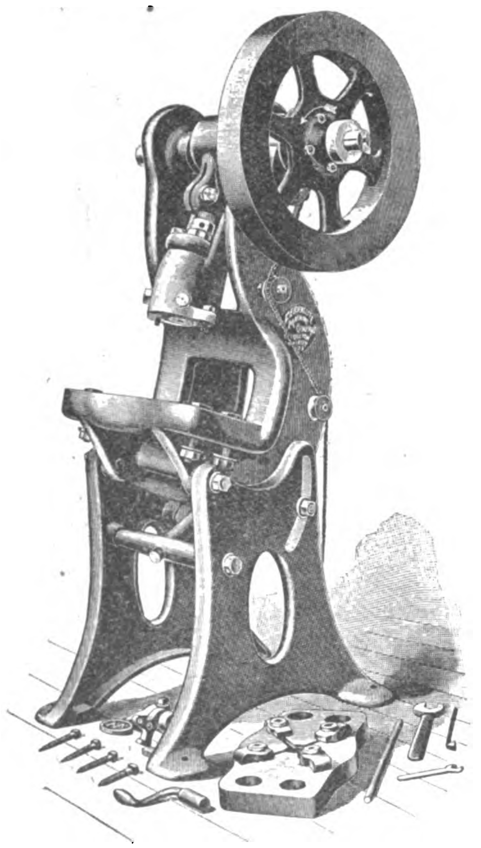
This attachment can be readily applied to annunciators already in use, and is made in two sizes.

A NEW FERRACUTE CUTTING PRESS.

THE Ferracute Machine Co., of Bridgeton, N. J., have recently placed on the market the new cutting press represented in the accompanying engraving, which is well adapted for work in tin, sheet iron, copper, brass and other light metals. There are six sizes of these presses, the smallest weighing about 700 pounds, and the largest 8,600 pounds. These machines are fitted up with forged steel shafts, carefully scraped working surfaces, hardened steel clutch, case hardened bolts and nuts, forged wrenches, etc.

Among the features to which the manufacturers call special attention is an arrangement of parts by which the centre of the die rises but little higher in the inclined position than in the upright, and a self-supporting device by which any inclination may be quickly obtained by slightly loosening the leg nuts and revolving the crank of the elevating screw. Reference is also made to the great height from the bed up to the ram, so that all sorts of high dies may be used when the ram is adjustable. The machines have long ram adjustment with a powerful grip for locking the pitman stem by a slight motion of the wrench upon a single bolt. A clutch of simple construction, working in a solid enlargement of the shaft with no nuts or screws to become loose, is also a feature of the machine. The construction is such that the whole device may be taken apart by pushing in a small pin. Another feature is a clutch tripping arrangement adjustable through a large arc about the axis of the shaft, and which is graduated to trip as early or late as desired. This adapts the press not only to a great variety of speeds, but to a great variation of loads upon the shaft as well as to different degrees of tightness in gib and other joints. A spring brake is placed under the shaft at the end where the fly-wheel would naturally wear down the journal boxes the most, and therefore compensates for its weight. A treadle-lock allows the treadle to be fastened down for continuous running, or up for the purpose of guarding against accidental starting.



NEW FERRACUTE CUTTING PRESS.

The machine is substantially built in all its parts, and is provided with four sliding steel clamps which grip die-plates of any size or shape within their capacity, and are firmly secured to the press by four bolster bolts shown in the bed.

PELTON WATER-WHEELS.

THE Pelton Water-Wheel Co. report a season of great activity both in their San Francisco and New York works, orders for 492 wheels having been filled during the past year, of capacities varying from 10 up to 1,200 h. p., an increase in number of nearly 100 over that of the previous year. The majority of these wheels have been sent to the mining districts of the Great West, although large numbers have gone to Mexico, China, Japan, Australia and many other foreign countries.

The extraordinary success that has attended the introduction of the Pelton wheel in all parts of the world indicates that it is fully meeting the varied requirements of such service, as well as the fact that there is a better appreciation of the value of water powers for all industrial enterprises. Any information relating to this system can be obtained by addressing the Pelton Water-Wheel Co., 143 Liberty street, New York City, or 121-123 Main street, San Francisco, Cal.

PASS & SEYMOUR SPECIALTIES.

THE accompanying illustrations, Figs. 1 and 2, show the latest novelty in ceiling rosettes introduced by Messrs. Pass & Seymour, of Syracuse, N. Y. As will be seen, the fuse is always visible, and can be removed, when blown, with the utmost ease and readiness. To do this the screw A is loosened two or three turns and the fuse inserted through the slot C and the screw A tightened.

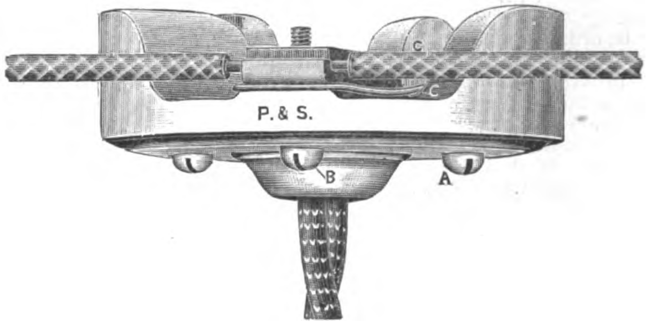


FIG. 1.

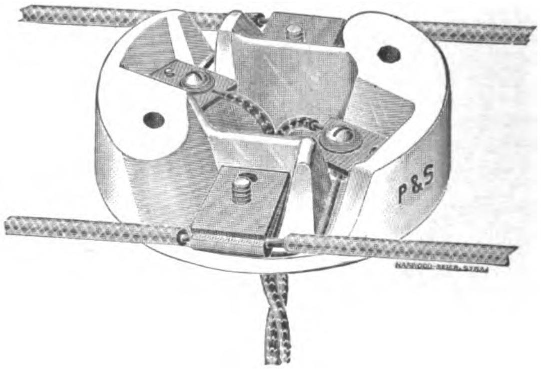

FIG. 2.

The screw B is then loosened two or three turns, the fuse wire is drawn under the wire clamp, and the screw B tightened. The wiring tube, Fig. 3, is particularly adapted to concealed work. The body of the tube is made an easy fit for the hole bored through the floor joists. On one end are several slight projections placed at irregular intervals so that when the tube is driven through the hole it cannot be withdrawn except in one position. The other end has an enlarged head, so that the tubes can not be displaced when the wire is drawn through. They are made of the exceedingly strong "Syracuse" china, and are practically indestructible.

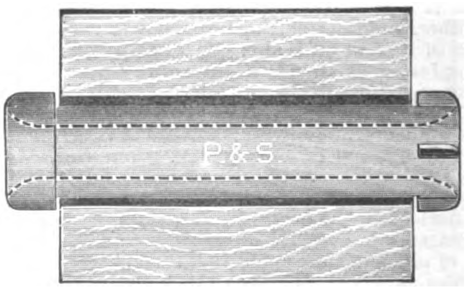

FIG. 3.

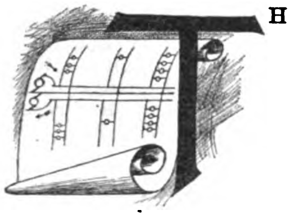
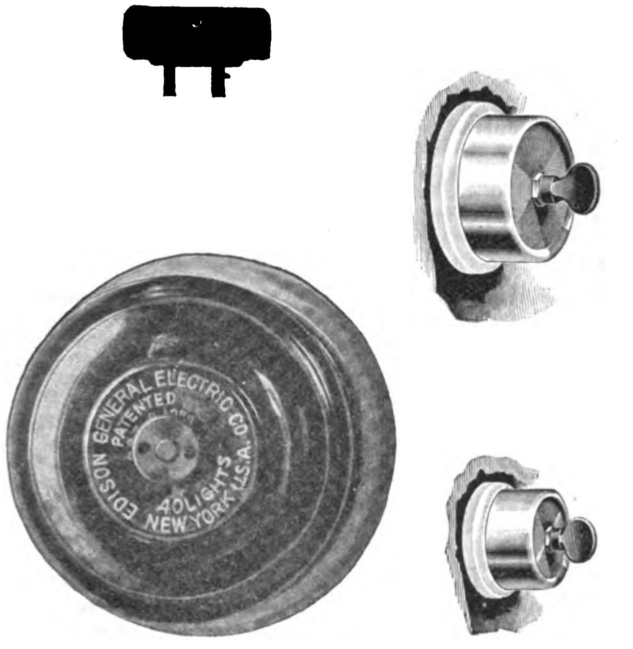
NEW EDISON SWITCHES.



THE ratchet switches made by the Edison Company are known and used wherever electricity is used for light or power. Quite recently, however, improvements have been made in these and entirely new styles have been devised to meet the ever-growing demand for small and effective ratchet wall switches, shown in the accompanying illustrations. These are of 5 and 10 amperes capacity, single pole, with bases and ratchets of hard vitreous porcelain, manufactured by the Edison Company at Schenectady. The ratchet is of peculiar construction, its sides being of unequal length, and when on the shorter sides of the ratchet are presented to the contact brushes These sides are rounded and the brushes specially curved, so that when the contact is made, the brushes and contact sides of the ratchet fit with precision. The ratchet itself is made of the best insulating material known. These switches are rendered instantaneous by an improvement introduced in the ratchet face. The cover is of metal which can be finished in any color, and is therefore peculiarly suitable for use in houses and buildings where artistic interior decorations are desired. The ratchet is removable and can be discarded in case of accident and another substituted, without destroying the entire switch.



New Edison Switches.

The Edison General Electric Company have also adapted their ratchet switches to the special use of hospitals, asylums, steamships and elsewhere, furnished with a small collar fitting outside the cover and firmly screwed down upon the ratchet pin, which cannot be turned except by means of the key in the possession of a competent person. These switches will doubtless be in great demand and have already met with gratifying success.

The Schenectady Works of the company have been compelled to enlarge considerably the department in which switches are manufactured, and the facilities now possessed for turning them out are perhaps greater than those possessed by any other manufacturers of similar appliances in the world.

THE HIMMER & ANDERSON "PERFECTED" DRY BATTERY.

The many advantages which a battery employing no liquid possesses over those in which a solution is used, has of late served to bring into prominence the dry battery. Cells of this type evidently can be set up exactly as they are received from the manufacturers, require no attention, such as the addition of water due to evaporation, and can, besides, be used in situations where a liquid battery would be out of the question, as, for instance, on cars, steamboats, yachts, etc.

The Himmer & Anderson Dry Battery Co., of 123 Chambers street, this city, have recently brought out their "perfected" dry battery which is in more than one respect a remarkable product. Tests made in our presence showed the cell to have an E. M. F. of nearly 1.8 volt, and on short circuit gave no less than 11 amperes; it held its E. M. F. and current for an appreciable time, and its recovery after a short rest was complete; the cell tested was circular, measuring 3 inches in diameter and 7½ inches high. These cells are made in a number of sizes, and arrangements are complete for turning them out in large quantities.

Mr. A. E. Kornfeld, formerly in the business department of *The Electrical World*, has assumed the business management of the Himmer & Anderson Dry Battery Co., and his energy will no doubt result in securing a large share of business for the company. He is well acquainted with the trade, and was never one to let grass grow under his feet.

NEW YORK NOTES.

A. B. & C.—The corporation of Alexander, Barney & Chapin, 20 Cortlandt street, has just voted an increase of their capital stock from $100,000 to $150,000, the new issue of $50,000 to be preferred stock bearing interest at 8 per cent. per annum. A statement of the affairs of the concern was submitted at the stockholders' meeting, showing a wonderful increase in the business, which could be much more enlarged by the addition of new capital. Quite a good many thousand dollars of the preferred stock are already subscribed for, and the balance is offered to the public.

Mr. W. J. Hammer, the electrical engineer and expert, of Temple Court, has gone abroad for a few months. He has been specially commissioned to place a number of very interesting American specialties in the electrical exhibition at the Crystal Palace. He will also visit various countries on the Continent before his return. Any one desiring to communicate with him may do so through his New York office.

Col. W. E. Sheldon, treasurer Fitchburg Engine Co., spent last week in the city. Col. Sheldon has been on an extended trip through the South, where he has closed up some handsome contracts for his company. During his stay here last week he sold an 80 h. p. engine to Healy & Co., the carriage manufacturers, located at 51st street and Broadway, this city.

Mr. F. C. Timpson, late of the Empire City Electric Co., has now opened an office in this city at 18 Cortlandt street, as the representative of the Electric Engineering & Supply Co. of Syracuse, N. Y. He has Room 511 in the Telephone Building and will handle all the electric light and railway supplies of the pushing manufacturers above named.

Mr. W. R. Mason, general manager of the Electric Merchandise Company, Chicago, was a visitor in New York last week. Mr. Mason has volumes to speak in praise of the favorite specialty handled by his company. This refers to the Burton electric heater.

WESTERN NOTES.

The Electric Appliance Company report that business prospects are very bright and state that although January had been a very quiet month in the electrical supply business all over the country they did a largely increased business during the month. The C. E. M. goods seem to have found general favor with the trade, and the Electric Appliance Company are unable to keep up with their orders for sockets and cut-outs of the Consolidated Company's manufacture. They are also showing an elegant line of jack knife switches in single pole, double pole, three pole and throw over, of which they carry a large stock ready for immediate shipment.

St. Louis Electrical Supply Co.—The recently elected directors of the St. Louis Electrical Supply Co. met last week for the purpose of organization for the current year. E. Ruebel was elected president and treasurer, William N. Matthew, vice-president and Joseph Hummell, secretary. This is the company of which the late W. L. Scott was president. Mr. Matthews, who is a son of Leonard Matthews, Esq., and who for many years has been connected with the Collins Bros. Drug Company, it is understood, has purchased the interest formerly held by Mr. Scott.

The Electrical Supply Co., of Chicago, are having an unusual demand for Habirshaw rubber covered wire for which they are the Western agents. A single order called for over $15,000 worth to be used in wiring one of the large office buildings in that city. The Sunbeam lamp is another one of their leading specialties and is rapidly growing in popular favor. The Electrical Supply Co. introduced this lamp by small trial orders, and are very much encouraged to get from these same purchasers duplicate orders in three to five thousand lots.

Great Western Electric Supply Co.—The directors of the Great Western Electric Supply Co., at the December meeting declared a dividend of two per cent. amounting to $7,000, on the £350,000 of preferred stock of the company. This was paid on January 10. It is worthy of note that the preferred stock of this company has added nearly one hundred names to the list of its holders during the last ninety days.

POND ENGINEERING CO.—The Electric Light Company, Albuquerque, N. M., have telegraphed an order to the Pond Engineering Company, St. Louis, for a 100 h. p. Armington & Sims engine, this being their third order within one year. The Equitable Gas Light & Fuel Co., of Chicago, Ill., have contracted with the Chicago office of the Pond Engineering Co. for an Armington & Sims engine to drive a large exhaust fan. This plant is already in use by two other gas companies in Chicago, and is proving very popular in gas plants.

THE ELECTRIC APPLIANCE COMPANY report that although it is very early in the season they are nevertheless having a demand for the swinging ball lightning arrester, and requests for information in regard to it that promise a big business when the season gets further advanced. The swinging ball lightning arrester has had a test of three years' practical service in stations in nearly every part of the United States and has a wonderful reputation, as it has never been charged with a single failure to do its work.

THE "BANNER" WEATHER PROOF WIRES handled by the Central Electric Company, are noted for the firmness and waterproof qualities of the insulation. The manner in which the braid is woven on the copper, gives it particularly firm and lasting qualities which braided wire rarely possesses. Nothing but the best grades of cotton and compound are used in the process of insulating, and these wires are particularly adapted for use among trees, where the circuits are subjected to severe abrasion.

THE MASONIC TEMPLE, CHICAGO, to be lighted by the Thomson-Houston Co., will have about 8,000 lights in generating capacity, and about 7,000 lights are being wired for. Simplex wire is being used for the purpose, requiring 6 tons of mains and feeders, 50 miles of No. 14 and 10 miles of No. 16. The building is 21 stories high, or 302 feet from street to roof. The Western Isolated Department of the Thomson-Houston Co. is also furnishing the lamps and sockets—at regular prices.

THE ERNEST L. CLARK CO. report an exceedingly large volume of business in poles, etc., for the past month and very encouraging prospects. This company is making a specialty of octagonal Norway pine poles which they are manufacturing in large quantities.

THE MOSHER ARC LAMP CO. recently shipped a number of their arc lamps for incandescent circuits to China, some of which were installed in a Chinese theatre and proved a drawing card among the Mongolians, large numbers of whom went to see the new moon.

THE CENTRAL ELECTRIC COMPANY report having on hand a large stock of the supplies manufactured by the Interior Conduit & Insulation Company, of New York, and are consequently enabled to fill all orders for these materials with exceeding promptness.

MR. F. S. TERRY, the general manager of the Electrical Supply Co., Chicago, has been seriously ill for two weeks. It was at first feared that it might result in pneumonia, but he is now able to be up and about.

MR. H. M. UNDERWOOD, who for some time past has been representing the Knapp Electrical Works and Safety Insulated Wire Co., has severed his connections. Mr. Underwood is widely known amongst electrical people both East and West.

MR. GEO. T. HEWES, well known amongst the electrical fraternity in the West, is now general manager of the Faribault Consolidated Gas & Electric Co., Faribault, Minnesota.

J. H. SIEGRIST, JR., & CO., St. Louis, are now placing an 80 h. p. "Ideal" self-lubricating engine in the new plant of the Jefferson City (Mo.) Gas and Electric Light Co.

MR. LAFAYETTE COLE, of Holmes, Booth & Haydens, was a visitor to Chicago last week on his way East. He reports a highly prosperous trade, especially in the far West.

GUSTAVE MONRATH, of 1302 Auditorium Tower, is superintending the plants which are now being installed at Marseilles, Ill., all of which are run by water-power.

THE ELECTRIC CO. have taken the general Western agency for the Pennsylvania lamp. They are already receiving a large number of orders and inquiries.

MR. GEORGE CUTTER is supplying the new plant at Elmhurst, Ill., with his well-known street hoods fitted to a bracket arm of novel design.

THE GARDNER-MORGAN MINING MACHINE CO. have their mining machine about ready for the market.

NEW YORK NOTES.

MR. I. P. FRINK has now on hand a large number of orders for reflectors and reflecting chandeliers in which electric lamps are used, covering all classes of public buildings, and well distributed over the States; among them the following prominent churches: Protestant Dutch Church, New York City; Christ Church, Jersey City, N. J.: First Presbyterian Church, Fostoria, O.; M. E. Church, Venturo, Cal.; Catholic Church, Owatonna, Minn.; Fourth Presbyterian Church, Pittsburgh, Pa.; M. E. Church, Plainfield, N. J.

THE INTERIOR CONDUIT & INSULATION COMPANY are making large shipments of their new Johnson switches to their agents, and the principal central stations in the United States. They are already some thirty days behind time in their orders, one illuminating company alone having ordered 1,100 of their well-known switches in two days. The company has in preparation a handsome illustrated catalogue setting forth the good qualities of this switch. This catalogue will be issued together with a revised edition of their well-known No. 4 catalogue, in the course of the next ten days or two weeks.

A. & F. BROWN & CO.—Purchasers of pulleys, hangers and shafting are reminded that Messrs. A. & F. Brown & Company, probably the largest manufacturers of these goods in the United States, will remove their office and salesrooms from 44 Park Place to 17 Dey street, New York, the quarters formerly occupied by the Edison Machine Works, in the same line.

THE ELECTRIC CONSTRUCTION AND SUPPLY CO. are introducing something entirely new in an arc lamp for use in the process of photo-engraving. The lamp and necessary apparatus are exceedingly compact and of course portable. They are also exhibiting in their offices this week a very handsome projector, one that is perfectly automatic.

NEW YORK ELECTRICAL CONTROL.—Various schemes on this subject are before the Legislature. It is proposed to extend the term of the New York City Board, while another bill provides for a State Board.

W. H. MCKINLOCK, president of the Central Electric Co., Chicago, has been a New York visitor for several days. He intends spending some time in the South before returning to the World's Fair city.

Mr. W. J. Cooke, vice-president of the McGuire Manufacturing Co., Chicago, makers of the McGuire truck for electric cars, was a New York visitor last week and called at this office during his visit.

GERRYCIDE.—The New York Legislature has modified the electrical execution law, so as to permit of a certain number of reporters being present at the performances.

THE PREMIER ELECTRIC COMPANY have received among others two handsome orders this week for their new fan motors, aggregating 400 motors.

MR. C. A. BENTON, manager of the railway department of the Detroit Electrical Works, was in the city last week.

D. B. DEAN, general salesman for the Electric Merchandise Co., Chicago, is in New York.

NEW ENGLAND NOTES.

THE MASSACHUSETTS WIRE COMPANY, of Malden, Mass., are installing a 400-light incandescent plant in their factory, which will materially assist them in the manufacture of their wires. The Massachusetts Company are large manufacturers of all grades and sizes of magnet wire, and have achieved quite a favorable reputation for the uniform quality of their goods.

THE MASSACHUSETTS ELECTRICAL ENGINEERING COMPANY, of Boston, through their testing department, have issued a neat little calendar and paper weight combined, consisting of one of their spools of tested fuse wire, tastefully finished, and having a small calendar attached. Any person can be supplied by applying to them at 4 Post Office Square, Boston.

THE JENNEY STAR ELECTRIC COMPANY, whose factory is at New Bedford, Mass., has moved its Boston office to 196 Summer street. Mr. A. W. Rounds, the treasurer of the company, reports that they are making good progress at the factory, and are now busy making several sizes of the motors, and that the general outlook for business was very good.

MR. IRA W. HENRY, constructing electrician for the Bishop Gutta Percha Company of New York, was in the city this week, and favored this office with a call. Mr. Henry reports that the Bishop wire is now on the list of wires accepted by the Boston Board of Fire Underwriters.

THE NEW HAVEN INSULATED WIRE COMPANY, of New Haven, Conn., reports business as very good, and their factory is taxed to its uttermost running day and night to fill orders, which will probably keep them busy for the next two months.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.

Vol. XIII. FEBRUARY 17, 1892. No. 198.

AMERICA'S PART IN THE DISCOVERY OF MAGNETO-ELECTRICITY—A STUDY OF THE WORK OF FARADAY AND HENRY.—V.

BY

Mary A. Henry

FARADAY and Henry have asked the same question of Nature, and in the same way, and Nature has replied to each by the tremble of a needle and has confirmed her assertion by that beautiful thing, a spark. The great discovery of magneto-electricity is made. They were not conscious rivals, these two great men. Widely separated, each was simply intent upon finding out what Nature had to teach. If one had failed to make this gift to the world the other would have done so. We desire to make no ungracious comparison between them, yet it is but just to consider the position which each held in reference to the discovery. As Mont Blanc raises its snowy peak unchallenged above mountains of lesser but still great height, so Tyndall regards this achievement. Let us look at the two men in their relation to it, as they seem to stand before us, side by side.

1. As to advantage of circumstance. To scale the dizzy height, the advantage is with the mountaineer best equipped in experience, training and tools. If such advantage may be claimed in considering this discovery, let us look back and see again the different circumstances of the two men. Faraday, with nine years of advantage in age, has been at work in the Royal Institution of Great Britain for eighteen years, surrounded by every facility for study; with ample time at his command and under the instruction of one of the most eminent men of the age. Henry, in what was then a frontier town of a new country, with no other aid than his own earnest purpose, has had to snatch his days of investigation out of busy years filled with other matters; his only apparatus rude tools made by his own hands.

2. Faraday has been at work upon the subject since 1824; has tried it again and again "without result," although the phenomenon, unperceived by him, has been actually produced under his hands. Henry succeeds in his first attempt. Faraday has been, as it were, climbing for years the ascent, while Henry, at one spring, is at the top. Is this due only to the aid Henry's magnet has given both men? We cannot but feel, that under any circumstances, Henry's quick experimental instinct would not have been long in catching the moment when the gnome was at work. Look at the two men when the phenomenon is produced in the same way. Henry sees immediately that Nature's answer to his question is in the affirmative, and recognizes as immediately the proviso, namely: change or motion in the magnet. Faraday is not sure his fish is "not a weed;" tries again, to fail, as he could not have failed if he had understood what he saw; and not until he has made the experiment in another and entirely different way, is he sure of the phenomenon and recognizes its principle.

3. As to the means of the discovery, Henry's magnet. He had sent it over to Faraday in *Silliman's Journal*. He had made it for himself, out of his own brain and with his own hands. In making it he had made the stepping-stone for both; had made it easy for Nature to answer the question. We might almost say the magnet made the discovery. [This does not conflict with our assertion, that Faraday, using the magnet in the form of a ring, did not really make with it the discovery, but with a permanent magnet later. The ring showed him the phenomenon, and if he did not fully recognize this, led to his subsequent perception of it.]

4. As to priority: And now we come to the chief object of our story. It has been hitherto supposed that Faraday could claim this, but is it so? Certainly, on the score of publication. His first series of brilliant experiments was given to the world in November, 1831, while Henry's paper did not appear until July, 1832; but the world, advancing rapidly in every way, will soon no longer ask who was the first to *publish* but who was the first to *do*. Which of these men was the first actually to make this discovery?

Let us attend first to Henry's spoken statements. Sympathy is the gold of the heart, by means of which mind may win from mind its burden or its treasure. Quick to feel sympathetic interest in the concern of others, a like interest in his own affairs was a strong need in Henry's nature. Often by the fireside in his home he told to his wife and daughters the story of this great early disappointment; the story in facts as we have given it. How he made the discovery of the extra current five years before Faraday. How the discovery of magneto-electricity followed in 1830. How eager he was to pursue it, and how baffled by lack of time and materials. How he wished to amplify his results before he gave them to the world, and how he had commenced his great preparations for this purpose, and then, one day, in the library of the Academy, seizing eagerly upon a newly-arrived periodical, how he suddenly came upon the notice which told him that although he had made the discovery so long before any one else, Faraday must claim it. He might hurry his results into print but Faraday was there before him. "He who publishes first claims the discovery" was a code strictly held by Henry, and so he laid down all claim to the discovery, and in the years which followed in Princeton always attributed it in his lectures to Faraday. An old friend (Rev. Theodore L. Cuyler, D. D.), one of Henry's earliest pupils in Princeton, said recently to one of his daughters, "Your father often spoke to me of his disappointment about that discovery. 'I ought to have published earlier,' he used to say. 'I ought to have published but I had so little time. It was so hard to get things done. I desired to get out my results in good form and how could I know that another on the other side of the Atlantic was busy with the same thing?'"

Let us now study the evidence which lies under our eyes, in the published statements, and the one or two letters we have collected in this article, and see whether they corroborate our story. Bence Jones says that Faraday commenced experimenting the 29th of August, 1831, and that "the first experiment detailed in his note-book records the discovery." The experiment with the ring was made that day or the next, but the discovery, as we have shown, was not really made until the 24th of September, when he first recognized positively the distinct conversion of magnetism into electricity. However this may be, *the 29th of August is the utmost limit for earliness to be claimed for Faraday.*

And now let us look at Henry's paper. We have given it entire, so that the reader may judge what it seems to say. It is published in July, 1832, but in its beginning it refers to last August, *that is August,* 1831, *the very August when Faraday is making his ring.* Henry says experiments were interrupted then, not to be resumed until "*the last few weeks,*" which we find from the latter part of the paper means "*the last two weeks* in June" (that is of 1832). A letter to Professor Silliman gives us the cause of this interruption, namely, that the room used by Henry was required for the opening of the Academy, and from another source we learn that the Academy opened the first of September. So this is the first thing we learn, that Henry is busy with the subject at the same time that Faraday is, in August, 1831, and that between that time and the last two weeks in June, there is an interval in which there are no experiments.

The second thing we learn from the paper is that in this interval, "in the meantime," Henry says, comes a brief notice of Faraday's results dated April, 1832, and which Henry gives in the paper.

Now look again into the paper. It consists of a description of two series of experiments, *the one made before, the other after, seeing the notice of Farday's result, dated April,* 1832. In the first series we find the great experiment. *If made before April,* 1832, *then before the close of August,* 1831, *the time when experiments stopped,* and into the very last of those August days must we bring the experiment in order to give Faraday priority, the utmost limit of earliness for Faraday being the 29th of August.

If our claim is just, that the discovery was not fully made by Faraday until the 24th of September, more than three weeks later than the last of August, the limit of lateness for Henry. Our point is proved here, but we desire to give every allowance to Faraday, so let us consider the ring experiment, the very earliest possible limit for Faraday.

This experiment was made the 29th and 30th of August, so there is but one day left, as we have said, into which we must squeeze Henry's experiment to give Faraday priority. It is not likely that Henry was at work on that last day; he had to give up his room to be cleaned, to remove his apparatus. But if at work, what is he doing? Not making this discovery—it has been already made. We are not left to conjecture; he tells us in his paper with what he is busy in those August days, "*making a great magnet and other preparations for a series of experiments with it on a large scale, in reference to the production of electricity by magnetism.*" We see exactly from the letters we have given, what he is doing when the cruel interruption comes; insulating with his own hands "*a mile of wire;*" "*bending a bar of iron weighing* 101 *lbs. into a horseshoe;*" and almost pathetic is the glimpse of the unfinished magnet, with all the labor it has entailed, in Henry's room in November, through the letter to Professor Cleaveland. Uncompleted is it still, when the following June comes and the experiments are resumed on a smaller scale. Henry does not say in his paper when in August the magnet was commenced, but considerable time must have been consumed in its construction before the 29th came. He had to stand over the workmen while they forged that bar weighing 101 lbs. He says in another letter to Professor Cleveland: "I can get nothing done in the philosophical line in Albany except I stand over the workmen myself, or, which is most often the case, do the work myself." The insulating and winding of that reel of wire, a mile in length, alone represents an enormous amount of time to say nothing of the winding of the magnet. Of the labor entailed by the latter, we may have some idea from what he says of the magnet prepared for Professor Cleaveland, in that letter of May 8, 1832. "The winding of the wire was done with great care and and under my constant inspection * * * * * the process was a very tedious one and occupied myself and two other persons every evening for two weeks." On this particular magnet was wound 1,000 feet of wire, and Henry's unfinished one was larger, while "the reel of wire a mile long" was as carefully prepared. Henry must have been at work from early in the month, on these preparations for his extensive series of experiments when that memorable 29th of August came, and so we drive back the initial experiment *made before these preparations were begun,* to pursue the subject on a large scale. But it matters not for our present purpose whether this experiment was made days, weeks or months before that 29th of August, since it was before, to give Henry priority.

And so again is our point proved, since on the only day into which we must force Henry's experiment in order to give Faraday priority, Henry is distinctly busy *about something else.*

Does the paper tell us anything else to throw light upon the date of the discovery? The magnet upon which it was made tells us something. Henry tells us in his paper that the galvanic magnet used was the one described in *Silliman's Journal* vol. xix.; the one he had made to sustain seven hundred pounds. The date of the paper in which it is described is January 1, 1831, and the magnet was made in 1830. Thus is fixed for us the limit of earliness for Henry, that is, 1830, but there is something more in the use of this magnet. It suggests the probability that in this year 1830 the experiment we are in search of was made, because in January, 1831, was constructed the great magnet for New Haven, which remained in Henry's laboratory until spring came to break up the ice in the Hudson and allow it to be taken to its destination. With this more powerful, more complete magnet, in his possession, it is natural to suppose Henry would use this to ask the important question, rather than the earlier and inferior one, unless the experiment had been made before the construction of the larger one.

ISOLATED ELECTRIC LIGHTING WITH LOW-TENSION ALTERNATORS.

BY

William Smith Horry

For the last thirteen years there has been little improvement in the methods of isolated electric lighting. The direct current dynamo has undergone some changes. It was very soon recognized that the series wound machine was unsuited to incandescent lamps in consequence of its want of regulating qualities. The shunt machine was then brought out and partially remedied this want and very soon after the two systems were compounded. It then took several years to finally perfect this principle and to achieve the excellent regulation we have to-day in this class of machines. Since then improvements in detail have been made and the insulation of the whole system has been improved. The armatures of dynamos are no longer driven at some thousands of revolutions a minute and the magnetic circuit has been greatly shortened and augmented in area.

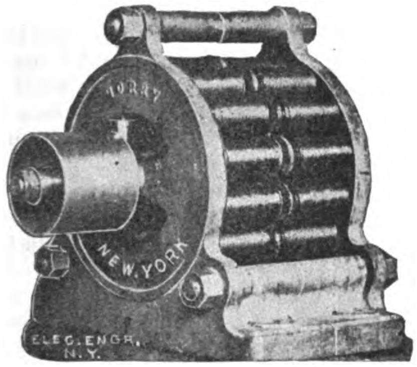
The great nuisance of the commutator has not yet been lessened in incandescent light dynamos except in so far as the speed has been reduced and it still remains an evil; the more especially as these isolated plants are mostly under the care of an engineer who rarely acquires the knack of taking care of it. The lamps themselves are infinitely more durable than they were.

Arc lamps two in series and with a resistance inserted, are now used with success and with a certain degree of economy, so that the general utility of the two wire system has been thereby extended. The principle however is greatly deficient in adjustability; both gas and oil surpass it in this one quality. When this is attained the direct current system will be as thorough as lighting can ever be that depends upon revolving commutators and moving machinery for its action.

It is quite usual to install two distinct types of machine, one for arc series lighting and another to work incandescent lamps. This is done in most installations of any considerable size. A double system of wiring is used for the different systems and the expense is great. Then there is an element of danger attending the series machines and moreover the lighting is still incomplete as it still lacks adjustability.

It is quite as important that the incandescent lamps shall be under control as that they shall be sufficiently powerful and economical. The invariable result is that with both systems of electric lighting in use in a building and with wires all over the place, gas has still to be used where adjustable lights are required. Therefore it cannot be said that isolated electric light plants, as at present installed, are perfectly successful unless helped out with gas and with two sets of mains.

It is proposed to overcome these objections by using the low tension alternator, so that one set of mains only will be needed, to answer all requirements for both arc and incandescent lamps; the latter are perfectly under control just as gas is, and the whole system is practical and economical.



HORRY LOW TENSION ALTERNATOR.

The alternating current system has fallen into disuse in isolated lighting. The main advantage it possessed was the absence of the commutator which made the manipulation of large currents very easy. Until recently there was no great demand for large currents; the extra exciting machine was therefore considered a greater evil than the commutator of the direct current dynamo. Unlike this machine, however, the alternator has been considerably improved and simplified during the last few years, so that the objections that were raised to it several years ago no longer apply. The alternator in one form or another is fast monopolizing every field where it has once gained entrance, and gives evidence of greatly extended usefulness in the near future.

The reasons for this are not far to seek. The alternating current is the natural form of electricity mechanically generated. It is unfortunate that the period of the alternations usually employed in this country for general distribution is too high to use motors profitably, but even this trouble may be overcome when we understand the laws of magnetism better than we do now. It would seem that the natural dynamic current is the one that must eventually be adopted for all dynamic purposes, rather than the peculiar current—mechanically speaking—that we obtain by the intricate and troublesome thing called the commutator.

The alternator in its most simple and latest form is now proposed instead of the direct current dynamo for isolated lighting, and possesses certain unmistakable advantages. It has neither commutator nor collectors; all the electrical parts may be fixed and the iron pole pieces alone revolved. So far as I have used this machine, however, its self regulating qualities leave something to be desired. However the difficulties arising from self-induction are not great, and can easily be met by careful designing. Another machine that is better in this way is one with a copper disc armature, similar to that shown in the accompanying illustration; here the self regulation is almost perfect, so that at all loads the electromotive force remains substantially the same, with the speed constant. The armature of this machine will stand an enormous current without injury, being open to the air on all four sides. It will run continuously with a current density of considerably over 4,000 amperes to the square inch and will transmit double that for some time without serious heating. These qualities and the great simplicity of the machine single it out as best suited for isolated lighting.

It is proposed to use this alternator wound for, say, 50 volts potential, and directly connected to the mains of the building to be lighted. Should there be grounds or large spaces to be illuminated, single arc lamps can be used in parallel where necessary, while incandescent lamps can be installed in the ordinary way. But for some purposes, especially on all the upper floors, adjustable lights are a necessity. The lamps are here inserted in the Ries regulating socket and the system then possesses all the adjustability of gas lighting.

The writer was prepared months ago to support the argument that there was considerable economy to be gained by the use of these sockets if the lamps were systematically turned down, as gas commonly is, when all their light was not required. But he was never opposed in this opinion by any evidence to the contrary, so he affirms it again here without fear of successful contradiction, and gives in detail the reason for this economy.

An incandescent lamp can be turned down by the Ries socket with very nearly the same result in economy as is gained in a gas light when turned down in the same way. Take, for instance, a fifty volt 16 c. p. lamp. This gives a sunset red glow with 12.5 volts and with somewhat less than a quarter of an ampere of current. That is to say, that the energy consumed by lamp and socket together only amounts to 3.125 watts. Sixteen lamps turned down only consume the energy of one lamp burning full on. Now a gas burner taking only a sixteenth part of five feet is very small indeed and it is carrying economy to a miserly stage to turn it down so low. Of course the incandescent lamp is a very uneconomical light giving device unless worked at its full brilliancy but a red glow can be very cheaply produced, and this is of great convenience as it indicates the position of the lamp in the dark, and also the position of its regulating mechanism. Gas also has its critical pressure and burns much less efficiently as a light giving agent when turned down. The very careful trials the writer has made with the Ries socket and the incandescent lamp satisfy him that in this respect it is very nearly on a par with water gas. Added to the economy of current, however, the lamps themselves last an infinitely longer time if their full duty be but little required. The economy of power will then be conceded just as the economy of gas is effected by its systematic adjustment as is universally practised in our stores and homes.

In carrying out this system the period of the alternator is low enough to prevent undue heating of the choking coils arising from hysteresis or eddy currents in the iron, and high enough to keep their size within reasonable proportions. About 100 periods a second is deemed best for the work. It may be objected that fifty volts entail very expensive leads in large buildings. In some cases perhaps this objection will hold good, and a higher voltage would be used, accompanied by a higher period, but it is the pressure best suited to the Ries socket and the 50 volt lamp is probably the most durable that can be made.[1]

It will be seen then that the low tension alternating system for isolated lighting is worthy of serious consideration. It is novel in so far as it possesses the quality of adjustability ; it enables the current to be taken from the machine without any rubbing parts ; it is quite simple and durable ; it admits of economical arc lighting ; and, lastly, the sphere of usefulness for the incandescent lamp is greatly extended, and is, in this system, quite applicable to bedrooms, hospitals and other places where on other systems it is so unsuited that it is for the present excluded in favor of gas. Indeed, the adjustability of this system to all requirements leaves nothing to be desired, and in this respect it is both unique and perfect.

THE PRACTICAL MANAGEMENT OF DYNAMOS AND MOTORS.—V.

BY

Francis B. Crocker and S. S. Wheeler.

CHAP. IV.—*Continued.*

Compound Dynamos in Parallel.—Since the field magnets of these machines are wound with series coils as well as shunt, the coupling of them is a combination of the cases of the shunt and the series wound machines just described.

Fig. 13 represents two compound machines in parallel.

Assume that one machine is already running, that switches F' in the shunt circuit and S^1 in the main circuit are closed, and that armature No. 1 is generating its full current and feeding the lamps on the main circuit, the shunt and series field coils of the machine carrying their proper current. Now to throw on the other dynamo, its armature No. 2 is brought up to normal speed, switch F^2 is closed, which excites its shunt coil. Switch E, on the "equalizer" is then closed, which excites its series coil with part of the main current from No. 1. The second machine then gives its full voltage, and its main switch S^2 is then closed and the voltage of the machine is regulated to make it produce its share of the current for the main circuit. It would be well to actually compare the voltage before closing the main switch, as just described for shunt machines, making the voltage equal at first, so that the machine generates little or no current, and then raise it till the machine does its share of the work.

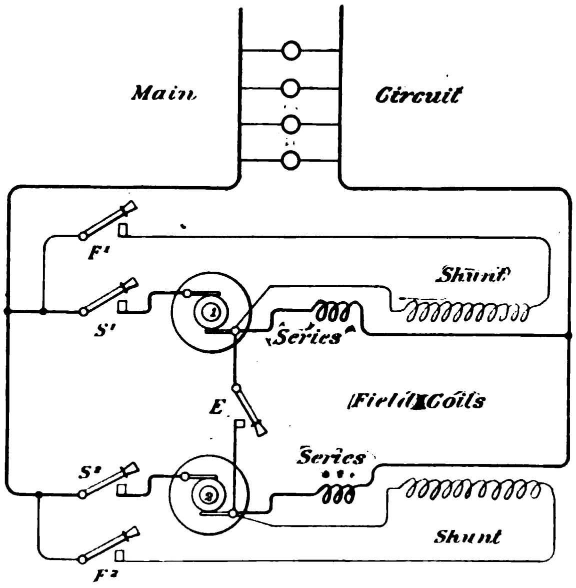


FIG. 13.—COMPOUND DYNAMOS IN PARALLEL.

In disconnecting a machine the same steps are taken, only exactly in the reverse order. More than two compound machines may be run in parallel in this way by connecting them in a precisely similar manner.

Compound dynamos of different size or current capacity may also be coupled in this way, provided of course their voltages are equal, and provided also that the resistances of the series field coils are inversely proportional to the current capacities of the several machines, that is, if a dynamo produces twice as much current its series coil should have half the resistance.

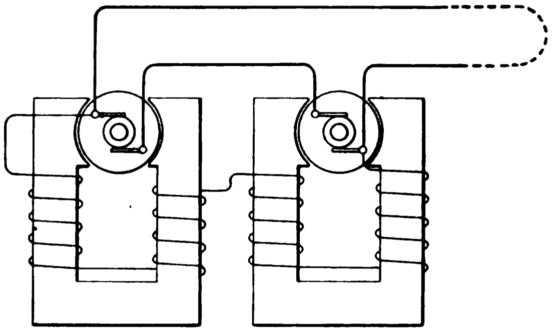

FIG. 14.—SHUNT DYNAMOS IN SERIES.

The switch E is often left closed all the time, in fact, a permanent "equalizing," connection may be made between the corresponding brushes of two or more machines. This has the effect of "compounding" the dynamos collectively instead of individually. For example when only one dynamo is working, its current divides among the series coils of all and these coils will not be highly excited, when however all the dynamos are working the whole current of each will pass through its series coil. Thus the greatest field strength and therefore voltage is produced when most needed—at full load. The equalizing conductor should be able to carry at least half the full current of one dynamo. This method of running compound dynamos in parallel is important because it makes the effect of the series coil proportional to the total load, not to the load on each machine. This is particularly desirable in central stations or where the dynamos are "overcompounded." Compound dynamos run in parallel in this way, as well as shunt machines, tend to steady each other, for if one happens to run too fast, it has to do more work which opposes the increase of speed, and it also takes part of the load off the other machines which will therefore tend to run faster, thus producing equality. This mutual regulation will take care of any slight difference between machines such as the slip of belt, but the difference must not be great.

Alternators in Parallel.—Since the alternating current consists of waves, it is necessary, in order to properly connect alternators together, that they should agree in two respects—first, in *frequency* or the number of waves produced per second, and second in *phase*, that is, they should be at corresponding points of the current waves at the same instant. The case is precisely similar to that of two persons walking together, they should not only have the same *rate* but they should also be in *step*. If an alternator is thrown into circuit with others when not in phase it will cause several severe fluctuations in the lamps, and then the machines will bring each other into unison since they exert a mutual control on each other, similar to that just described in the case of compound machines, only much stronger. In fact, an alternator resists being thrown out of step with others by an amount equal to the full torque or pull required to drive it.

---

[1] Since writing this, the writer has obtained excellenr results with 175 periods a second. The choke coil sockets are considerably smaller than the general size: in fact, they need be but very little larger than ordinary key socket. It stands to reason that a much better result can be obtained when the dynamo is adjusted to suit the socket than when this latter has to conform to a certain fixed system.—W. S. H.

Therefore to throw an alternator into circuit with others, bring its speed up to the proper point, regulate the field exciting current to make the voltage of the machine equal to that of the circuit.

The phase may then be determined by connecting one lamp to the secondary circuits of two transformers at the same time, one in circuit with the machine to be switched in and the other on the main circuit. The secondaries of, say, 50 volts each should be connected in series with each other and to a 100 volt lamp. When the machines are opposed the lamp is dim and vice versa. If the lamp flickers badly the phase is not right, but if the lamp is steady the machine is in phase and it may be connected by closing its main switch without disturbing the circuit. If dynamos are rigidly connected to each other or to the engine so that they necessarily run exactly together, there is no need of bringing them into step each time, but they should be adjusted to the same phase in the first place.

Dynamos in Series.—This arrangement is much less common than parallel working and does not usually operate so well. The conditions are exactly opposite in the two cases.

To connect machines in series the + terminal of one must of course be connected to the — terminal of the next and so on. If dynamos are in series each of them must have a current capacity equal to the maximum current on the circuit, but they may differ to any extent in E. M. F.

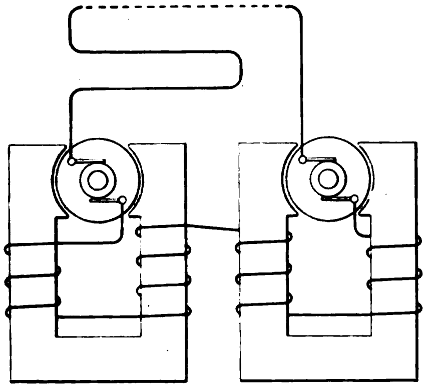

FIG. 15.—SERIES WOUND DYNAMOS IN SERIES.

The voltages of machines in series are added together, and therefore danger to persons, insulation, etc., is increased in proportion.

Shunt or Compound Dynamos in Series may be run well, provided the shunt field coils are connected together to form one shunt across both machines as indicated in Fig. 14.

Series Wound Dynamos in Series may be connected in the simple way represented in Fig. 15, but usually machines are connected in series for arc lighting when, for example, two forty-light dynamos are run on one circuit of eighty lamps, in which case the dynamos usually have some form of regulator. These regulators do not work well together because they are apt to "see-saw" with each other. This difficulty may be overcome either by connecting the regulators so that they will work together or by setting one regulator to give full E. M. F. and let the other alone control the current. This latter plan can only be followed when the variation in load does not exceed the power of one machine.

Alternators in Series.—The same mutual regulating tendency which makes alternators run well in parallel causes them to get out of step and become opposed to each other in series. It is impracticable to run them in series unless they are rigidly connected to run exactly in phase so that they add their waves of current instead of counteracting each other. This is a case that rarely arises in practice.

PHYSIOLOGICAL OBSERVATIONS AT THE McILVAINE ELECTROCUTION.

BY

A. E. Kennelly

THERE are certain physiological facts brought to light in the last electrocution at Sing Sing, N. Y., on the 8th inst., which have a certain importance from a purely physical point of view, especially as this has been the first occasion on which the particulars of the event have been published under the revised legal enactment.

The electrical pressure at the electrodes was determined from a Cardew voltmeter in circuit with a non-inductive resistance. The current passing through the electrodes was observed from a direct reading dead beat ammeter, and the indications of these carefully calibrated instruments afford reliable inferences as to the resistance of a human body, under definite conditions of surface contact, to an alternating current making some 150 periods per second.

From the official records as already published it would appear that in the first application the pressure at electrodes was maintained at approximately 1,600 volts and the current which commenced at 2.0 amperes steadily increased during the 50 seconds of contact up to 3.1, indicating a resistance between electrodes diminishing from the initial value of 800 ohms to a final value of 516, a reduction during the interval of more than 35 per cent. The electrodes were metal plates in large wooden receptacles nearly filled with tepid salt water, and in which the hands of the criminal were immersed. Judging from the fact that although the skin of the hands was blistered over the areas above the water level that had been wetted by first immersion and then withdrawn, yet the skin that remained immersed was entirely uninjured, it seems reasonable to suppose that no very large proportion of the whole resistance of the body would reside in the integuments at the electrodes.

In the second application 43 seconds later, the pressure was observed to be maintained at approximately 1,500 volts, and the current which passed between the forehead and the calf of the right leg continued at 7.0 amperes during the 36 seconds of contact, indicating a resistance practically steady at 214 ohms during that time. The electrodes were of sponge kept thoroughly wetted with cool salt water and backed by metallic plates, the area covered by each being about 100 sq. cms. Since no blistering took place immediately beneath the head electrode, although some blistering occurred at the other, it would appear that no large proportion of the total resistance existed in the contact areas.

The mean activity developed in heat during the first application was thus 4,080 watts and in the second 10,500 watts or about 14 E. H. P., this large expenditure of energy accounting for the considerable post mortem temperatures that are stated to have been observed.

The average resistance of the human body between the hands immersed to the wrists in dilute solutions of salt or soda, is often overstated in measurement owing to the vitiating influence of polarization on observations taken with feeble currents in the Wheatstone bridge. Correct readings can, however, be obtained either by bridge measurement to "immediate false zero" or by the use of large resistances inserted directly in the electrode circuit through a galvanometer so as to employ a higher pressure without pain to the subject and so reduce the influence of the possible 2.5 volts of polarization counter E. M. F. In either case the mean resistance under these conditions is about 1,000 ohms.

The inference appears to be drawn that the resistance of the body between hands to an alternating pressure of 1,500 volts is only about one-half what it is to continuous pressures of 5 volts or to alternating pressures of 2 or 3 volts, and from the observations above mentioned it would seem that the resistance between forehead and calf is very much lower than between immersed hands. While in conclusion the general belief is further substantiated, that the quantity of current which may pass through the body from a contact with high pressures will entirely depend upon the area and moisture of the contact surfaces, being large with extended and wet surfaces, but perhaps comparatively small for brief contacts on dry and limited surfaces of touch.

PORCELAIN AND GLASS INSULATORS.

BY

James Bowstead Williams M.A.C.

Having spent several years in the practical examination and use of insulating materials, I would like to contribute to the columns of the Engineer some of the results obtained from actual tests of glass and porcelain insulators now in general use. These tests were made with a quadrant electrometer designed and made by myself in 1886, for the express purpose of testing insulating materials by means of charges of several thousands of volts, and upon the indications of which I could rely.

My method of testing the insulators is substantially as follows: I take a "pony" glass insulator, mount it upon an insulating pillar, and secure a fine wire in the groove which is intended for the reception of the line wire. The fine wire is then connected with one pair of quadrants and charged to a potential of about 5,000 volts. As long as the insulator remains untouched by any conducting body no leakage of the charge occurs, and the spot of light will remain stationary at one end of the scale for hours; but the instant *any* portion of the insulator is touched with the finger, or even with the point of a pin, the charge escapes and the spot of light rapidly passes down the scale to zero. If a large porcelain insulator is subjected to the same conditions as the glass insulator, the charge also escapes, but not so fast, and the spot of light passes down the scale to zero a trifle slower than when the glass is touched.

Now, if these insulators are washed perfectly clean, and dried without touching the outer surface, and then tested as soon as dry and cool, their insulation resistance is practically infinite, using the same potential as before. If we allow either of them to remain on the insulating pillar and untouched for a few minutes, in an ordinary atmosphere, and then test as before, we find that there is some leakage; and this leakage continually increases until, in from one-half to one hour's time, according to the state of the weather, it is almost as great as at first. The reason why it is not quite as great as at first is because there is only a film of moisture, for the conducting body, on the surface of the insulator; whereas, when purchased, the insulator contained a conducting film composed of moisture *plus* dirt. If we compare the amount of leakage of the glass and porcelain insulators we find that the amount is less on the porcelain, and that it does not augment as rapidly as it does in the case of the glass, after both have been cleaned and dried.

Then why is the surface leakage of the glass greater than that of the porcelain? For it is over the surface that the charge escapes, and not through the mass. And why does it not increase as rapidly in the case of the porcelain as it does in that of the glass? In order to answer these questions to my own satisfaction, I tested many kinds of glass and found that the richer the glass was in silica (as I believed) the higher was its surface resistance, and therefore its specific resistance. In fact, I once found a flint glass vessel, having about the same surface area as that of the ordinary glass insulator, a vessel that had been handled for some time without being washed; and yet there was no surface leakage, even when a zone or band of tinfoil was placed on the glass about one inch from a fine wire secured around the vessel and the tinfoil electrically joined to the earth. If the vessel was filled with water and emptied, and then tested, there was still no leakage. These tests, were made in San Francisco, in the summer time when there is always considerable moisture in the air, and the insulators tested were those supplied to the trade, and of Eastern manufacture.

From the many experiments and tests I have made I concluded that the best answer to the above questions I could make to myself—whether the answer will satisfy others I do not know—was simply this: The glazing on the porcelain insulators contains more silica and less alkaline matters and metallic oxides than the body of the glass insulators.

How can the present trouble be remedied? If the leakage over the surface of the insulators can be prevented we need not trouble ourselves much about leakage through the mass, unless the compositions contain a considerable amount of ingredients which conduct electricity. Secure a pretty wide zone or band of highly insulating material, somewhere on the inner surface of the bell, of glass or porcelain insulators, the insulating material to be to a high degree anhygroscopic, and which can be renewed from time to time as required, and surface leakage will be prevented on those insulators just as long as this material is kept free from dust and moisture, provided the material does not deteriorate or change by exposure to the atmosphere.

The writer has often wondered whether a "double bell" insulator, with its inner bell formed of glass containing a large proportionate quantity of pure silica, and well protected from rain, dust and mechanical injury by the outer bell, could not be made, which would afford sufficient insulation for wires carrying high-tension currents. It is evident that if the stems which support the insulators could be made to possess good insulating properties the more efficient would be the insulation of the line wire.

NOTE ON THE ELECTROMOTIVE FORCES OF BATTERIES.

BY

Townsend Wolcott.

In his article in your issue of December 30, Mr. Maurice Oudin mentions the fact that the calculated E. M. F. of a battery does not always agree with the observed value of the same, and then passes on with a mere conjecture as to the cause of the discrepancy. A little study of the matter, however, will show ample cause for all differences.

We know that a given amount of electrolysis in the cell represents a given quantity of electricity; further, that this same electrolysis represents a definite quantity of energy furnished by the chemical action. Now if we divide the energy by the quantity of electricity we obtain the E. M. F. which the battery would give if all the energy from the chemical action went into the current. Even though we were entirely without experimental data regarding actual batteries, we would have no right to expect (according to the theory of probabilities) that the efficiency of conversion would be exactly 100 per cent. in all, or in even a majority of cases, and if cases of 100 per cent. conversion were found they should be regarded as exceptions.

But, as a matter of fact, we are already in possession of sufficient data to speak more definitely on the subject. No theory of a cell would be complete without taking account of every bit of work done in the cell. For instance, in the ordinary "gravity" cell, there is dense copper deposited on the bottom, and the centre of gravity of the cell is somewhat lowered, and energy is given out. This energy must either go to heating the solution or else be added to the electrical energy by increasing the E. M. F. of the cell; which we cannot assert without an intimate knowledge of everything which takes place in the cell. However insignificant the amount of this energy from a practical point of view, it illustrates a theoretical principle just as well as though it were larger in amount.

There is, however, a much more important principle concerned, namely, that the energy from a chemical action is, in part at least, subject to the laws of thermodynamics. We know the electro-chemical equivalents of most substances with a degree of accuracy which is probably all-sufficient for practical purposes, but the energy of chemical action has not been so accurately ascertained, and even if it had been under given conditions, it does not follow that the conditions would be fulfilled in the battery cell.

When a body passes through a cycle of changes regarding temperature and volume, it is not sufficient to know the initial and final states of the body in order to compute the total energy given off or absorbed, but the state of the body at each instant of the intervening time must be known. We may know exactly what chemicals we put into a battery when we charge it and what we throw away when the cell is exhausted; but, unless we know the exact history of the whole for the intervening time, we cannot calculate the thermodynamic part of the E. M. F.

We know that the E. M. F. of all batteries is more or less affected by a change of temperature, and it would seem probable that a cell whose E. M. F. increases with the temperature might in some cases even absorb heat from surrounding objects and convert it into electric energy. Or, at all events, we should expect to find the reverse; that is, if we had a battery which was found by experiment to absorb heat and convert it into electrical energy, we should expect to find that it had a positive temperature coefficient. For, supposing the cell enclosed in a heat insulating case, the refrigerating action of the current would gradually use up the whole supply of heat and the E. M. F. must sooner or later drop to that value which it would have without the absorption of heat, so that the temperature coefficient would, on the whole, be positive, though not necessarily following any predicable law.

In a battery with a positive temperature coefficient we must either show that the actual available energy of the chemical actions is greater at a higher temperature, which is not particularly likely; or else assume that the efficiency of conversion is higher, perhaps above 100 per cent. Suppose the efficiency of conversion less than 100 per cent.; then the surplus energy of combination, after doing what mechanical work (if any) was necessary upon the contents of the cell, would go to heating the latter. Now, supposing the cell enclosed, as before, in a heat insulating case; we are not so sure of the result as before, but it is most probable that the temperature coefficient is negative, as in this case the accumulation of heat would tend toward a finite limit. The only way of reaching a finite limit with a positive temperature coefficient, is to suppose the efficiency of conversion to increase faster than the heat accumulates, until no more heat is given off, beyond which point heat would be absorbed.

ELECTRICAL HORTICULTURE.

A Paris electrician has succeeded by means of his battery in forcing violets. The first bunch, it is said, was raised in four hours, at the end of which time it was plucked, tied with a ribbon and sent to the ex-Empress Eugenie. It would be interesting to learn just how much truth is contained in this statement.

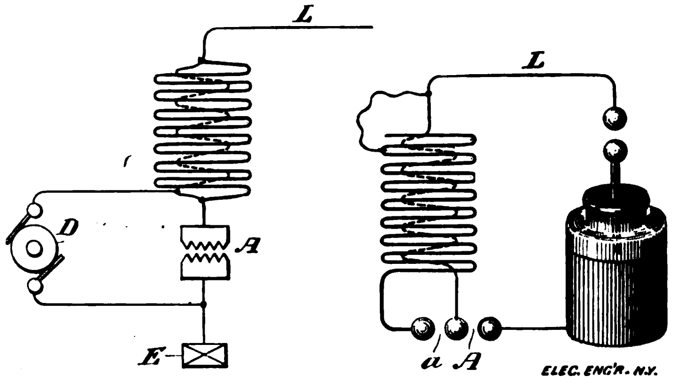
INDUCTION BY HIGH POTENTIAL DISCHARGES.

BY

Elihu Thomson

It is well known that electric lines are strongly affected by induction during thunder storms, and it would naturally be inferred that a line in a direction parallel to the flash would receive the strongest inductive influence, and that the induction would not necessarily be static induction, but currents would be set up by dynamic induction, complicated in many cases by static inductive actions occurring at the same time. What are known as "return strokes" in lightning flashes, according to this view, may be nothing more or less than parallel induced discharges along fairly good conducting paths, and it is possible that in the neighborhood of a lightning flash such induction may be of a very intense character. These considerations led to my making the experiment of inducing, by a Leyden jar discharge, passed through a single turn of insulated wire, a discharge in a ring shaped vacuum tube placed alongside, which was found to illuminate the vacuum. Similar experiments had been made and published by Prof. J. J. Thomson.

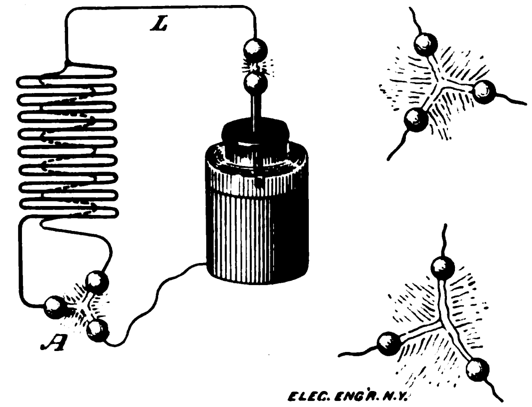
In working to devise a means for the protection of electrical apparatus from the effects of such induced discharges of lightning, it occurred to the writer to employ the inductive effects of the discharges to counteract, as far as possible, the effects of such discharges, or, as it were, to interpose a barrier between the discharges and the apparatus to be protected. This gave rise to a lightning discharge protector or lightning arrester, the principle of which is shown in the accompanying sketch, Fig. 1. Let L be a line leading from the dynamo or other electrical apparatus and subject to induction from lightning discharges, or subject to lightning discharges themselves, as in a railway trolley line. Let D represent a dynamo with one terminal grounded and the other connected to line. In such a case were there no provision for protecting the dynamo D from a lightning discharge it would be in danger of injury in case of induction occurring along the line or in case of a flash reaching the line. To avoid this I place between the dynamo and the line a sort of induction coil which consists of a double coil, each coil being made of a few turns of coarse wire, highly insulated from each other. One of the coils may be wound upon the outside of a glass cylinder and the other may be wound in the interior thereof. Both are connected to line at one end, as shown, and one or both are connected to earth through the discharge plates of a lightning arrester A provided with an arc rupturing device, such as a magnet to blow out the arc in case the potential of the dynamo is high enough to maintain such an arc. The coil in the dynamo circuit has been found to need a few more turns than that in the earth circuit and the di-



Figs. 1 and 2.

rection of winding in the two coils is such that they are opposed in their inductions, or that a discharge passing from line to earth through one of the coils tends to induce a discharge in a direction towards the line in the other coil, or the coil in the dynamo circuit.

The manner of experimenting to determine the relation of the coils was substantially as follows: A double coil was made, Fig. 2, in which the inner turns were about 12 and the outer turns 20. These were kept separate from each other and a branch wire taken from the line and slid from point to point on the outer wire enabled the effective length of the same to be adjusted. The inner coil was connected through a small spark gap, as at A, to the outer coating of a Leyden jar, while the wire L was brought near the pole of the jar which was continually being charged from a Toepler-Holtz machine. The discharge in passing from the knob of the jar to the wire L, representing the line, passed by the inner coil. When a certain length of the outer coil was employed only a very short, almost imperceptible spark was obtainable at *a*. If the balance of the turns were disturbed by including more or less than the proper number of the outer turns, not only did a vigorous spark occur, but the gap at *a* could be quite considerably extended, in accordance with the amount of departure taken from the proper number of turns required to produce the balance. This experiment indicates that it is possible to make a selective path for the Leyden jar discharge and to have, as in Fig. 1, a structure so proportioned that the discharges reaching line will pass to earth without tending to go through the circuit of the dynamo D. The action is apparently due to a balance of electromotive forces such that the discharge which tends to pass from the line in going to earth induces in the coil connected to the dynamo a counter-electromotive force which nearly wipes out the potential of the discharge before it reaches the dynamo. This balance of inductive effects is certainly very striking, and once obtained, it is disturbed, as, in the experiments, by changing the relative lengths of the coils in inductive relation through so small an amount as an inch or two.



FIGS. 3, 4 AND 5.

It may be mentioned here that some curious effects of spark were obtained in these experiment. When a disturbance of the balance exists and a spark is obtained at *a*, the character of the spark is different from that of the Leyden jar discharge. It appears to be less luminous, the noise less sharp and its color would indicate a greater power of volatilizing metal and perhaps a greater duration. It is in part, no doubt, due to a current local to the coils in series with one another.

Another curious effect was the production of **T** shaped and **Y** shaped sparks, or three-branched sparks—such as are shown in Figs. 3, 4 and 5.

These were obtained by separating the electrodes at A an inch and a half or thereabouts and bringing the third electrode from the outer coil to the position shown in Fig. 3. The discharges were now obtained as before from the charged jar. In this case the discharge appears to split and unite in air, producing the curious shaped sparks shown. It would seem that to obtain these effects—particularly the sparks which were three-branched from a common point in the centre between the discharge electrodes—the dielectric air must break down simultaneously between the three electrodes. It would easily explain the **T** shapes to assume the straight part above to form first, and the cross or transverse spark to strike from the side of this spark to the third electrode.

The induction effects obtained with the apparatus described soon led the writer to reason that the passage of heavy condenser charges through a coarse wire primary coil of few turns might be made to induce in a finer coil of more turns wound parallel thereto discharges of much higher potential and less current. In this case the Ruhmkorff coil would, as it were, have its primary subjected to the oscillations of a condenser discharge of high potential, instead of low potential battery discharges raised in potential by the condenser and interrupter.

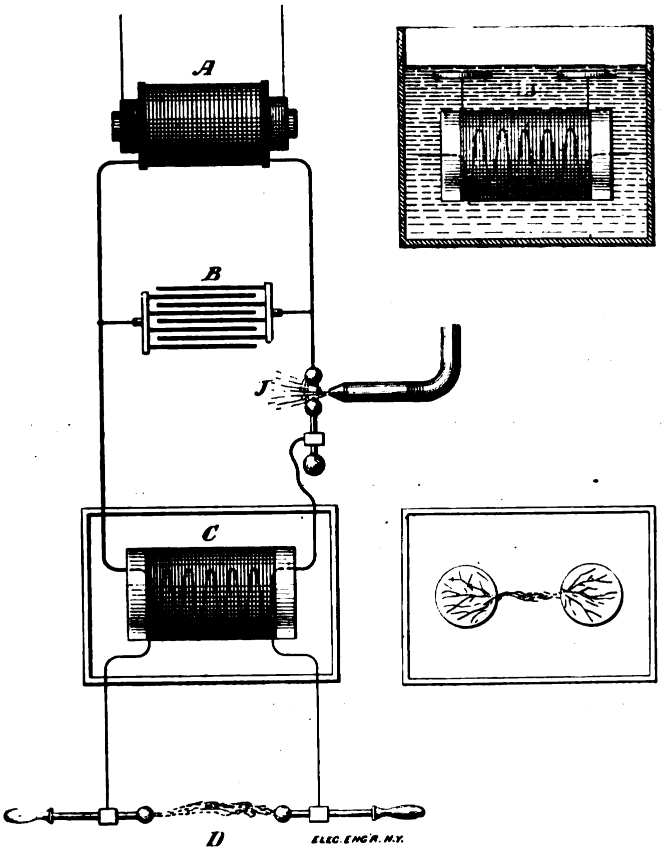
On trying the experiment with a coarse heavily insulated wire coil of about ten turns enclosed in a glass tube, without any iron core, and with a secondary of one layer of fine silk covered wire outside the glass, it was found that the passage of the Leyden jar discharges of about ½ inch spark in the coarse coil would give rise to such high inductive effects in the secondary as to spark from turn to turn in the single layer. By immersing the whole in a jar containing insulating oil, however, the insulation of the turns was better kept and sparks of two or three inches were obtained between the terminals of the secondary at every discharge of the jar. The glass tube used was about 2 inches in diameter and about 5 inches long. There were about 120 turns in the secondary layer. The induction must have been at least as high as from 100 to 150 volts to the inch of wire. It was soon found that the glass tubes ⅛ of an inch thick were frequently punctured under the oil, and that the spark of the jar could not be unduly lengthened without producing discharges under the oil or between turns of the secondary.

The sparks from the secondary were peculiar in that they appeared to be prolonged and quite like those of a Ruhmkorff coil worked in the ordinary way but with small condensing surfaces on each terminal of the secondary.

Arrangements were now made to obtain frequent condenser discharges at high potential and to carry on the experiments on a much larger scale. The results have shown that it is now in our power to obtain torrents of long sparks, and that this may be done without any very great expense for apparatus, the expense being very great in the case of the large Ruhmkorff coils hitherto made. Sparks of two or three feet long will, I think, be readily obtainable. The sparks are like those obtained from small jars and if the terminals be connected to jars in the same way as the condensers are attached to a Holtz machine the thickness of the sparks can be increased at the sacrifice of length.

I will now describe the apparatus I use. This will give a torrent of sparks of 7 to 8 inches in length making a loud roaring sound and the length of spark seems limited only by the capacity of the secondary coil to maintain the insulation. This will be improved in the next construction.

In Fig. 6 is shown a view of the apparatus used. A is a large induction coil or transformer capable of using in its primary ordinary alternating lighting currents of 50 to 100 volts and transforming up to 10,000 to 12,000 volts alternating. So used it will spark over ½ inch to one inch between its terminals and give the uprising thin arc now well known. A blast of air blown on such an arc charges it into a beautiful pale purple flame. A condenser B the capacity of which can be changed, is connected to receive the current from the secondary of the A. The spark or arc with moderate condensing capacity is not much changed unless a blast of air be blown upon it. In this latter case it becomes a most beautiful electrical phenomenon. It becomes a mass of flame filled with fine and thick shreds representing the condenser discharges, a gorgeous network of electric fire changing with any change of the pressure or direction of the air blast. Sometimes, as on breaking the primary circuit, the oscillations of charge and discharge are seen as minute parallel lines or sparks on the borders of the flame joining the terminals. With greater condensing surface the discharge between terminals becomes more thick and white even without the blast, and when a forcible air jet is turned on it roars very loudly. At C is a second and peculiar transformer, the primary of which is an open helix of but a few turns, about 15 or 20 convolutions, of heavily insulated line wire, about four or five inches in diameter. This is surrounded by a thick glass cylinder upon which has been wound say 150 turns of fine silk covered wire in one layer with a silk thread between the turns so as to cause the turns to be well insulated laterally.



Figs. 6, 7 and 8.—Apparatus for Obtaining High Potential Discharges.

This simple induction coil is now immersed in a jar of heavy oil and the terminals, on leaving the oil, are kept as far apart as possible and surrounded by glass tubes. The terminals of the coarse and short primary are connected in circuit with the discharge balls upon which the jet of air plays at J. The finer secondary terminals are connected to discharge terminals, as at D, for obtaining the spark. On passing the alternating current in the primary of A and adjusting the spark gap and jet at J, as well as the distance between the discharge terminals at D, it is easy to obtain sparks of 7 to 8 inches in a perfect torrent at D, while sparks of $\frac{1}{4}$ inch are passing at J. In fact coil A and condenser jars B constitute the source of very rapid electric oscillations and correspond to the primary battery and condenser of a Ruhmkorff coil, while the air jet and spark gap at J bear a similar relation to the interrupter.

The discharges obtained at D represent, it would appear, at least 150,000 volts in potential, or about a thousand volts to each turn of the secondary. The potential may be higher, for we have no data of spark length at such high pressures. It should be mentioned that the limit of spark was apparently that of the insulation of the secondary turns, for on attempting to increase it by separating the terminals at D to over 8 inches, the sparks jumped in the jar of oil and could be seen passing under the oil from the secondary to the primary wires. Were it not for the required insulation between the turns of the fine wire secondary of C, they could be wound in one layer so as not to cover more than two or three inches of the glass cylinder and could be made to give out sparks of a foot or more in length. The volts per inch of wire obtained in these experiments are extraordinary and it is quite certain that the limit will depend on the insulation. We are now possessed of the means for obtaining artificial lightning in a steady stream, and can experiment at will with extremely high voltage. The advantages of oil insulation are emphasized by these experiments, and although sparks frequently passed under the oil the insulation renewed at once.

It is necessary that the coil C be sunk well below the surface of the oil as otherwise the discharges will perforate the oil layer at each end and pass over the surface. It is curious to note the agitation of the oil over the coil when the apparatus is in action and the coil is not deeply immersed and yet sufficiently so to prevent discharge.

A curious discharge without electrodes is obtained by providing each terminal of the secondary layer C with a metal plate which the oil just covers, the plates being parallel to the oil surface, Figs. 7 and 8. Great agitation of the oil over the plates ensues, and sparks pass over the surface of the oil and spread over the surface just above the plates. If the oil layer be too thin it is perforated by discharges passing from plate to plate, and oil is scattered. Geissler tubes are lighted in the vicinity of the coil, outside the jar or near the terminals, an action long well known in the case of the working of Ruhmkorff coils of considerable power. The frequency of the alternations used was 125 or 250 alternations per second. By raising the alternations the spark torrent will be more continuous. On the completion of still more powerful and perfectly insulated apparatus, the effects will doubtless be greatly enhanced.

The experiments demonstrate that lightning discharges, aside from electrostatic effects, may be the source of most vigorous electro-dynamic inductions, and that high potential discharges may result. The bearing of this on a "return stroke" has already been mentioned.

It may also be pointed out that in the electro-dynamic inductions set up we have a means for the study of the rate of oscillation, potential and current of lightning discharges which are now but little understood. It is too much to assume that all such discharges take the oscillatory character of Leyden jar discharges, and it would be useful to distinguish between rates and characters of discharge. The writer remembers that during a storm a few years ago he noticed a ringing or humming sound accompanying a not very distant flash of lightning. The sound was remarkably clear and almost musical. Could it have recorded the oscillations of a discharge in which the capacity and self induction were such as to give the oscillations a defined rate within the ordinary range of pitch of musical sounds? It is an observation which the writer takes the present occasion to record, as a strong impression was made on him on account of the loud, clear, ringing tone which followed the flash.

ELECTRICITY IN AGRICULTURE.

It is stated by our contemporary, the *Electrical Engineer*, of London, that W. W. Rawson, market gardener, of Arlington, has found that the use of electric light has increased his profits from the growth and sale of lettuces, etc., by more than 25 per cent.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, FEBRUARY 17, 1892. No. 198.

The good engineer aims not only to attain his results, by the best means, but to attain only such results as will pay.—Ashbel Welch.

MR. EDISON'S MISTAKE.

IN the consolidation of the Thomson-Houston and Edison companies, the former comes out a little ahead, in many ways. The discontinuous, frequently changing, though often able, organization and management of the Edison interests have doubtless contributed largely to bring about this result, but may not a more fundamental cause be found in the attitude taken, and persistently held, by Mr. Edison towards alternating current distribution? He could see no merit in that system. But upon its advent, its possibilities were promptly perceived by others. It was soon reduced to commercial availability, and, since its introduction for long-distance service, six years ago, it has practically driven the direct system from the field of much central station business. Mr. Edison set his face against it as a flint from the first, and has sought on every possible occasion to discredit it through the weight in the community of his justly great name. But the tide would not turn back at his frown. A great prestige may often prevail against arguments merely, but not against established facts. It is both interesting and pleasing to note, at this time, the extent to which one of Mr. Edison's most deeply rooted convictions has been carried out in the electrical work of the last few years. We mean his advocacy of the multiple arc system of distribution as against the series system. It was soon found requisite to resort to parallel circuits to make alternating current distribution economical, that is, commercially practicable; street railways are operated in multiple; and the use of arc lamps in multiple, on distributing circuits, is constantly and rapidly increasing.

Under whatever name, and by whomsoever conducted, the industries of electric lighting and power transmission will bear the impress of Mr. Edison's genius in many of their most salient features. His name and fame are too deeply impressed upon the world to incur any risk of obscuration through any changes of business or methods.

THOMSON-HOUSTON AND EDISON.

ALTHOUGH awaiting till May 1 the formal assent by holders of a majority of the stock of both companies, the consolidation of the Thomson-Houston and Edison companies is evidently a foregone conclusion, on substantially the plan announced a week ago. The parties to the agreement would hardly have entered into it without possessing a majority control of both stocks. It seems quite reasonable to expect, as many do, and as rumor has it, that the absorption of the Westinghouse Company into the proposed new corporation will soon follow. The provision of $16,600,000 of stock—$6,000,000 of which is in preferred shares—remaining to the treasury after taking up the Edison and Thomson-Houston stocks, is thought by many to imply the use of a considerable portion of it in taking over the Westinghouse Company when convenient; but no definite information of such a plan has been made public.

The title under which the new company will organize is not officially announced, but it is confidently asserted, in several quarters, that it will include neither "Thomson-Houston" nor "Edison." "The General Electric Company of America" has, we understand, been considered as a proper title. But more important than changes of name will be the necessary changes in personnel and in administration. The general office will doubtless be in New York. Current opinion, apparently well founded, assigns the presidency to Mr. Hamilton McK. Twombly, and the general managership to Mr. Charles A. Coffin, now vice-president of the Thomson-Houston Company and its active manager. Mr. Twombly has been prominent in New York financial and business circles for some fourteen years; first as a director and one of the vice-presidents of the Western Union Telegraph Company, in which offices, among other duties, he had the supervision of the purchasing and supply departments as well as of the extensive factory which that company then maintained for the manufacture of its apparatus. Some readers connected with the telegraph service will recall the assiduity, energy and efficiency that characterized Mr. Twombly's participation in the Western Union management. He has, for the past ten or twelve years, been chiefly occupied in railroad and transportation affairs, in connection with the Vanderbilts.

Every one acquainted with electric lighting and power is aware that Mr. Coffin has for years been the daring and successful executive of the Thomson-Houston Company; the leader who has brought it, step by step, in quick succession, to its present commanding position. Mr. Villard, who had just been re-elected president of the Edison General Electric Company, presented his resignation to the trustees at their meeting on Friday last, to take effect not later than April 1.

Changes of one sort and another must be inevitable in the assignment of prominent positions in the managment and the conduct of the combined business of the two companies; but in view of the steady growth of the industry it is quite certain that all persons of approved efficiency will, if they choose, find their services in demand in the work of the new corporation.

MR. TESLA'S LATEST WORK.

THOSE who had the good fortune to attend Mr. Tesla's famous lecture at Columbia College last May, will probably have evinced no surprise on reading the account of his lecture delivered in London, as given in our cablegram last week. It must indeed have been apparent to even the most casual observer that Mr. Tesla's researches had extended much further than the limits of a single evening would permit him to touch upon, while, on the other hand, it was but natural to expect that so skillful an experimenter as Mr. Tesla would make considerable progress during the time intervening between his first lecture and the one just delivered. The latter, is, if anything, even more striking in its results and in its possibilities than that of last May, which came as a revelation to electrical engineers. In it Mr. Tesla has demonstrated not only a number of facts of the highest importance as bearing upon the modern views of the nature of electricity, but has actually shown how to apply some of his results in actual practice. Thus, the operation of a motor running on one wire and even without any connection with the generator would alone have sufficed to make the occasion a memorable one; but the numerous other beautiful experiments performed confirm the opinion, already well grounded, that Mr. Tesla has opened up a new and vast field not only of research but of practical applications. The London Institution of Electrical Engineers and the Royal Institution are to be congratulated on having had Mr. Tesla's latest results first brought out before them, and it is understood that the American Institute of Electrical Engineers will be similarly favored by Mr. Tesla on his return.

TECHNOLOGICAL TRAINING IN CHICAGO.

THE CHICAGO ELECTRIC CLUB has done a very timely and creditable piece of work in setting the ball rolling for the foundation of a technological school that shall be in some degree commensurate with her other institutions and her place as a great American city. The matter was brought up in an able paper by Mr. F. W. Parker and was discussed by President B. E. Sunny and others in a highly practical and forceful manner. From the presence of President Harper, of the University of Chicago, at the meeting, and the fact that he has since conferred with a club committee composed of Messrs. Parker, Sunny and Besley, it looks as though a technological institute, on broad lines, affiliated with the university, may be the result of the movement—very much as the School of Mines is a part of Columbia College in this city. It is an honor to the electrical fraternity that they have been so active in so vital a matter, and we can only hope that in return the work of the new school will take full recognition of the manner in which electrical engineering touches every other interest and profession. Nothing is too good for such a progressive city as Chicago, and she should see to it, therefore, that the training given by her new school is the very best that men and money, and a high ideal, can make it. We note that it is proposed to combine with the Institution a Physical Laboratory and a Museum of the Mechanical Arts. The World's Fair should leave behind it a liberal equipment for both, without cost.

THE BUFFALO ELECTRIC LIGHT CONVENTION.

OUR readers will have gathered from the news already published in these columns and from the programme which appears in this issue that the Buffalo Convention of the National Electric Light Association will be a meeting of great importance and interest—one that is likely to be up to the highest level yet attained by these gatherings, and perhaps, owing to the special conditions of the hour, destined to mark a distinctly new departure in electric lighting development in America. While the exhibitional and social features will wisely be subordinated, they will not be altogether missing, and promise to supplement in due proportion a business programme of unusual strength. The officers of the Association have shown good judgment in this, and as President Huntley is a man with a lucky star, the result may be depended upon as pleasing to everybody. In all probability a year will pass before the Association convenes again, and we advise our electric lighting friends therefore to make the most of this opportunity of reunion.

PORCELAIN vs. GLASS.

THE controversy regarding the relative advantages of porcelain and glass insulators was the subject in our last week's issue of a communication from Mr. Frank W. Jones, electrician of the Postal Telegraph Cable Company, in which he gave the results of actual tests made on these two types, and which demonstrated the superiority of porcelain in the most striking manner in all conditions of weather. In this week's issue Dr. J. B. Williams adds his testimony to that of Mr. Jones, and demonstrates by another method of testing, the superiority of the porcelain insulator. He also adds an interesting note as to the probable cause of this superiority, which he attributes largely to the inferior quality of the glass used on insulators as usually manufactured.

High-Tension Electricity.

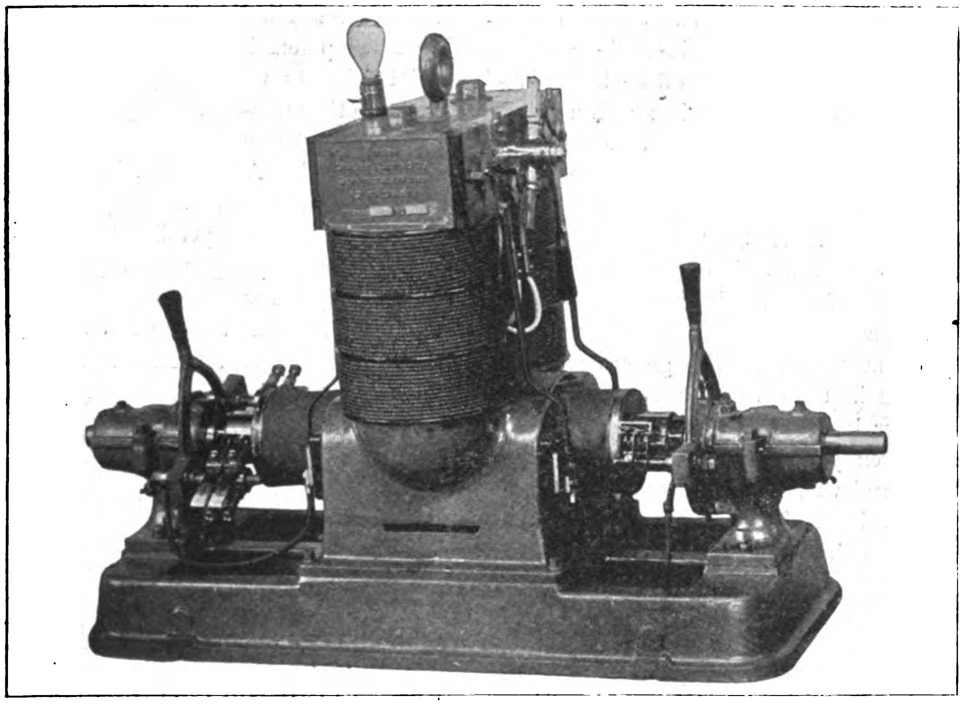
ON another page we print a highly interesting communication by Prof. Elihu Thomson, in which he describes apparatus that cannot fail to fascinate the large number of students and experimenters who are gradually taking up the work of high-tension electricity. The results obtained by Prof. Thomson with such simple apparatus will largely aid in fostering this work, and will, as he suggests, prove specially valuable in studying the nature of lightning discharges and similar phenomena, a subject which is of the utmost importance in its effect on systems of distribution. It may, indeed, be the means of opening up fields in other directions now barely thought of.

THE NEW EDISON MOTOR-GENERATOR.

Another interesting product of the Edison Works which has been called forth by the application of street railway circuits to stationary power and domestic lighting purposes is the motor-dynamo illustrated in the accompanying engraving.

This machine has been designed for special use on street railway circuits, and is employed to convert the current from 500 to 125 volts, thus furnishing a current of low tension for either lighting or power.

The motor-generator, is, as its name implies, a combination of two machines in one. The armature is so wound that it has two distinct windings, and each end is furnished with its commutator, rocker-arm and brush-holders. The engraving shows the appearance and arrangement of one of these transformers, designed for six kilowatt capacity. The dimensions are those of the standard Edison 12 K. W. generator; with the exception of the length of the bed-plate and pole-pieces. The head-board at the motor end of the machine is provided with a double-pole switch, that at the generator end being furnished with a single-pole switch.



The New Edison Motor Generator.

It is evident that this type of machine can be applied with equal advantage to long-distance transmissions where high potentials can be employed at the source of power, such as a water-fall, and reduced to a safe working voltage at the distributing point. On the other hand the machine is equally well adapted to increasing the potential from low to high. These machines are now manufactured in various sizes and for various voltages, the highest being built for 1,200 volts in the primary circuit.

CRYSTAL PALACE ELECTRICAL EXHIBITION.

The Siemens high tension current has been tested at the Crystal Palace Exhibition. Over 50,000 volts tension was obtained, 500 16-candle-power incandescents of 105 volts resistance each being lighted. All were kept brilliantly lighted in series. Some lamps burst, but the current arced over from the platinum wires without fusing them. The current brought by a brass disc on to a thick sheet of plate glass 2 feet by 2 feet square sent off great zigzag streaks of vivid lightning over its surface, continuous, and not in flashes. The results were magnificent.

THE EDISON TRIPLE EXPANSION ENGINE AND MULTIPOLAR GENERATORS.

One of the most serious problems that to-day confronts the management of electric illuminating companies, in large cities, is the cost of the land necessary to accommodate the large station buildings. When land costs $1,000 and upward a foot front, every square foot of ground space that can be saved materially reduces the necessary investment of the company. Recognizing this fact, the Edison General Electric Company have recently brought out a new line of central station units, consisting of two multipolar dynamos coupled direct to a triple expansion engine, and ranging in capacity from 50 to 800 h. p. This combination does away with all belting and countershafting; thus securing an increase of efficiency, and a large saving of floor space—two most important factors in central station practice.

The multipolar generator is peculiarly adapted to this purpose, as it may be designed to generate any desired electrical output, at an armature speed corresponding to that of a slow-speed engine. This type presents the additional advantages of requiring but small floor space, of being able to withstand sudden variations of load, and to carry heavy loads continuously without danger of overheating.

Our illustration represents the 2-100 K. W. combination. The armature, it will be noted, is of the Gramme ring type, of very simple construction. The number of brushes correspond to the number of poles of the generator, and it is found that the large current output can be divided among these brushes much more conveniently, than if only one set of brushes were used to carry the whole current generated. The mechanical device for controlling these brushes allows of their being operated together, so that when once adjusted, the whole can be handled as though but one set were used.

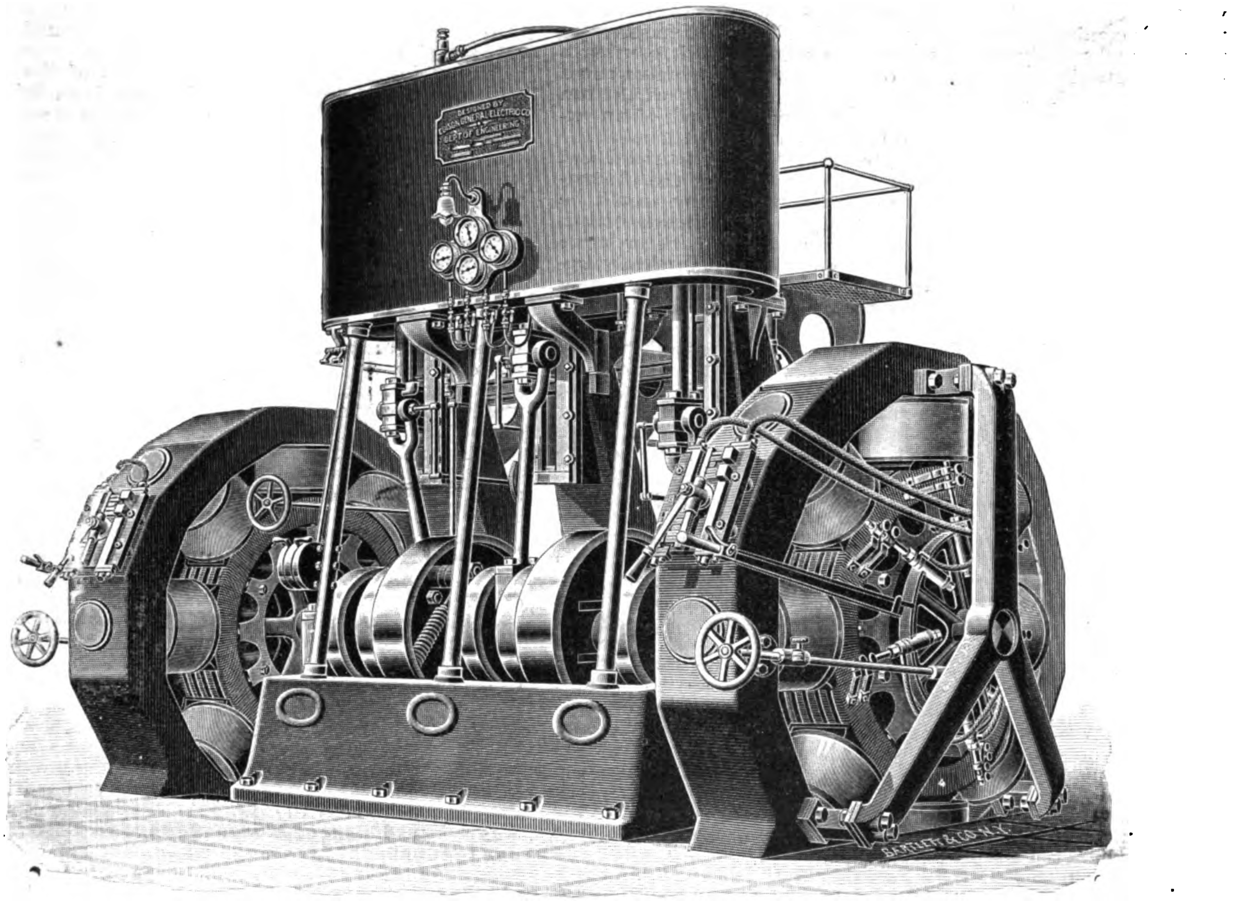
This machine is designed to give 150 volts and 666 amperes at 172 revolutions per minute. The magnet frame consists of a heavy cast iron yoke which has eight inwardly projecting steel pole-pieces. The foundations on which the dynamo rests are cast in the same piece with the bed-plate of the engine, the two supporting feet of the dynamo resting on this iron foundation. The armature spider is placed directly on the engine shaft, and the armature is built up of discs, each disc consisting of two bars. No paper insulation is used between discs.

The armature winding consists of 768 bars, the cross-section of each being 215 mils by 260 mils. The insulation between the bars is 25 mils of shellacked fuller-board. The weight of copper on the armature is 860 pounds and its resistance .005 ohm. The bars that make up the winding are **U** shaped, being joined at the front end in one continuous spiral by means of bars 1¼ inch in depth. These latter bars serve as the cummutator of the machine. The magnet wire is wound on sheet iron spools having fibre ends. Each spool is wound with 113 pounds of No. 10 B. W. G. The total weight of wire is 904 pounds and the resistance of each spool, 1.2 ohm, all spools being connected in series,

The dimensions of the 100 K. W. direct driven dynamo is as follows:

COMPARATIVE FLOOR SPACE REQUIRED BY TWO GENERATORS AND ONE ENGINE.

Two bipolar generators belted to one high speed engine.			Two multipolar generators coupled direct to one Edison triple expansion engine.		
Total capacity two generators.		Minimum floor space in square feet.	Total capacity two generators.		Minimum floor space in square feet.
K. W.	16 c. p lamps.		K. W.	16 c. p. lamps.	
50	900	270	50	900	56
90	1,620	374	100	1,800	121
200	3,600	511	200	3,600	180
350	6,300	571	400	7,200	356



THE EDISON 2-100 K. W. MULTIPOLAR DIRECT DRIVEN GENERATORS.

External diameter of armature body	58	inches.
Length of armature body	13½	"
Radial depth of armature body	4½	"
Bore of field	59⅛	"
Length of magnet core	11½	"
Diameter of magnet core	12¾	"
Width of yoke	14	"
Thickness of yoke	9 1/16	"

The field coils are wound on separate spools, which are slipped over the field magnets; these field magnets are then inserted in an annular or polygonal field frame, mounted on the bed-plate of the engine, the bed-plate being heavy and massive and of special design, so as to secure perfect alignment and rigidity of the field frame with relation to the engine.

The increased diameter of the armature in the multipolar type of machine, gives a very large heat-radiating surface. This point, in connection with the special construction outlined above, allows these generators to maintain heavy loads for long periods, a factor that will be admitted to be eminently desirable in central station work.

The engines are of the marine triple expansion, automatic inverted cylinder type and embody the latest improvements, while operating at the high efficiency obtainable with the compound condensing type. We give above a table showing in a striking manner the economy in space attainable with these direct connected engines and dynamos as compared with belt driving.

THE STANLEY EXPERIMENTAL LABORATORY.

We learn that the Stanley Experimental Laboratory of Pittsfield, Mass., has been reorganized into a stock company consisting of W. R. Plunkett, president of the Berkshire Life Insurance Co.; W. A. Whittlesey, treasurer and manager of the Pittsfield Electric Co.; Wm. Stanley, Jr.; John F. Kelly, C. C. Chesney and Boardman Tobey. The Laboratory is organized for the purpose of forming the central point from which to develop scientific industries.

FLY-WHEEL ACCIDENTS IN ELECTRIC LIGHT STATIONS.—II.

It is possible that failure of a pulley or fly-wheel may commence nearer one edge than the other and thereby tend slightly to disperse the pieces, but the breakage entirely across the face would follow so nearly at the same instant that the component of force due to the velocity in the plane of the wheel would be much the greater, and only such of the flying particles as flew high in the air could disperse laterally any considerable distance. Any piece that was thrown straight up after the roof or other obstructions had been removed would, with an initial velocity of 19,235 feet per second, rise to a height of nearly 1,600 feet or, say, over 1,000 feet, allowing for the resistance of the air, and such piece in falling, if diverted to the slightest extent, might reach to a considerable distance laterally, though such a result would be prevented by obstructions in a building. One of the most interesting experiences during the bombardment of Forts Jackson and St. Philip, on the Mississippi River, during the war, by the Porter bomb fleet, as told by soldiers of the Southern army afterward, was the way in which the pieces of shell scattered. In most cases the shells coming down nearly vertically buried themselves in the mud and merely threw up a large volume of it, causing a general scattering of the groups of soldiers for the moment and a laugh afterward. Sometimes men playing at cards would run like mice to the casemates and avoid the direct result of an explosion and then be back as quickly to their positions in the game, and on several occasions after they had all returned and were laughing over the last Yankee shot and noting the discomfiture of some one who was covered with mud, they would be startled by a sudden whirr and the "lazy piece," as it was called, would come back from the skies and perhaps injure one or more of them. The "lazy piece" meant one thrown vertically upward at the time of the explosion and which, therefore, being unobstructed rose to a great height and took considerable time to rise and return.

It was also claimed by defendants that if the jack pulley broke before the main fly-wheel and pieces of the former were carried on the belt underneath the latter, the upward strain would not necessarily break the fly-wheel, or at least not without breaking the frame of the engine or the pillow blocks, cap or bolts, which was not the case. The plaintiffs showed that the frame of the engine had been racked, but this the defendants accounted for by the shaking of the engine on its bed when running away.

The defendants, the insurance companies, after answering the theories of the plaintiff, claimed that the whole accident was caused by the running away of the engine, due to the slackness of the governor belt or the slipping out of the lacings, whereby the governor acted rather slowly or entirely ceased to act. No safety attachment was provided for such an emergency, but the engineers have applied one since the accident. As to the cause of the fire, it only required a little moisture on the wood of the tower to which the lightning arresters were screwed to cause a slight leakage between the terminals of the dynamos when a very moderate increase of electromotive force would cause additional current to cross the shunt formed by this leakage and char the wood so that it would become a good conductor and thus form a short circuit, which, though only throwing out, say, one-fourth the lights, would start the woodwork in a blaze and cause the slight damage by fire in the tower, which apparently cost only about one hundred dollars to repair.

It was in evidence that the governor belt was new, though this was denied by the engineer in charge. An engine controlled through a governor belt with the lacing coming out would accelerate speed quite rapidly, and the speaker claimed that if the current regulator of a dynamo required 10 to 15 seconds after a short circuit to control the current as claimed by plaintiffs' experts, it would also fail to promptly control the current due to a rapid increase of voltage from a rapid acceleration of the speed of the engine and dynamo and therefore cause a short circuit and the fire, and that at any rate it was doubtful if the regulator could control the current within unusual limits such as would obtain if the speed of the dynamo were doubled; or much less if it were raised from 850 to over 3,000 revolutions per minute, as would have been the case if the engine ran away. In answering this the expert of the Thomson-Houston Co. made another close distinction, as he claimed that though the regulator was slow in checking an electrical phenomenon like a short circuit, still, being itself operated by electricity, it really changed at a faster rate than it was possible to cause a mechanical change, such as an acceleration of the engines. This by no means follows, as it will be shown that the engine would quadruple its speed and that of the dynamos in 70 seconds or less, according to the work being done. The Thomson-Houston Company's expert, moreover, acknowledged that it was doubtful if the regulator would control the current when the speed of the dynamo increased to more than 1,700 revolutions per minute. The insurance companies also put in the evidence of an electrician, that one of the station transformers was burned out, indicating increased speed of the alternator and exciter, but the other side denied this. The plaintiffs put in testimony that any increase of speed would have been noticed at the start, but evidently men occupied with a fire might not observe it. The roaring noise heard by the fireman could not have been that due to a short circuit which instantaneously caused the break on the theory of the plaintiffs, as the noise and the breakage were, according to such theory, coincident and over in an instant. A man who was called from the fire-room, therefore, could not have heard the roar, so-called, of a short circuit before the breakage occurred. He could, however, have heard the increased buzz due to the more rapid passage of the gaps between the commutator segments under the brushes. The defendants naturally suggested that the man did observe that the engine was running away, and that the watchman went to the throttle valve for that reason and commenced closing it, but by that time the speed was so great that the pulleys of largest diameter on the line shaft were being disrupted by centrifugal force, and it is probable that the one driving the dynamos being slightly distorted by regular strain was the first one to go and that the others of same diameter on the line shaft followed in succession. The acceleration of speed once started could not be controlled by the governor belt, so the speed increased until the main fly-wheel was disrupted by centrifugal force, breaking the jack pulley, throwing down the roof of the building and cutting a gap in the roof and sides as shown in the photographs.

The plaintiffs claimed that if the speed of the alternator and exciter increased, the lamps would have been brighter, but evidently the men would not have noticed this if occupied with the fire. They also claimed that since the rim speed of the armatures was greater than that of the pulleys they should have been disrupted first, which was answered by the statement that the materials of the armatures were of higher tensile strength. In fact, the globular shape of the armatures of the Thomson-Houston arc light machines is well adapted to prevent any injury to the winding by centrifugal force, and the wrought iron cores of the spools in the alternator were evidently able to resist much more speed than any cast iron construction. Tests were made by the plaintiffs to find if a governor like that on this engine would regulate with one ball in use. The sleeve lifted by a governor of this size was quite heavy, so it was found that the speed of engine under such circumstances would have been increased to about 118 revolutions per minute, but even this was well within the safe limit even of the pulleys with the most rapid rim speeds.

The speaker made calculations to determine the speed at which the engine and several pulleys would be disrupted by centrifugal force. The normal speed of the rim of a fly-wheel at the diameter of the approximate radius of gyration was 4,715 feet or $\frac{9}{10}$ of a mile per minute. The rim speed of the jack pulley must therefore have been substantially the same, or a trifle less on account of slip, and the rim speed of the 6-foot pulleys on shaft operating the dynamos as well as the rim speed of the pulleys of the dynamos themselves have been about 50 per cent. greater than that of the fly-wheel. From the formula above referred to it was calculated that for a tensile strength of 10,000 pounds per square inch the fly-wheel should have been disrupted at 310¼ revolutions per minute, or, roughly, four times the normal speed. The 6-foot pulleys on the jack shaft should, however, have been disrupted when the engine was running at a speed of 207 revolutions per minute. In order to ascertain approximately the time it would require for an engine under these conditions to run to destruction in case the governor belt were entirely disabled, it was assumed that even with the increased draft on steam pipe, due to running away, a mean pressure of 48 pounds would be obtained, referred to the large cylinder. By "referred" we mean simply that the mean pressure in the small cylinder, divided by the ratio of the area of the two cylinders, is added to the actual pressure in the large cylinder. This mean pressure was sufficient to give 900 horse power at normal speed, and of course the power increased with the speed. It was, however, considered that 13.5 pounds mean pressure out of the 48 were required until the first pulley broke to operate the dynamos and shafting, this pressure being sufficient to produce 253 horse power at normal speed, which is probably a liberal allowance. The mean pressure of 48 pounds is also well within limits, at least for the initial increase of speed, so the time stated hereafter as required to destroy the wheels is probably somewhat greater than would be the case in practice. To ascertain such time it was considered that not only the fly-wheel but every pulley connected therewith, as well as the armatures of the dynamos, really formed fly-wheels which would require force either to accelerate or retard their velocity. To ascertain the effect on the result, the revolving weights of each were ascertained or estimated and multiplied by the ratio of the speed of same to that of the fly-wheel. The sum of those quantities showed the additional weight which it would require in the fly-wheel rim to produce the same result. It was found that the aggregate result was the same as if 10,120 pounds had been added to the fly-wheel rim, making it weigh practically 48,000 pounds instead of 38,000.

On this basis it was calculated that it would require 45 seconds for the engine to increase its speed from 76 revolutions to 207 revolutions, when, on the basis of 10,000 tensile strength, the pulleys on the line shaft should have been disrupted, and as the disruption of such pulleys would have reduced the load on the engine, with the exception of friction, it would only have required 27 seconds, or in round numbers 1½ minutes from the beginning to raise the speed to 310¼ revolutions per minute and disrupt the fly-wheel. There was testimony in the case to the effect that the engineer on watch confessed to his brother engineer that when the fire in the tower was discovered, he pulled the plugs cutting out the arc lights and thus released the load on the dynamos. With this state of facts the load on the engine would have been released earlier and the time required to run to destruction have been diminished. If, however, the governor belt was not broken, but simply slack, so that it took care of changes of load slowly, the acceleration could have progressed at a much less rapid rate.

From what has been stated it will be seen that the combined mechanical and electrical conditions involved in an accident to an electric light plant involve even greater refinements and complications in tracing cause and effect than has heretofore been the case with simple mechanical questions. It will also be observed that a very important question of principle arises in relation to damages occurring in connection with a fire, but not actually caused by the action of the fire itself. It has become necessary in many of the States by law and judicial decisions to exclude what are called "consequential damages," particularly in relation to public works, and this was founded on precedents long established in the older countries. For instance, under the common law a man in digging on his own land was not responsible for damages to a building on adjoining property. It is well understood that a man who fails to pay a debt is only liable for the amount of the debt and interest, although his delay may have caused failures which injured many other persons. So, also, in case of accident, or in fact of any injurious change of condition, there is always a direct result followed by others more or less indirect also in the nature of damage. The indirect results are so far reaching, a damage to one causing more or less injury to another, that litigation would never cease unless some legal estoppel were put upon it, as has been done in relation to many kinds of transactions. Evidently, occurrences of a kind like that in the electric light station will have the effect of causing some such limitation in regard to insurance. If a fire which caused a direct damage of only $100 by fire, and immediate injury to only a few hundred dollars of fixtures in the neighborhood, can in addition be charged with the cost of injuries caused by a runaway engine, there might conditions arise where still further consequential damages would go on almost without end. For instance, questions of personal injury might be involved from many people struck by flying fragments, or a large fragment might knock down a drawbridge in the vicinity and wreck a train of cars, or such a fragment might strike a vessel loaded with explosives and cause a gunpowder or dynamite explosion which would wreck the whole neighborhood, and if such explosives were required for use by a then friendly government and that government failed to prevail in an impending war for a lack of such material, the one hundred dollar fire in the beginning might cause international complications and result in a general war. Somewhere in the progress from first cause to final effect the law of consequential damages should, and will sooner or later, be made to apply, and special policies will be written when accidents to machinery are to be included. Without anticipating what will be done, it would seem natural to limit the damage at a point where the carelessness of the employees or of the insured, by defects in mechanism or material, caused the increased damage.

In the case under discussion the Judge ruled, for the purpose of the trial, that even if the pulley was defective which it was claimed broke first, so that it broke with less strain than such pulleys should, still the insurance companies would be liable. Evidently if this were the case any slight accident, such as short circuiting the electric lights outside but near the station, or the dropping of a tool in some part of the machinery, might without fire have caused the other more important damages. It therefore appears equitable that at such a break in the chain as this, a limitation of damage arising from fire should be made, on the general principles that have made it necessary to provide limitations in other cases, and also on a principle like that of contributary negligence in case of personal injury, whereby it would be provided that whenever the insured were themselves also at fault, either through the action of their employees or by the use of defective machinery, which would be liable to cause such accident without fire, the damages from *fire* should be limited at that point. Who knows but what the courts may finally hold that this is a fair interpretation of the law as it stands?"

"THE MOST VALUABLE AND THE MOST SCIENTIFIC."

A WELL-KNOWN professor of physics and chemistry in one of the State Universities writes us: "I have recently become a regular reader of THE ELECTRICAL ENGINEER. I consider it the most valuable electrical periodical which I receive, and I take all the leading ones. That which leads me to this opinion is that it is the most scientific of the publications referred to."

ON THE LAW OF HYSTERESIS.—IV.

BY CHARLES PROTEUS STEINMETZ.

The second set of tests, which is specially interesting on account of the very low magnetizations reached therein, is given in the following:

TABLE VI.

Frequency, $N = 170$; $\eta = .00421$. $\varepsilon = .2083 \times 10^{-6}$

B.	H_1	H_2	H. calc.	H. obs.	$H. - H.$ calc. obs.	= %
85	5.2	3	5.5	5.6	− .1	− 1.8
182	17.3	1.3	18.6	16.9	+ 1.7	+ 10.0
211	22.0	1.7	23.7	23.5	+ .2	+ .9
560	105	11	116	122	− 6	− 5.0
670	140	15	155	146	+ 9	+ 6.1
685	145	16	161	157	+ 4	+ 2.6
775	176	21	197	202	− 5	− 2.4
800	186	22	208	200	+ 8	+ 4.0
1000	265	35	300	300	……	……
1070	296	41	337	353	− 16	− 4.6
1130	322	47	369	386	− 17	− 4.3
1250	379	56	435	430	+ 5	+ 1.2
1380	445	69	514	514	− 26	− 4.7
2200	940	170	1110	1130	− 20	− 1.8
2420	1090	208	1298	1268	+ 30	+ 2.4
					+ 38 − 90	+ 27.2 − 21.6
					± 10	± 3.4

Therefore we get the formula for the loss in the iron,

$$H = .00421\, B^{1.6} + .2083 \times 10^{-6}\, N B^2$$

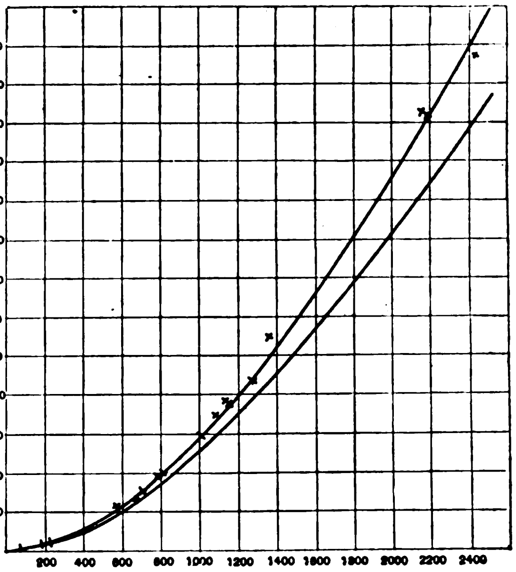


FIG. 3.

In Fig. 3 are shown,

1. The curve of true hysteretic loss, $H_1 = .00421\, B^{1.6}$

2. The curve of the whole loss in the iron, $H = H_1 + H_2$; with the observed values marked by crosses +.

Especially interesting are these two sets of readings in so far as they cover quite a different range of magnetization as the tests in I. to III. In I. to III. the tests cover the range from 1,790 to 19,340 lines of magnetic force per cm.,^{2} that is, for medium magnetization up to high saturation, while the tests in IV. cover the range from 85 to 2,600 lines per cm.^{2}, that is, from medium down to very low magnetization.

The law is found exactly the same,

$$H = \eta\, B^{1.6} + \varepsilon\, N B^2$$

and herewith proved for the full range from 85 lines per cm.^{2} up to 19,340 lines, a ratio from 1 ÷ 230.

This seems not to agree with Ewing's theory of the molecular magnets. According to this theory, for very small magnetization the hysteresis should be expected to disappear, or almost disappear, and the cycle be reversible. Then for medium magnetization, where the chains of molecular magnets break up and rearrange, hysteresis should increase very rapidly, and slowly again for saturation. Nothing of this is the case, but hysteresis seems to follow the same law over the whole range of magnetization, and is certainly not zero for even such a low magnetization as 85 lines per cm^2.

Magnetometer Tests.—The method used in the foregoing has the great advantage that: 1. It allows the taking of a greater number of readings, over a wide range of magnetization, in a short time, by mere simultaneous instrument readings, and thereby reduces the probable error by increasing the number of observations. 2. It allows the use of electro-dynamometers, as the most reliable electric measuring instruments.

3. It deals with large amounts of energy, counting by watts or even hundreds of watts, whereby much greater accuracy can be reached than by the ballistic galvanometer.

4. It measures the hysteresis under the influence of an harmonically, and not suddenly, varying M. M. F., that is, under the same conditions, where it becomes of importance for practical engineering.

But it has the great disadvantage that it can be used only for testing sheet-iron or other thoroughly laminated iron, where eddies are either inappreciable or can be calculated also. For testing solid iron and steel pieces, this method cannot be used, because of the tremendous amount of eddies which would flow in a solid piece of iron. To determine the hysteretic loss of energy in steel and cast-iron the Eickemeyer differential magnetometer was used. Complete description of this instrument and its use is to be found in THE ELECTRICAL ENGINEER, March 25, 1891.

To get absolute values, the instrument has been calibrated in the following way: In the front and in the back the magnetic circuit of the instrument was closed by 4 cm.^{2} of Norway iron. Then another piece of iron, and of any desired size, was added in the front. This piece, y, carrying some magnetism also, disturbed the equilibrium. Then through a coil of exactly 110 turns, surrounding this piece y, an electric current i was sent and regulated so that equilibrium was restored. In this case no magnetism passed through y, or in other words, the M. M. F. of the current *i. e.*, 110 ampere turns is equal to the differences of magnetic potential between the pole-faces of the instrument. In this way, for any strength of current in the main coil C of the magnetometer, the difference of magnetic potential produced thereby between the pole faces of the instrument, was determined and plotted in a curve, for convenience in ampere turns per cm. length.

Now, the Norway iron standard was compared on the magnetometer with sheet-iron, of which, from tests with low frequency alternating currents, the magnetization corresponding to any M. M. F. was known, and therefrom was derived the magnetic characteristic of the Norway iron standard, and plotted in a curve also.

In the way explained before, the iron sample that was to be determined, was balanced in the magnetometer by Norway iron, thereby giving its susceptibility in per cent. of that of the Norway iron standard, the magnetometer current read, from the curves taking the M. M. F. corresponding thereto—denoted by F—and the magnetization of the Norway iron, corresponding to this M. M. F., F, and from the determined per centage of susceptibility of the examined sample, the magnetization B of this sample corresponding to the M. M. F. F.

With this instrument a number of magnetic cycles of different samples of steel and cast-iron were determined. First, a powerful alternating current was sent through the magnetometer and around all the iron pieces used, to destroy any trace of permanent or remanent magnetism. Then the examined sample was laid against the front, the standard against the back of the magnetometer, balanced, and a larger number of magnetic cycles completed between given limits, for instance, $+ 95$ and $- 95$ ampere turns M. M. F. per cm. length. Then readings were taken from maximum M. M. F. $+ 95$ down to zero, and again up to the maximum $- 95$, down over zero and up to $+ 95$, thereby completing a whole magnetic cycle, and then of a second magnetic cycle, a few readings were taken as check for the first one. In this way for different M. M. F.'s the curve of hysteresis was found, and by measuring its area the loss by hysteresis determined.

The further calculation was done in a somewhat different way. Generally the number of cycles was not large enough to determine conveniently the exponent by analytical methods. Therefore the law of the 1.6th power, $H = \eta B^{1.6}$, was assumed as true, and for each cycle from the known values of H and B determined the coefficient η.

If for different cycles the values of η agreed, this would prove the assumption, the correctness of the law of 1.6th power, while a disagreement would disprove it. In the following the magnetic cycles are given for a number of samples.

(*To be continued.*)

A PLANT FOR ST. CLAIR, MICH.

MR. SIMON LANGELL, the Mayor of St. Clair, Mich., writes us that the city contemplates putting in a plant. He will be glad to receive data and information on the subject.

Reports of Companies.

ANNUAL REPORT OF THE EDISON GENERAL ELECTRIC CO.

WE give below the full text of the annual report of the Board of Trustees to the stockholders of the Edison General Electric Co., presented on February 10, 1892:

The submission to you of this the Third Annual Report of the Board of Trustees has been delayed in consequence of the new general corporation law of the State of New York, which went into effect May 1, 1891, pursuant to the provisions of which the Annual Meeting is held on the 10th day of February, 1892, instead of on the 18th day of January, 1892.

INCREASE OF CAPITAL STOCK.

In the last annual report the statement was made that, owing to the large and rapid increase of the Company's business, it had become necessary to provide for the enlargement of its manufacturing plants and for additional working capital, and that for these purposes your Board had disposed of most of the unissued capital stock of the Company held in the treasury, and had borrowed $2,000,000 through the Sprague Electric Railway and Motor Company, in repayment of which loan the lenders agreed to take a like amount of the stock of this Company. To make corresponding provision, a special meeting of the stockholders was called and held immediately after the annual meeting, at which, in accordance with the recommendation of the Board, the increase of the capital stock from twelve millions to fifteen millions was authorized by a unanimous vote.

Two millions of the increase were used in liquidation of the loan to the Sprague Company, and the remaining one million was left unissued in the treasury to meet future requirements.

The net earnings in the fiscal year 1889-90 having exceeded eight per cent. on the total stock of the Company, the trust existing under three certain agreements with the Farmers' Loan & Trust Company (whereby dividends had been temporarily deferred on some $2,482,700 of the Company's stock), reached its termination. The stockholders at the last annual meeting were therefore asked to authorize the payment of the regular dividends on the deferred stock (so called), and such other action as was required for the exchange of the trust certificates for the regular dividend-paying stock. The recommendations of the Board in these respects were also unanimously approved.

In consequence of the steadily-growing financial requirements for current business, as more fully explained in another place, the Board deemed it prudent to dispose of the remaining $1,000,000 of stock in the treasury, so that of the $15,000,000 authorized $14,964,900 is now outstanding, the difference being reserved for the retirement of the outstanding Edison Electric Light Company's stock, unless the Board should decide to dispose of the same in some other manner.

WORKING OF THE NEW DISTRICT ORGANIZATION.

Reference was made in the last annual report to the new working organization, which went into effect on August 1, 1890. Under it, the United States and Canada were divided into eight geographical districts, each in charge of a head official entitled "District Manager," instructed by, and reporting and directly responsible to, the Executive Officers of the Company. The organization has now been tested by an experience of fifteen months, and the Board feel warranted in saying that the practical results from it have been fully up to expectations. The change has contributed not only to the greater efficiency of the service in every way, but directly and indirectly to the growth and stability of our business, and to the prompt execution of orders. The new system has entirely superseded the old one of securing business mainly by the payment of commissions, and all officers and employees of the Company are now under salaries. The Company was fortunate in securing able, faithful and experienced men for the management of all the districts. The first of a series of conferences, intended to be held annually, of all the district managers with the chief executive officers of the Company, was recently held in New York.

SHOWINGS OF THE GENERAL BALANCE SHEET.

In order to enable the stockholders readily to compare the general balance sheet for the past year with that of the previous one, the figures for both have been printed in parallel columns, together with the differences they show.

The footings of the general balance show $21,507,284.42 in 1890-91, against $17,958,852.81 in 1889-90, being an increase of $3,548,431.61. The increase of assets includes additions to "Manufacturing Plants" of $1,262,410.91, to "Patents" $26,604.14, to "Real Estate" (completion of main office building in New York) $136,624.81, to "Capital Stock of Edison Electric Light Company" $12,693.32, to "Stocks and Bonds" $502,846.65, to "Cash" $348,274.53, to "Bills and Accounts Receivable" $261,663.36, to "Work in Progress" and "Materials and Supplies" $771,963.75. The balance also comprises two new items, "Laboratory Account," $66,815.72, being the share borne by the Company towards inventive work completed or in progress in Mr. Edison's Laboratory under the new contract with him, referred to in the last annual report, and "General Liquidation Account," $158,534.42, representing unliquidated items, making part of cost of acquisition of various Sub-Companies and stock of Sprague Company.

Included in the liabilities is an allowance for "Depreciation of Manufacturing Plants." This account shows that $271,592.29 had been taken out before the year's profits were figured. The total amount now carried in this account is slightly over ten per cent. of the entire cost of this Company of the manufacturing plants, notwithstanding the fact that the amount of cash expended to enlarge those plants during the past two fiscal years is $2,211,685.61, and on this new investment the actual depreciation so far is little or nothing. "Mortgages on Real Estate" ($200,000 of which is on the main office building in New York) shows an increase of $65,000, Capital Stock" $1,115,500, "Bills Payable" $1,709,238.75, "Accounts Payable" $44,350.59. The surplus of "Profit and Loss" carried forward, viz., $1,260,067.11 (after payment of eight per cent. dividends on capital stock), is larger by $64,513.98 than that brought over from the preceding year.

The increase of $1,262,410.91 in "Manufacturing Plants" represents investments in lands, buildings, machinery, tools and miscellaneous equipment, which were rendered necessary by the growth of business, and this expenditure has secured to the several works an enlarged capacity and technical efficiency. Your Board are happy to say that with the large expenditures during the past year no considerable outlay in the same direction is likely to be required for some time, unless there should be an exceptional growth in electrical business throughout the country.

The "Bills and Accounts Payable" represent a total of $4,201,417.75, against $2,447,828.41 in 1889–90, making an increase (as already stated) of $1,753,589.34, or (deducting the $348.274.53 excess in "Cash on Hand" at the close of the past year) of $1,405,314.81. The reasons for this large increase in the Company's liabilities are readily seen. In the first place, the peculiar character of the manufacturing and contracting business calls for the employment of more cash or working capital in proportion to production than in perhaps any other existing industry. The continuous purchases of expensive raw material consumed in large quantities. such as copper, require the constant use of a great deal of ready money. The rapid progress of the technical art, too, involves the necessity of devising and manufacturing new articles, the marketing of which is sometimes slow at first. In the second place, the system of District Agencies amounts to nothing less than the opening of as many wholesale stores, fully supplied with stocks of the Company's manufactures, from large motors and dynamos down to the smallest incandescent lamp fittings, in order to save time and expense in filling local orders. To this cause the increase of $849,585.63 in "Materials and Supplies" on hand over 1889–90 is directly and specifically due. Lastly, as has been shown, the addition to the items "Manufacturing Plants," "Real Estate," "Stocks and Bonds" and Laboratory Account," amounting together to $1,968,698.09, represent a corresponding absorption of working capital, thereby necessitating the raising of additional capital by increasing the stock or the use of the Company's credit as a substitute. In order to keep its use within prudent limits, the $1,000.000 of treasury stock was disposed of as stated, and it is the opinion of your Board that an issue of another $1,000,000 of stock should be made at an early date.

The properties of the Company in fixed form, *i. e.*, in manufacturing plants and real estate, having been increased by $1,399,035.72 during the year, now represent a cost on the Company's books of $5,748,548.70, less $537,663.56 standing to the credit of "Depreciation Account," Besides this, at the close of the year, the Company owned (in addition to patents) the stocks of controlled companies and other stocks and bonds (including the stock of the Edison Electric Light Company) appearing in the balance at the aggregate nominal value of $5,936,668.60, and had in cash on hand, bills and accounts receivable, work in progress (booked at cost), and materials and supplies (also at cost), no less than $9,273,868.86, and all this against bills and accounts payable of $4,201,417.75. These figures show the intrinsic strength of the Company.

THE BUSINESS OF THE YEAR—PROFITS.

Summarily stated, the gross business of the General Company amounted to $10,942,640.34, on which the profits, including the $271,592.29 written off against the cost of the manufacturing plants, were, according to the books of the Company, $1,666,535.72. To this amount must be added the General Receipts at the Main Office, $83,013.99, making a total of net earnings of $1,749,549.71.

Deducting from the above net receipts of the Edison General Electric Company (exclusive of those of the Edison Electric Light Company) the sum of $271.592.29 charged off on manufacturing plants, and $286,477.59 charged off against "Liquidation," "Materials in Stock" and "Experimental Account," we have $1,191,479.83 as the net result of the year from the business of the Edison General Electric Company alone. Adding $1,100,432.48 surplus profits carried over from the preceding year, we have a total of $2,291,912.31 profits available for distribution. After paying $1,031,845.20 in dividends, $1,260,067.11 is carried forward into the new year.

As set forth elsewhere, the Edison Electric Light Company has received during the year $631,672 in bonds and stocks, as license fees from licensee companies, worth, at a moderate valuation, say, $500,000, of which the Edison General Electric Company (through its holdings of Light Co. stock) is entitled to over ninety-nine per cent., or say $495,000, which is equal to 3.16⅔ per cent. additional on the capital stock.

The year's profits were not so large as those for 1889-90. This is largely due to the considerable decline in the prices obtained for the product of the manufacturing establishments owing to increased competition and other causes. Another general cause of the diminished profits was the depression prevailing in all classes of business during the greater part of the year, and the unwillingness of capital to engage either in old or in new enterprises. This was especially noticeable in the business of large central stations, of which fewer were organized than usual, while those previously organized proceeded more cautiously than usual in enlarging their plants. The general condition of the country imposed great caution upon the management. The General Company could have done a much larger business if it had been willing to accept securities in payment for orders; but in view of the commercial and industrial situation at large, a strict rule was adopted of declining all such, and doing business exclusively on a cash or short credit basis. In order to effect settlements of a number of contracts taken prior to the present organization, securities were, however, accepted. This accounts for almost the whole of the increase of $502,846.65 in "Sundry Stocks and Bonds." The result of the general policy pursued proved at once the wisdom of the course adopted, and the remarkably safe and solid character of the Company's business. For, although the gross sales reached nearly $11,000,000, the bills and accounts receivable increased only $261,663.36 during the year, showing the promptness with which collections were made.

THE EDISON ELECTRIC LIGHT COMPANY.

The changes in the condition of this Company are fully set forth in the accompanying comparative Balance Sheet. As will be seen, its relations to the local companies licensed by it have again yielded very gratifying returns. Much progress has been made by this Company during the year toward sustaining the position to which the ownership of the Edison patents entitles it, namely, the exclusive ownership of the fundamental patents relating to the business of incandescent electric lighting.

On July 14th last, Judge Wallace, in the United States Circuit Court, at New York City, filed a decision in the test suit on the principal lamp patent, sustaining that patent as covering broadly all existing incandescent lamps. The case had been most stubbornly contested for several years by the infringers, and, as was to be expected, an appeal was taken, which will come up for early hearing. A favorable decision by the Appellate Court, which is confidently expected by our counsel, will give the Company the control of the manufacture and sale of the incandescent electric lamp.

Satisfactory advance has also been made in the suits prosecuted to establish the right of this Company to the only system of electrical distribution and regulation suitable for incandescent lighting upon an extensive scale. Among them are the test suit upon the feeder patent and that upon the three-wire patent, in which a great mass of testimony has been taken during the past year. These cases will be ready for argument during the coming year.

A patent has lately been granted to Mr. Edison on the principle underlying the high-tension transformer system, and suit is about to be brought upon that patent to establish this Company's right to the transformer system, as well as to the direct-current system.

This Company's patents upon electric railways (including the Sprague patents), which are universally infringed, have also been, during the past year, made the basis of suits against competitors, with a view of establishing its rights in the electric railway business.

From the date of its organization in 1878 up to the present time, the Edison Electric Light Company has accumulated all its profits in its treasury. These profits are mainly in valuable stocks of local illuminating companies. Recognizing the justice of a distribution of some part of them, the Directors of the Light Company have, since the close of the fiscal year, declared a dividend of about $1,500,000, par value of these securities.

Over ninety-nine per cent. of them come to this Company as the owner of nearly all the stock of the Light Company.

Reference is made to the subjoined report of the Second Vice-President on the business prospects of the current year.

The thanks of the Board of Trustees and Stockholders are again due to the Officers and Employees for the faithful performance of their duties.

By order of the Board of Trustees,
HENRY VILLARD,
President.

EDISON GENERAL ELECTRIC COMPANY.

Profit and Loss Account, October 31st, 1891.

EXPENSES.		
General expenses..............		$794,788.63
Items now written off :		
Net amount charged off during the current fiscal year against liquidated items, taken over from various sub-companies...........	$148,083.99	
Amount charged off against materials in stock upon taking inventories.........	128,393.60	
Experimental account.......	10,000.00	286,477.59
Dividends declared or paid, including interest on notes payable in stock.................		1,031,845.20
Balance—Surplus carried forward, October 31st, 1891 ...		1,260,067.11
		$3,373,128 53

EARNINGS.		
Profit and Loss — Surplus brought over, October 31st, 1890.	$1,195,553.13	
Less amount chargeable to 1889-90 against liquidated items taken over from various sub-companies.........	95,120.65	$1,100,432.48
Profits from November 1st, 1890, to October 31st, 1891 (not including those of the Edison Electric Light Company)............		2,272,696.05
		$3,378,128.53

E. & O. E.—New York, February 10th, 1892.
J. P. ORD, *Comptroller.*

This is supplemented by a report from Mr. Samuel Insull, second vice-president, on the prospective business of the Company. It states, among other things, that the Edison Co. in San Francisco is to install a plant of 20,000 lights; that the Chicago Edison Co. will spend $2,000,000 within the 'next five years, and most of the sum immediately; that the companies in Boston and New York are enlarging; and that heavy work is in hand for Milwaukee and Cincinnati. The "cash" stations and isolated plants promise to run about 500 000 lights for the year; and the Company already has on its books orders for 2,000 arc lights and corresponding dynamo capacity. Other departments of the business were in equally good shape.

At the annual meeting of the stockholders the following trustees were elected for the ensuing year: C. H. Coster, Thomas A. Edison, J. H. Herrick, Samuel Insull, Edward H. Johnson, A. Marcus, Carl Schurz, Francis S. Smithers, Samuel Spencer, Henry Villard, J. Hood Wright. The only change from the former board is the election of Samuel Spencer (of Drexel, Morgan & Co.) in place of James B. Williams. The old officers have since been re-elected, but Mr. Villard has handed in his resignation, to take effect in due course.

Society and Club Notes.

DES MOINES ELECTRIC CLUB.

THE Des Moines Electric Club has organized, adopted a constitution and elected the following officers: President, Charles C. Buckley; vice-presidents, L. L. Barge and H. Wheaton; secretary, W. L. Youngerman; treasurer, Jesse O. Wells; managers, H. B. Day, C. Berry, J. A. Innes and C. A. Felkee. It is intended to provide an assembly room where members and any others interested may meet and listen to papers or talks concerning electricity and discuss questions arising in this branch of science. Rooms have been secured and the time of the first meeting for such a purpose will be duly announced.

CHICAGO ARCHITECTURAL SKETCH CLUB.

THE CHICAGO ARCHITECTURAL SKETCH CLUB, at its meeting, February 8th, listened to a talk by Mr. Chas. G. Armstrong on "Some Electrical Experiments." In his capacity of electrical expert, Mr. Armstrong is already well known to architects and this opportunity of impressing them with some whys and wherefores of electrical plants may have helped them to appreciate the need of the intelligent and independent supervision of the electrical work in buildings.

The majority of those present—and they filled the neat hall—had been repeatedly confused by the variety of opinions and arguments advanced by non-electrical people, but were soon led along the clearly defined line of thought suggested by the series of experiments. Illustrations of the relations between magnetic and electric circuits, and of those expressed by Ohm's law, paved the way for a consideration of wires as conductors. After showing the need of cut-out devices and their operation, Mr. Armstrong's experiments proved the relations between life, light and efficiency in the incandescent lamp—a point rarely understood by architects and contractors. Other touches on insulations and methods of testing them, on arc lamps and their proper sphere of usefulness and on the comparisons between electric lights and other means of illumination, followed each other in the course of an off-hand talk, which closed with a note on the coming electric lamps.

The discussion brought out a number of points which are commonly misunderstood by the layman, and the interest shown by the members of the Sketch Club would seem to promise a better understanding of the work to be done by the supervising electrical engineer.

PRESIDENT CHANDLER'S REMINISCENCES OF LINCOLN.

The anniversary of Lincoln's birthday was celebrated at the Electric Club, on Friday, February 12, and the club members and invited guests were entertained by reminiscences of the great President by Mr. A. B. Chandler, president of the Postal Telegraph Cable Company. Mr. Chandler was a United States military telegrapher at Washington during the Civil War, and for years was thus in the closest confidential association with Mr. Lincoln. Among the many interesting things told by Mr. Chandler was the following:

"The second time I remember Mr. Lincoln speaking to me was very early one morning, perhaps 6 o'clock, soon after I went to Washington. I had been on duty all night. He left the office as late as 10 or 11 o'clock the night before, but so anxious was he for news from the armies that he often came over from the White House soon after daylight to see the dispatches which had come in during the night. He happened to find me on this morning in just the same position (writing at the desk that we then called Colonel Stager's) in which he had seen me the night before, and as he came in he said: 'Have you been sitting right there all night?'

"Then he read over the new messages, carbon copies of which we made on letter-size tissue paper and put, without folding, in a little drawer in what we called the cipher desk. The contents of this drawer were for his special information. The messages were placed in it in the order of their reception, and he was quite careful to keep them so. It was his habit to read from the top down, and when he came to those which he had already read, with a smile he said: 'Well, I guess I have got down to the raisins.'

"As I seemed in doubt as to what that might mean, he explained that a little girl, having eaten improperly, both in quantity and quality, beginning with a lot of raisins, was made quite ill, and could only find relief in the process a sick stomach is apt to compel. After an exhausting siege of throwing up, she gave an exclamation of satisfaction that the end of her trouble was near, for she had 'got down to the raisins.' I suppose that I have heard Mr. Lincoln use the expression twenty times at least, when he had finished reading the new messages in his drawer, and had reached those which he had read before."

Mr. Chandler told a great many other stories about Lincoln never heard before, and wound up a most intensely interesting lecture by a strong appeal for justice to Stanton, Mr. Lincoln's Secretary of War. Aside from its historical value, the whole address by Mr. Chandler had a literary charm of delivery and diction that pleased the members immensely.

Mr. Chandler was followed by Mr. Holloway, president of the Engineers' Club, who spoke of what he saw at Lincoln's nomination; and by Gen'l O'Beirne, who was with Lincoln in his few hours of life after the assassination. The lecture and speeches were interspersed by war songs given by the Brunswick Quartette; and at the speakers' end of the parlor a bust of Lincoln stood, draped with the Stars and Stripes.

During the evening, before the lecture, Steward Reynolds served one of the best table d'hote dinners that the club has ever enjoyed.

SOUTHERN BERKSHIRE SOCIETY.

The fifth annual meeting and dinner of the Southern Berkshire Society at Clark's on Twenty-third street, February 11th was attended by 80 members and guests. This society is composed of natives of Berkshire county and their families residing in this city and vicinity. Among the electrical representatives present were F. L. and R. W. Pope, Richard S. Brown and Chas. B. Williams, with their wives. Ralph W. Pope, secretary of the American Institute of Electrical Engineers, was elected president for the ensuing year.

THE BUFFALO N. E. L. A. CONVENTION.

The following is the official programme of the Convention:

Tuesday, February 23, 1892.

Meeting of the Executive Committee, at 9 a. m. Parlor Iroquois Hotel; morning meeting, 10.30 a. m., at Library Building. Address of Welcome by Hon. Charles F. Bishop, Mayor of Buffalo. Address of President Huntley. Report of Committee on Underground Conduits and Conductors, M. J. Francisco, Chairman.

AFTERNOON SESSION, AT 2 P. M.

Report on Safe Wiring, M. D. Law, Chairman. Report of Committee World's Columbian Fair, B. F. Sunny, Chairman. Paper by Richard Hammond, How to Fire a Steam Boiler.

EVENING SESSION, AT 8 P. M.

Paper by Carl Hering, Transmission of Power. Discussion by William Stanley, Jr., L. B. Stillwell, H. Ward Leonard, Elihu Thomson, and others.

Wednesday, February 24.

MORNING SESSION, AT 10 A. M.

Paper by D. Ashworth—The Allied Powers. Paper by Wm. Stanley, Jr.—The Alternating Current Motor. Paper by Erastus Wiman—Electric Lighting from a Financial Standpoint.

AFTERNOON SESSION, AT 2.30 P. M.

Paper by M. C. Sullivan—Switchboards, Their Safety and Operation. Paper by Chas. A. Schieren—From the Tannery to the Dynamo. Paper by Allen R. Foote—Municipal Franchises for Quasi-Public Corporations.

Thursday, February 25.

MORNING SESSION, AT 10 A. M.

Paper by E. F. Peck—Overhead Construction. Paper by E. A. Leslie—Operation of High-Tension Currents Underground. Paper by J. B. Craven—Underground Construction of Buffalo Railway Co.

AFTERNOON SESSION, AT 2.30 P. M.

Paper by L. B. Stillwell—Report of Secretary and Treasurer. Report from Executive Committee. Election of Officers.

A CHICAGO INSTITUTE OF TECHNOLOGY.[1]

"The Necessity and Present Opportunity for the Establishment of a Technological Institution with Physical Laboratory and Museum of Mechanical Arts in Chicago," was the title of a paper of considerable length read by Mr. Francis W. Parker before the Chicago Electric Club on the evening of February 3, in which patriotic citizens were called upon to repay the debt Chicago owes the profession of engineering, by founding an institution of technical education that should be unsurpassed by anything of the kind now in existence. The gist of Mr. Parker's address is summed up in the following extracts:

There is a necessity for technological education in Chicago. First, because Chicago is so entirely the product of engineering; second, because she is so profoundly interested in and her future is so largely dependent upon engineering; third, because her wealth is so abundant and her citizens are so liberal; fourth, because all other kinds of education are so abundantly provided for; fifth, because this is the highest and best form of education; and sixth, because the coming of the World's Fair necessarily provides both the occasion and in a large degree the means for the establishment of such an institution.

Other cities have grown to greatness—Chicago has been built and engineered to greatness. They have increased by addition. Chicago by multiplication. Chicago as the creation of engineering will be the chief exhibit at the World's Fair, and yet how that exhibit will be marred by the absence of any means by which men may be educated in the arts whereby the city has been created. The first question asked by an intelligent stranger who has beheld our material advancement will be, "Where is your school of technology?" and our answer must be, "We have none." Every one of the great engineering works either completed or actively agitated in 1890 and 1891 was of direct and immediate interest to Chicago, except the Croton aqueduct, and of seven great bridges undertaken five were directly tributary to Chicago. The remainder of the paper was devoted to Chicago's greatness in commerce, theology, music, the fine arts, and, in fact, in all directions except that of technical education, and closed with the following words:

"All honor to those whose generosity has given us our universities, libraries, Art Institute, World's Fair and other institutions, but still more honor to those who will round out the work by creating at Chicago the world's greatest school of technology and engineering."

---

[1] Abstract of a paper read by Francis W. Parker before the Chicago Electric Club, Feb. 3, 1892.

Letters to the Editor.

THE MORSE-VAIL TELEGRAPH CONTROVERSY.

IN your issue of February 10, there appeared a communication, signed, "Park Benjamin," which, it seems to me fair to presume, was written in the interest of those who would stifle all discussion of the claims of my father, Alfred Vail, to the invention of the electric telegraph, generally styled the "Morse System." I should be glad to learn as to the authority of Mr. Benjamin, by means of which he so confidently interposes "a respectful but *firm* objection to the trial, at the present time, of the Morse-Vail telegraph controversy in the columns of the *Evening Post*," on behalf of "*all the readers* of electrical matter in the daily press."

I am happy to state that my experience does not warrant my acceptance of Mr. Benjamin's status (as assumed by him in his *self-appointed* position), for I find a universal interest on the part of the public in learning that, to Alfred Vail, and *not* to Morse, is the world indebted for the great invention that has brought the ends of the earth together.

I also observe, I am happy to state, an equally universal expression of the desire and hope that the name of Alfred Vail, will receive the full credit due him for the great part he had in the invention. I have before this expressed a desire to be informed, *what it was, of the electric telegraph* (as it is to-day, and as it has been since it became a practical success), *that Morse did invent;* but I am, to this date, without the desired information, and I shall, in all probability, remain so, for, as the telegraph consists of a wire, a battery, a magnet, a receiver, a key, and an alphabet, *none of which were invented by Morse,* he evidently was not "in it"!

Mr. Franklin L. Pope, has thus written: "From 1837 to 1844, the telegraph was a combination of the inventions of Morse, Henry and Vail, but, as we have seen, *the elements contributed by Morse, have gradually fallen into desuetude, so that the essential telegraph of to-day, and the universal telegraph of the future, comprises solely the work of Henry and Vail.* The grandeur of Vail's conception of an alphabetical code, based upon the elements of time and space, has never met with the appreciation which it deserves."

If I grasp the argument of Mr. Benjamin (in support of which he draws so extensively upon his profound acquaintance with electrical controversy), it is, that the importance of an invention, and the justice involved in placing its true inventor before the world, is only to be gauged by the relative *numerical position* it has, *by date,* in the line of undecided cases, which is neither good law nor good logic.

I know of no power by which Mr. Benjamin can be required to read any matter, telegraphic or otherwise, that may appear in the daily press, and I am therefore compelled to think that his article was inspired by some other feeling than that of a public philanthropist.

STEPHEN VAIL.

NEW YORK CITY.

THE SERVICES OF GILBERT AS REGARDED BY MR. THOMAS D. LOCKWOOD.

I HAVE respectfully read the rescript handed down by Mr. Thomas D. Lockwood, in which he approves of THE ELECTRICAL ENGINEER. That is good. He also "coincides" with me in my sentiments about Gilbert, which is not English, but still good too. And he says that "I (meaning Mr. Thomas D. Lockwood) have always availed *myself* (still meaning Mr. Thomas D. Lockwood) of opportunities to pay the tribute of full appreciation to the worth of Gilbert's services to electricity;" which is troublesome to parse, but yet, on the whole, the best of all. No more can ox-like Briton trample in the dust that fair repute. Mr. Lockwood is going to preserve it; for now we know that so long as "Practical Information for Telephonists" pursues its exciting career down the eons, there banging and rattling after it and tangling itself up with its hind legs, will always be found *his* (Mr. Thomas D. Lockwood's) "tribute of full appreciation to" etc., etc. Now is Gilbert's reputation made forever!

It is interesting to learn from Mr. Lockwood that the translation of "de Magnete," so long promised by the Gilbert Society, does not appear because "the revisers are all busy men who can only devote a small portion of time to that work." To many, that will have all the spice of entire novelty. Perhaps Mr. Lockwood may be shrewdly hinting that *he* has somewhere a corps of overworked British "revisers" torturing their cheese-like and indurated brains over the thing; in which case, somebody ought to remonstrate with him for his cruelty to animals. As a matter of fact, however, the average American school boy who has read Latin enough to translate Sallust and Cicero, ought to be, and probably is, able to render "de Magnete" into good English in about a fortnight.

Of course, in a matter concerning which the Lord Thomson and one plain Michael Faraday seem to be entirely divergent in opinion, the universe holds no one who is better able to arbitrate and set the whole affair to rights than Mr. Thomas D. Lockwood. It will always, therefore, be a source of regret to me that I should, however innocently, have incurred his displeasure by perpetrating what he calls "the unnecessary slur of the Gilbert article upon the acknowledgment by the Crown of Sir William's great merit and ability;" but, oh, shades of Jeames and Jenkins! when did you ever descend to such arrant snobbery and flunkeyism as even to imply that a great reputation in science could be made greater by "acknowledgment by the Crown"?

Of course Mr. Lockwood is far too good an American seriously to intend any such implication as this. He merely thinks, no doubt, that Lord St. Albans is a better name to conjure with than Francis Bacon; or perhaps mildly deplores that among all the statues of Benjamin Franklin which we have erected not one of them represents that philosopher in the official garb of a Royal Postmaster of New Jersey.

PARK BENJAMIN.

NEW YORK CITY.

EARLY IDEAS ABOUT RAILROADS, SPEED, ETC.

THE statement of Mr. Pope in your issue of January 20th suggests the addition of some others as to the ideas entertained by able men, in regard to railroads, in the infancy of the art.

In 1825, the *Quarterly Review*, in England, said, "We trust parliament will, in all railways it may sanction, limit the speed to eight or nine miles an hour, which is as good as can be ventured on with safety."

When it was first proposed to build railroads in the U. S., Chancellor Livingston, of New York, published a statement demonstrating, as he thought, the impracticability of the project. His reasons were, first, that the foundation would have to be of masonry, and would therefore be so costly as to render the scheme impracticable. Second, that the momentum of such a moving body as a train of cars would be such that the train could not be stopped until it had gone several miles past the place; and to clinch his argument, he wound up with the exclamation, "and who would want to risk their lives flying through the air at the rate of fifteen miles an hour!"

At the opening of the first section of the Baltimore & Ohio R. R. several prominent gentlemen were invited to take a trip, and among them was Mr. Seaton, editor of the old *National Intelligencer* of Washington, D. C.

He gave a lengthy account of the trip, the car being drawn by horses, on the old strap rail, and he states that they were kept in mortal terror lest some of the cows feeding by the wayside should get upon the track and derail their car. He discussed at length the future possibilities of the road and concluded that as a means of conveying freight it might be successful, as a horse could draw considerable more on the smooth rails than it could on a common road.

As to speed, he thought they might possibly go "twelve miles an hour, which is as fast as any one will ever want to travel."

The records of the past are full of such ideas and statements. For instance, about 1777, Smeaton was of the opinion the rotary motion of the axis of a steam engine direct "would never be useful economical," and he used his engine to pump water up into a cistern, and then used the water on a wheel to produce a rotary motion! Within the past ten years a party came to me with a proposition to do the same thing; and he was an educated man, too.

Watt had no faith in steam carriages or steamboats, and he refused to license parties to use his patent on the steam engine for such purposes. He also declared that Trevethick deserved hanging for introducing the high pressure engine!

All this sounds very strange to us now, but probably not much more so than our present ideas on many subjects will to our successors fifty or a hundred years hence.

W. C. DODGE.

WASHINGTON, D. C., January 22, 1892.

RINGING HOTEL BELLS WITH A MOTOR-DYNAMO.

IN reply to the very kind criticisms of Mr. Miner and Mr. Bartlett on my article in regard to ringing bells with a motor-dynamo, I wish to say that I have tried the plan suggested by Mr. Miner, viz., using a bell in series with a lamp resistance, and did not find it satisfactory; in fact, I find, as Mr. Bartlett did, that an arc would set up without ringing the bell, or that a destructive spark would soon pierce the platinum and finally oxidize the contact so as to entirely open the circuit. I overcome this by shunting the bell circuit with a resistance to correspond with the resistance of the bell circuit. This method, while very satisfactory under expert care, would not be a safe general plan for bell ringing, hence I did not mention it in my article of December 23.

I fear from the remark Mr. Bartlett made, that I did not make myself clearly understood as to my method of winding. My windings are both on the same shaft. I use but one machine with a commutator on each end of the shaft, with two windings upon this shaft. The windings are insulated from each other by a thick disc of fibre. This armature when withdrawn from the pole pieces appears like one long armature, with drum winding and a commutator on each end. The whole machine weighs but about 75 lbs. and yet will safely handle 500 bells, if necessary.

I have had these machines in use long enough to know that they are a practical success and hasten to assure Mr. Bartlett or any one else who has need for a constant supply of current for bell ringing in a considerable quantity, that they will make no mistake by adopting my method.

CHAS. S. ARMSTRONG.

CHICAGO, Feb. 6, 1892.

SOME NEW METHODS OF STORING ELECTRICITY.

HAVING for several years paid much attention to the study of the electric current, I have arrived at the following results:

1. Electricity can be produced in the most economical way directly from heat. (Coalfire.)
2. Electricity can be stored in steel by means of heat.
3. Electricity can be stored in steel by means of electricity.

To No. 1 I would add: Currents of any quantity and potential can be produced. These only limited by the capacity of wire and amount of heat used.

To No. 2: Any amount of electricity of variable potential can be stored, kept, used and transmitted independent of producer. Electricity so stored produces a tension of magnetic nature. The same can be used as motive power or recharged independent of the producer in electric current.

To No. 3: This way of storing is not economical, but will be of value where motive power (water power) is abundant and cannot be consumed directly.

These assertions are based on principles which explain the nature of the electric current and whose correctness I assert on the ground that the principal phenomena in electricity can be explained. I am willing any time to explain these principles when a compensation is guaranteed for my labors, providing their practical value is beyond any doubt.

PROSPER NABICH.

MOTOR-DYNAMOS FOR ANNUNCIATOR AND BELL CIRCUITS.

In reply to Mr. Bartlett, on the bell work question, in your issue of Feb. 3, I would say that I did *not* overlook the voltage on open circuit, but, perhaps did not express myself plainly enough in my former communication, in which I proposed using two or more lamps in series, the bell circuits being in shunt with one of the lamps.

As to the vibrating bell not working, as I suggested, on account of arcing at the contact points, I have been informed by thoroughly reliable parties that they have had bells working in that manner for a year or more, giving perfect satisfaction.

The motor-dynamo suggested by Mr. Bartlett is the same as that used to automatically balance the Thomson-Houston three-wire system of distribution, and I doubt if it would be any improvement, for bell work, over that of Mr. Armstrong's.

W. M. MINER.

PLAINFIELD, N. J.

DRY BATTERY LITIGATION.

IN an article in issue of February 10, on page 147 of THE ELECTRICAL ENGINEER, your attention is called to the last two lines under the heading of "Dry Battery Patents."

This company is not the manufacturer of any Dry Battery. We have been handling a number of different makes of dry batteries, and the battery in suit which the Burnley people claim this company has been unlawfully selling, is not the "Mesco" but the "Johnson" dry battery.

Yours respectfully,
Manhattan Electrical Supply Company,
J. J. GORMAN, President.

NEW YORK, Feb. 13, 1892.

Literature.

The Electric Railway in Theory and Practice. By Oscar T. Crosby and Louis Bell, Ph. D. *The W. J. Johnston Co., Ltd.* New York, 1892. Cloth; 400 pp. 6 x 9 inches. Price $2.50. *First Notice.*

ELECTRIC traction has so largely absorbed the time and energy of electrical engineers during the past five years that to undertake the complete record of the work accomplished would be a task of no small magnitude. The treatises which have thus far appeared have in the main been devoted to the very interesting history of this subject and to a mere detailed description of the apparatus employed, a part of the subject which will be admitted to be of no little importance, but which is hardly adequate to satisfy fully the minds of those who may be looking for the solution of those practical problems which present themselves in every-day electric railway work. It is largely with the idea of bringing together information on this latter subject that the authors have projected the work before us. In other words, they have made the present practice of electric railroading the subject of their labors.

The reader is introduced to the subject by a chapter on general electrical theory illustrating the principles of dynamo machinery and the nature of the magnetic circuit, following which is a chapter on prime movers, in which the general principles of water wheels and steam engines are briefly explained. The various types of motors and car equipment are then taken up and the nature of the street car motor is fully explained with special reference to the class of work which it is designed to do. In this connection the authors discuss the various advantages and disadvantages of motors operated with rheostats, commutated fields, etc. They also discuss the motor in its relation to the other necessary parts of the car, such as the connection of the armature with the axle, in which regard the various types of gearing are pretty thoroughly discussed. We also find an interesting section on trolleys, methods of car wiring and miscellaneous equipment, such as lightning arresters and general instructions for the care of motors.

That most important part of an electric railway system, the line or conductors, is then taken up and the authors show plainly the necessity of devoting as much attention to this part of the equipment as to any other, in order to attain success. The track, car houses and snow machines also receive their proper share of attention, and the arrangement of the station has very properly been made the subject of a chapter. For those who are of a critical turn of mind, the chapter on the efficiency of electric traction will afford much interesting information, entering as it does into the discussion of the various losses which are met with between the generating dynamo and the motor on the car.

In a work like this, naturally, storage battery traction must find a place, although it can hardly be said that the space devoted to this branch of the subject is adequate to its importance, the authors being evidently of the opinion that the time has not yet arrived for its serious consideration, owing to the present condition of the storage battery art. Underground electric traction is also touched on, though in a very small way, the authors being limited, no doubt, by the small amount of practical work which has yet been accomplished in this direction. We also find a short description of the telpherage system.

High speed electric railway service, the study of which Mr. Crosby has made peculiarly his own, is very properly given a chapter, in which we find a description of the City & South London Railway, and a very good discussion of the subject, based on the paper read by Mr. Crosby before the American Institute of Electrical Engineers.

"Commercial Considerations" is the title of Chapter XI, which constitutes one of the most important chapters of the work. In it the authors lay before us quite a complete résumé of the original investment, cost of maintenance and operation and gross income of electric railways, based on figures which are probably as nearly correct as they can be obtained at this time. Paradoxical as it may seem, the authors have reserved the last chapter in the book for a historical review of the electric railway, which we think might have been more in place at the beginning. The value of the work is also increased by a number of appendices, among them the decisions of the Supreme Court of the State of Ohio on the Electric Railway *vs.* The Telephone; very complete "Instructions to Linemen;" and "Engineers' Log Book," showing the method of keeping the records and classification of the expenditures of electric railways; and finally an appendix, "Concerning Lightning Protection," due to Prof. Elihu Thomson, in which he discusses lightning in relation to railway circuits and apparatus, with special reference to methods of protection.

We have here confined ourselves to but a brief outline of the contents of this work, which we have no hesitation in saying is the most valuable, on the lines which the authors have taken up which has thus far appeared. We can go further and say that every electric railway engineer and street railway manager will find in it many suggestions which may lead to increased economy in the operation of a road, while to the student the practical discussion of the principles involved will be of the utmost interest. We are sorry to note, however, that so good a work as this should have been put in so poor a dress.

DR. F. A. C. PERRINE has a very interesting article in the January *Engineering Magazine* on "The Altruistic Effects of Electric Power" dealing with some very important social and ethical questions raised by this new agent in the economical distribution of energy.

THE AUTOMATIC FIRE ALARM AND EXTINGUISHER CO., LTD., of 413 Broadway, has declared a dividend of 2 per cent.

Patent Notes.

THE PATENT OFFICE REPORT.

COMMISSIONER Simonds of the Patent Office has recently submitted his annual report to Congress. The report recommends the following amendments to the Patent and Trade-Mark law :

First—That no improvement shall be patentable which has been, for more than two years before application for patent thereon, disclosed in any patent or printed publication issued in this country.

Second—That a patent shall not expire with the expiration of a prior foreign patent for the same invention.

Third—Compelling an applicant to take action upon his application at least once in every six months, in lieu of once in two years, as at present ; and that a patent shall in no case live for more than twenty years from the date of the first application.

Fourth—Requiring patent licenses to be recorded the same as assignments and grants.

Fifth—Putting aliens upon the same footing as citizens as to the filing of caveats.

Sixth—Abolishing interference contests in the Patent Office and relegating them to the courts.

Seventh—Requiring a fee of $10 for every appeal or petition taken from a primiary examiner directly to the Commissioner of Patents.

Eighth—Providing that no damages or profits shall be recovered in a suit for infringement except such as accrue within the six years last preceding the bringing of the suit.

Ninth—Providing that an injunction issued by a court against the transfer of a patent may be registered in the Patent Office and thereupon be constructive notice to all the world.

Tenth—Giving courts of equitable jurisdiction power to pass on the title to letters patent in a proper case without any action on the part of the defendant.

Eleventh—That the Commissioner of Patents may refund to the payer money paid into the Patent Office by mistake.

Twelfth—Defining the duties of the Assistant Commissioner of Patents.

Thirteenth—Permitting registry of trade-marks which are used in commerce between the States, the permission now being restricted to trade-marks used in foreign commerce or in commerce with the Indian tribes.

The following is a summary of the business of the office during the last calendar year : Total number of applications received, excluding applications for the registration of trade-marks and labels, 40,552 ; total number of patents granted, 23,244 ; total number of registrations, 1,899 ; total receipts, $1,271,283 ; total expenditures, $1,139,713 ; leaving a surplus of $131,572 ; making a total balance in the Treasury to the credit of the patent fund of $4,004,317.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED FEBRUARY 2, 1892.

Alarms and Signals :—

Electric Signal for Mine-Shafts, F. W. Bacorn, 467,985. Filed July 28, 1891.
An annunciator signal for mine elevators.

Electric Signal System, H. F. Eaton, 468,107. Filed Mar. 16, 1891.
A police signal employing a metallic circuit for one class of calls and a ground circuit for the other call for the purpose of distinguishing them, and also that the occurrence of an accidental ground will not derange the system.

Electrical Annunciator, W. Ebert, 468,170. Filed May 20, 1891.
An annunciator for signaling back and forth between two distant places.

Conductors, Conduits and Insulators :—

Trolley-Wire Hanger, C. T. Lee, 467,940. Filed Mar. 20, 1891.
A double insulated hanger for use in connection with a yard arm.

Insulator, C. T. Lee, 467,941. Filed Sept. 28, 1891.
A line wire insulator consisting of two links imbedded in an insulating material.

Insulator, C. T. Lee, 467,942. Filed Nov. 11, 1891.
A mica insulator for trolley wires.

Insulating-Swivel, A. H. Englund, 468,053. Filed Oct. 12, 1891.
An insulating swivel for trolley line wires, etc., adapted to resist very severe longitudinal strain.

Electric-Wire Coupling, W. B. Lillard, 468,086. Filed Apr. 20, 1891.
Relates to means for readily connecting electric wires between railway cars.

Conduit Electric Trolley, M. Wheless, 468,166. Filed Dec. 1, 1891.
A trolley having three pairs of wheels one pair for each line of wire ; the two pairs which are for the lines of wire in the same circuit being insulated from each other.

Connector for Electric Wires, C J. Coleman, 468,293. Filed June 15, 1891.
An open sided sleeve having on its inner periphery a series of circularly arranged inwardly projecting teeth.

Conduit for Electric or Cable Roads, C. H. Bates, 468,314. Filed Jan. 26, 1891.
Relates to means for automatically opening and closing conduit slot as the car passes along.

Distribution :—

System of Electrical Distribution, H. W. Leonard, 468,099. Filed May 12, 1891.
A system of distribution adapted to localities where the demand for current spreads over a large area, not however being sufficient in the outlying districts to warrant the construction of a central station in the neighborhood, and where there is a large variation in the required current at different hours in the day.

System of Electrical Distribution, E. Thomson, 468.122. Filed Mar. 11, 1891.
Provides an effective means of maintaining a fairly equal potential on the different branches of a system in spite of inequalities of load.

System of Electrical Distribution, E. Thomson, E. W. Rice, Jr., 468,123. Filed Mar. 19, 1891.
Claim 1 follows :
The combination, with a multiple-series distributing system, of an equalizer connected to the intermediate conductor and reconverting the excess of energy into an electromotive-force-feeding current to the outer mains.

Dynamos and Motors:—

Electric Motor, J. W. Darley, Jr., 467,924. Filed May 24, 1890.
A motor in which the current passing through the armature remains constant.

Electric Railway Motor, H. M. Byllesby, 467,969. Filed June 16, 1891.
A railway motor in which the fields and armature are concentric with one another and independently rotatable about their axis, the armature being connected to one axle and the fields to the other so that the opposite rotations of armature and fields shall impart rotation in the same direction to both car axles.

Dynamo-Electric Machine, E. Thomson, 468,121. Filed Oct. 16, 1890.
Relates to means of building up the stationary magnet frame and also certain parts of the revolving consequent pole, in sections, thus facilitating construction and avoiding heating from Foucault currents.

Electric Motor Regulation, F. O. Blackwell, 468,128. Filed June 5, 1889.
Claim 8 follows :
The combination, with an electric motor, of a speed controlling device therefor, a reversing device and a common actuating handle for the two provided with connection to each corresponding to different movements of the handle.

Regulator for Electric Current Generators, G. Pfannkuche, 468,260. Filed June 22, 1889.
Has for its object to insure a prompt, sensitive and accurate regulation of the generator.

Lamps and Appurtenances :—

Incandescent Lamp Socket, W. L. Silvey, 467,958. Filed May 17, 1889.
A strong and simple double brake switch for lamp sockets.

Incandescent Electric Lamp, D. H. Piffard, 467.982. Filed May 26, 1891.
Employs a sheathing of solid non conducting moisture-proof cement covering the connections of the leading-in wires and line wires.

Incandescent Lamp Socket, D. H. Piffard, 467,983. Filed June 25, 1891.
A socket consisting of a tube of soft rubber adapted to fit snugly the socket of an incandescent lamp thereby preventing corrosion from acid fumes, etc.

Device for Raising and Lowering Suspended Electric Lights, S. M. Terry, 468.159, Filed May 4, 1891.
Consists of a spring barrel with a flexible connection wound thereon and incased in the ceiling rosette from which the lamp hangs.

Measurement :—

Electrical Measuring Instrument and Current Direction Indicator, J. J. Wood, 468,020. Filed Nov. 3, 1891.
An indicator showing at a glance the direction in which a current is flowing over a circuit.

Metallurgical :—

Process of Separating Aluminum, C. S. Bradley, 468,148. Filed Feb. 23, 1883.
Claim 4 follows:
The process of separating or dissociating aluminum from its ores or compounds consisting in fusing and maintaining the fusion and electrolytically decomposing the ore or compound by the passage of the electric current therethrough.

Miscellaneous :—

Electric Elevator, H. W. Leonard, 468,1000. Filed Aug. 31, 1891.
Claim 5 follows:
A method of reversing the motion of an electric motor consisting in reversing the field magnet of the generator supplying the armature of said motor.

Electric Fare Register, W. H. Gilman, 468,172. Filed Dec. 1, 1890.

Illuminating Sign, L. J. Webster, 468,185. Filed Aug. 5, 1891.

Electric Light Tower, C. A. Beardslev, 468,186. Filed Sept. 18, 1890.

Electric Elevator, A. Neuburger, 468.258. Filed July 31, 1891.
Relates to means for conveniently regulating the travel of electric elevators.

Magnetic Toy, G. A. Goodson, 468,274. Filed Mar. 21, 1891.

Railways and Appliances :—

Electric Railway, M. Wheless, 468,163. Filed Dec. 1, 1891.
Improved system of electric railway for underground work.

Electric Railway, M. Wheless, 468,164. Filed Dec. 1, 1891.
Similar to No. 468,163.

Electric Railway, M. Wheless, 468,165. Filed Dec. 1, 1891.
Similar to No. 468,163.

Switches and Out-Outs :—

Electric Cut-Out, A L. Clough, 467,919. Filed Aug. 24, 1891.
A device for opening electric circuits at some determinate time after their closing.

Cut-Out, J. B. Murphy, dec'd, M. J. Murphy, administratrix, 468,101. Filed June 14, 1890.
Relates to mechanism for automatically breaking the current the intensity of which has become too great.

Electric Switch, E. Thomson, 468,119. Filed July 14, 1890.
The combination of switch contacts with a series of three or more conductors of different resistances operated serially in the order of their respective conductivities.

Method of and Means for Interrupting Electric Currents, E. Thomson, 468,120. Filed Sept. 1, 1890.
A method of avoiding arcing on the interruption of electric currents of high potential for lightning-arresters circuit-breaking switches, etc.

Electric Switch, A. Wright, 468,125. Filed July 13, 1891.
A spring-actuated quick-break switch.

Telephones and Apparatus:—

Telephone-Holder, J. A. Christy, 467,917. Filed July 12, 1890.

Telephone Receiver, E A. Grissinger, 468,246. Filed May 29, 1891.
Receiver for intensifying the sound waves.

Cut-Off for Telephones, E Cann, 468,281. Filed Oct. 3, 1890.
Relates to means of reducing the number of conducting wires by enabling the number of telephones to be attached to one circuit.

MR. EMIL KOLBEN, for the past four years the electrician of the Edison Works at Schenectady, was tendered a farewell banquet on Wednesday evening, February 3, by about fifty gentlemen prominent at the Edison factory. An excellent musical programme was given, and speeches were delivered which showed that Mr. Kolben has made many warm friends in the Edison company.

A presentation was made of a handsome Weston voltmeter and a silver bronze plaque with the head of Thomas A. Edison in relief. Mr. Kolben will take back with him to Europe the regards of many friends who wish him success in his work on the Continent. It is rumored that he will be associated with the Oerlikon Works in Switzerland.

TRADE NOTES AND NOVELTIES

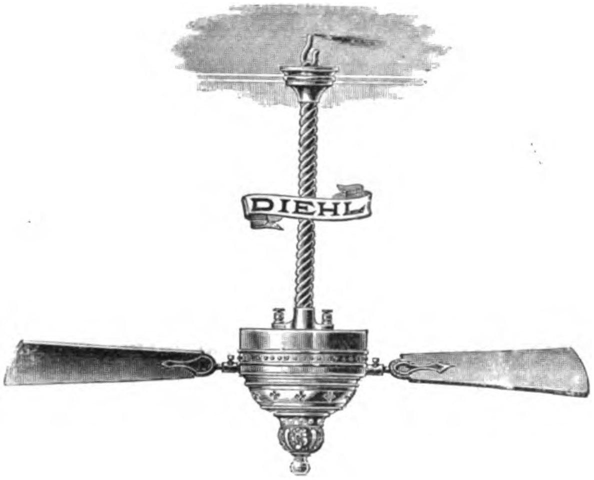
AND MECHANICAL DEPARTMENT.

If you advertise well, you will have something to "consolidate."

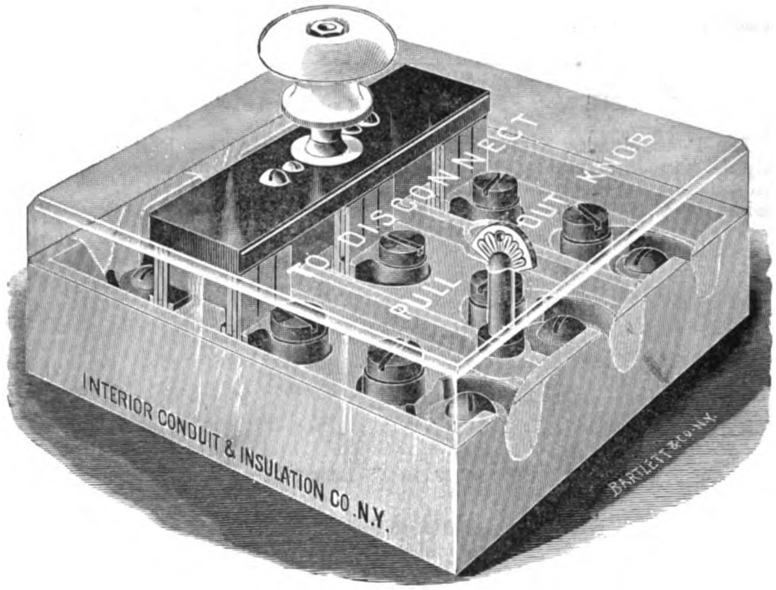
THE DIEHL ELECTRIC FANS.

The Diehl suspended motor fan, as shown below is one of the many designs in electric ventilating devices which Diehl & Company, No. 385 Broadway, this city, will place upon the market the coming season. The motor from which the power is obtained is contained within the basket. To the wheel which encases the revolving armature are attached the blades. The spindle revolves on a roller bearing within a tight oil cup which affords lubrication. The wires pass up through the tubing connecting with the line wires at the top. All liability of the motor heating has been overcome, its electric efficiency is unquestioned and its mechanical construction is of a correspondingly high class. It can be operated on a direct incandescent or arc current with equal success.

No more ornamental or attractive appliance could be desired than the suspended fan finished in handsome nickel or polished brass. No unsightly shafting or belting is required and there is no more disfigurement to the ceiling than in the hanging of a chandelier.



Diehl Electric Fan.



TO DISCONNECT PULL OUT KNOB
INTERIOR CONDUIT & INSULATION CO. N.Y.

The "V. V." Combined Plug Switch and Main Line Cut-Out.

By the simple turning of a switch they are set in motion; and where desired a novel attachment can be supplied to each fan not only for starting and stopping but for regulating the speed.

The firm also have an attractive assortment of floor, counter, column, bracket and their improved propeller fans.

The popularity with which those goods were received last season compelled the company to greatly increase their manufacturing facilities and they are now prepared to meet all demands in a thoroughly prompt and efficient manner.

THE "V. V." COMBINED PLUG SWITCH AND MAIN LINE CUT-OUT.

Electrical switches for breaking currents of both large and small capacities may be divided into two classes. 1st, those that are required for constant use. 2nd, those that are but seldom called upon to perform the service for which they are designed. The key socket is a ready illustration of the former, and the huge feeder switch of the latter class. To the first class many new designs are contributed from time to time, but in the latter, the use being to a certain degree limited, but few are well known enough to deserve recognition. The device illustrated herewith, is a switch of the second class, and is known as the "V. V." Service Cut-Out, the invention of Mr. J. H. Van Vleck, the electrician and chief engineer of the Edison Elect. Illg. Co., of New York, for whose special requirements the switch was originally designed.

The Fire Underwriters in the principal cities require the placing of a switch and cut-out in the main line of every circuit entering a building, which can be readily disconnected, in case of necessity by the firemen, and when so disconnected insures that the current is absolutely shut off.

The above switch combining in a compact form within itself a switch and cut-out, has filled this requirement to the entire satisfaction of the N. Y. Edison and other well known illuminating companies.

In this device, the extra cost of the switch arrangement is but a small additional expense over the necessary safety cut-out, so that the combination fills a gap between the conditions where the expense of a regular snap switch and cut-out would be unwarranted, and where a cut-out without a switch would be incomplete.

The switch is constructed wholly of fire-proof material; its base and cover being of the best quality of porcelain. It is made for the two and three-wire systems on the plan illustrated, from which it will be seen, that one-half of the device embodies the ordinary safety cut-out principle for holding the safety fuses, while in the other half there is a novel form of quick acting snap switch.

The connections are of bronze of ample capacity, with strong screws for the binding posts; the contacts made by means of the plug are admirably fitted, and when the plug is withdrawn to open the circuit, the movement is accelerated by means of a strong spring which is contained in the plug itself, insuring a rapid and complete break with a sharp snap action. The only exposed portion of the plug is finished hard rubber, the whole presenting a neat and attractive appearance.

The use of this appliance is however by no means limited to the above particular purpose, but is offered by the Interior Conduit & Insulation Company, of New York, for general use.

SIOUX CITY ENGINE WORKS, SIOUX CITY, IA.

It is now practically assured that the business of the Sioux City Engine Works will be reorganized, and that there will be placed at the disposal of the Company what has long been needed—ample capital to conduct the business upon business methods. It is long since the business outgrew its capital. In spite of all obstacles, however, the sales have been doubled in 1891, and at the beginning of the present year, the Company had a large number of contracts upon its books, a large and valuable stock of material on hand, and excellent business prospects for the future, the only thing lacking being sufficient working capital.

STRATTON SEPARATORS FOR U. S. GOVERNMENT CRUISERS.

The Stratton Separator Company, 32 Cortlandt Street, New York City, have recently furnished to the Columbian Iron Works & Dry Dock Co. of Baltimore, Md., several large separators for use in the new cruisers Nos. 9 and 10 which they are now constructing for the government. These separators are of the naval type especially constructed with steel shells and brass heads to meet the requirements of the United States Navy.

THE SHORT GEARLESS MOTOR.

A series of interesting tests has just been made in Cleveland in order to determine the relative merits of the various new types of street car motors recently put out by the different companies. A prominent engineer of the West was sent by his clients to report particularly upon the Short Gearless motor and the single reduction motors of other makes. The tests were made by attaching two motor cars together and running the train with each alternately over a measured stretch of track. The power consumed was measured by the Thomson-Houston wattmeter. Dynamometers were placed between the cars, the readings taken showing the power required to pull each car as a trailer. The utmost care was taken to secure reliable results. It is interesting to note that the doubt in the minds of many street railway people concerning the power consumption of a gearless motor, was proven to be without foundation. The gearless motor was nearly at the bottom of the list, showing an extremely high efficiency, greater even than several of the double reduction motors, which were also tested as a basis for general comparisons.

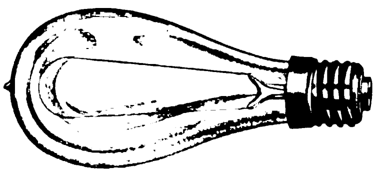
It was found that the gearless motor car was slower in speed than any of the single reduction motor cars, showing that Mr. Short's efforts to make a slow-speed motor have been entirely successful; in fact it has been found necessary to wind the motor for a higher speed in order to meet existing conditions of street railway work.

Another feature of the Gearless motor car was the fact that the power required in drawing it as a trail car was less, as shown by dynamometer readings, than that required for the single reduction motors.

The Short single reduction motor showed a very high efficiency in all the tests made.

THE NEW "PENNSYLVANIA" LAMP.

The Pennsylvania Electric Engineering Company, of Philadelphia, have lately put upon the market a new lamp, which they claim has all the merits of the best lamps of other manufacturers, besides overcoming the difficulty presented by the vapor of mercury. Their lamps are exhausted with mechanical pumps, which are claimed not only to produce a higher vacuum, but secure far more uniform results than are possible by the old method. The above-named company claim that with their process of mechanical pumping they can produce a lamp which shall have an average life of 1,000 hours, and can be successfully operated, maintaining 14.2 sixteen candle-power lamps per horse-power.



THE "PENNSYLVANIA" LAMP.

The following is an impartial test made by an electrical expert:

Candle-power, (English Standard).	E. M. F. in volts.	Current in Amperes	Efficiency Consumed in Watts.	Efficiency per Watts, Candle-power.	Lamps per Horse-power.
16	50	1.02	51	3.19	14.2
16	75	.70	52.5	3.28	14.0
16	100	.54	54	3.37	13.8
16	110	.50	55	3.44	13.5
25	50	1.55	77.5	3.10	9.6
25	100	.80	80.8	3.20	9.8
32	50	2.02	101	3.16	7.4
32	100	1.00	100	3.12	7.5
50	50	3.30	165	3.3	4.5
50	100	1.70	170	3.4	4.4
75	50	4.90	245	3.26	3.0
75	100	2.60	260	3.46	2.9
100	50	6.85	342.5	3.42	2.2
100	100	3.60	360	3.60	2.1
125	150	2.80	420	3.36	1.7
150	50	10.00	500	3.33	1.4
150	100	5.40	540	3.60	1.4

Other notable features of this lamp are the unusual brilliancy of the light, graceful uniformity of the bulbs, and the length of the filaments, as shown in the accompanying illustration. Altogether, it is a lamp of the highest grade of manufacture.

THE PELTON WATER WHEEL CO.

THE above company have recently furnished the Commercial Mining Co. of Arizona a power plant which affords a good illustration of the results that can be obtained from a small quantity of water under a high head, as also the estimate of value placed upon a water power even under such extreme conditions. This plant consists of a 4-foot Pelton wheel which runs under a 1,200-foot head at 690 revs. per min. developing 45 h. p. using a nozzle tip $\frac{58}{100}$ of an inch in diameter. Also a 24-inch Pelton wheel running under the same head at 1,380 revs. developing 20 h. p. with a nozzle tip $\frac{35}{100}$ of an inch diameter.

These wheels are to run a concentrating and smelting plant including rock breaker, blowers, pump etc. The pipe line is 20,000 feet in length the upper end being 5 and 6 inch casing, the lower end 5-inch lapweld pipe. All the water supply that can be counted on during the dry season is a flow of about 30 cubic feet per min. The large expenditure here made in pipe line for a comparatively small amount of water, will indicate the advantage that water power has over steam even under what may be considered, unfavorable conditions.

HUNT ENGINEERING CO.

WE take pleasure in noting the fact that arrangements have been made for the reorganization of the Hunt Engineering Company, which will take effect on February 1st. Mr. J. M. Brown, of Brooklyn, well known in business circles as an energetic financier and capitalist, has purchased the balance of the treasury stock of the company, has been elected treasurer, and will have control and management of the finances, Mr. George W. Hunt retaining the presidency and Mr. Albert F. Rich continuing Secretary and General Manager. Mr. H. C. Willis, formerly of the firm of T. F. Hunter & Co., 33 Church St., well known to all connected in the electrical supply business as an energetic and pushing salesman, will have charge of the supply department. New quarters have been leased for the manufacturing of their many electrical devices, which are meeting with a ready sale, and they look forward to a successful year's business.

POND ENGINEERING CO.

THE Electric Light Company, Albuquerque, N. M., have telegraphed an order to the Pond Engineering Co., St. Louis, for a 100 h. p. Armington & Sims engine. This is their third order within one year. The Equitable Gas Light & Fuel Co., of Chicago, have also contracted with the Chicago office of the Pond Engineering Co. for an Armington & Sims engine, to drive a large exhaust fan. This plan is already in use by two other gas companies in Chicago, and is proving very popular in gas plants.

RAW-HIDE PINIONS ON ELECTRIC RAILWAYS.

THE Auburn City Railway Co. have addressed the following letter to President T. W. Meachem, of the New Process Rawhide Co., of Syracuse, N. Y.:

We wish to state to you our approval of your patent raw-hide pinions furnished by you and now running on our motors here.

We have had a nine months' experience with them and find they fill all requirements.

Motors equipped with them run a great deal more quiet, and they will with ordinary care outlast the metal gears used.

They require to be kept free from oils and the ordinary car equipments can be kept much cleaner in that respect.

You are at liberty to use our recommendation and may refer any parties to us whom you may see fit.

Very truly yours,
(Signed) AUBURN CITY RAILWAY CO.
A. H. UNDERWOOD, Secretary

LA ROCHE ELECTRIC WORKS.

AN excellent catalogue of apparatus for electric light and power has just been issued by the La Roche Electric Works, of 116 and 118 North Sixth street, Philadelphia. The apparatus is built under the patents of F. A. La Roche, and includes a variety of machines and lamps for both direct and alternating work, as well as meters, indicators, etc., and the other appliances that go to a complete plant. The pamphlet includes also pictures of some of Mr. La Roche's installations recently shown in these pages. Another section embraces a number of testimonials as to the thorough and satisfactory work of the concern, which has built up a rapidly progressive business on solid merit.

FARADIC, PAR EXCELLENCE.

FROM among many flattering testimonials lately received by the Jerome Kidder Manufacturing Co. the following letter is selected. To attempt higher praise would be to paint the lily:

JEROME KIDDER MANUFACTURING CO.,
820 BROADWAY, NEW YORK.

The No. 1 Electro-Medical Apparatus arrived all O. K., and it is certainly one of the most faradic batteries we have seen and we are highly pleased with it.

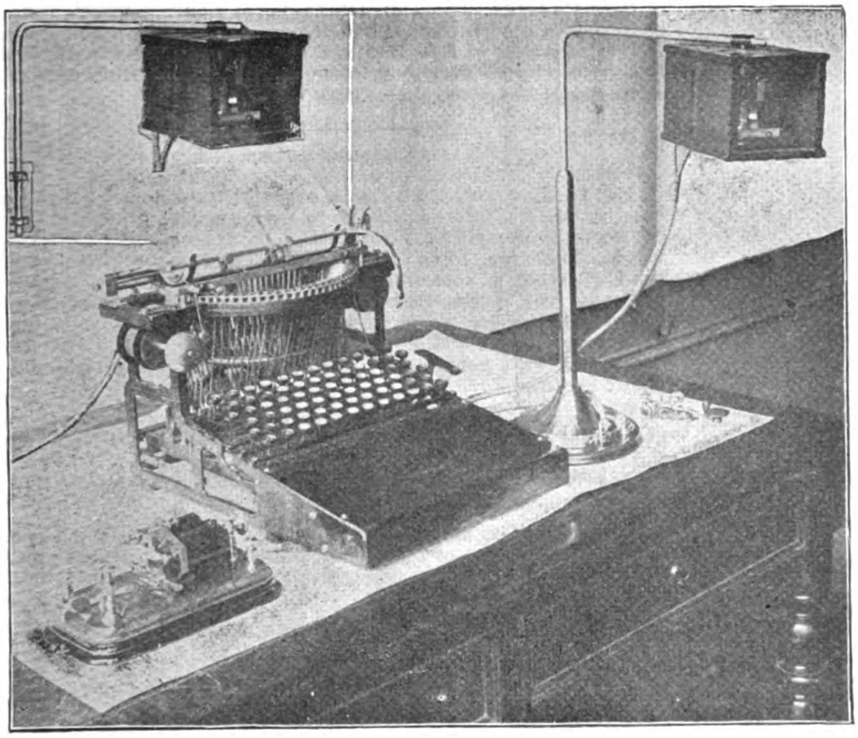
Very respectfully,
TEX. MED. PUB. CO.,
Per W. B. BROOKS,
Manager.

THE BUNNELL ADJUSTABLE SOUNDER SUPPORT AND RESONATOR.

THE typewriter, in place of pen and pencil has been extensively adopted during the past two or three years in numerous telegraph offices, but its use has been attended with some difficulty owing to a tendency to confuse the receiver, caused by the click of the machine being sometimes as loud as that of the sounder. This interference being now entirely eliminated will doubtless bring typewriter receiving into still more general use.

To avoid this difficulty, Messrs. J. H. Bunnell & Co., of this city, have just brought out the novel device illustrated in the accompanying engraving, designed to increase the sound of the instrument and to adjust its position so as to bring it as near as desired to the operator.

The sounder, which is of the well-known Bunnell "Giant Sounder" pattern is clamped within a very resonant box which is open at both ends and is sustained in mid air by a swivel pendant on a swinging arm. This arm is also adjustable to be raised to, or lowered from, any height within the necessary range, and as the arm also swings laterally on its support the operator can have the sounder wherever it is wanted. The effect of clamping the sounder within this peculiar resonating box, is to increase its loudness and distinctness to a startling extent, leaving nothing more to be desired in that direction unless the operator is nearly stone deaf, for the instrument, with its enormously increased sound, can be brought so close as to almost touch the ear if desired.



THE BUNNELL SOUNDER SUPPORT AND RESONATOR.

Under these circumstances, no typewriting machine, however noisily it may click or clatter, can interfere in the least with receiving by sound. In railway telegraphy, at noisy stations, in stock exchange telegraph offices and in every possible situation where the telegraph must be operated in the midst of the roar and din of such forms of modern daily business as are inseparable from noise, this device will be a welcome facility and will add to the accuracy of the work done. On the other hand it is frequently desirable that no eavesdroppers should become aware of what is coming over the wires, and to accomplish this, the device can be so adjusted that the instrument cannot be heard by any one except the operator who is taking the message.

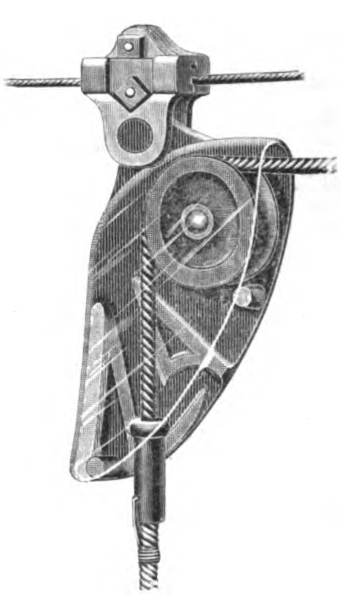
PARTRICK & CARTER CO. OF PHILADELPHIA, advertise their "New" box bell in this week's issue. This bell possesses many points of merit, and is likely to be well liked by the trade. They are made in three sizes only at present, of all the regular woods such as walnut, oak, cherry, plain and antique oak and cherry stain. The circular which the firm has issued gives special prices according to quantity ordered.

CUTTER'S LATEST PULLEY.

AMONG the devices which have seen marked improvement during the past few years, are the pulleys used for suspending arc lamps. The ordinary galvanized block was not adapted to be readily secured to a suspension wire and was by no means weatherproof. What is more, there was the need of some means for keeping the lamp from falling in case the hoisting rope should slip.

A simple and effective pulley which met all these requirements was the lamp-supporting pulley illustrated by us a year ago. This had the same arrangement of a knob and guides which is found in the most recent form, and its success is well vouched for by the attempts made by others to accomplish the same end. These have been quite numerous, and all have a system of cams or catches exposed to the weather. With them, it is necessary to stop the pull on the hoisting rope at a certain point, which is quite a problem when it is getting dark or when the trimmer's hands are benumbed with cold.

Cutter's lamp-supporting pulley evidently scores a point here, as it enables the trimmer to pull on the hoisting rope until the knob reaches a dead stop; then on slackening the rope the lamp is left hanging from the pulley. The new pattern shown in the cut has a swivel clamp which is readily secured to the suspension wire or cable, and which allows the pulley to tilt slightly when engaging or releasing the knob. All parts are strongly made and are well protected from sleet and ice. This new form is already in service in scores of places, and George Cutter is well pleased with the comments made by the users.



A NEW CUTTER PULLEY.

THE ELECTRIC MERCHANDISE CO.

THE founders of the Electric Merchandise Co., of Chicago, whose growing volume of business has surprised even themselves as the Spring opens up and the preparations of scores of new electric roads make themselves felt, are reaping some of the fruits of the wisdom of their early plans and methods. Their very choice of a name might be said to be indicative of coming success, it was so shrewd and novel; while their prompt selection of a new field for exploitation displayed the courage that has made not a few great institutions. In studying the devolpment of industrial and commercial enterprises it is interesting to observe sometimes the ingenuity and felicity with which an idea will be pushed to its full, so that when the mind is turned to any given branch of trade, a certain concern is sure to crop up in thought at once, as though it had secured a broad title of pre-emption to the territory, and had covered the domain with its name, very much as one of the old feudal leaders carved out a big principality with his sword, and then associated his impressive dignity with it for ever. This kind of thing is more difficult in commerce than in con-quest, just as brain is higher than brawn; and the newspaper man when he dubs the geniuses or workers or financiers who have "arrived", by some fancy title that once marked the old form of pre-eminence, he is not so very reprehensible after all. If there is anybody to-day who can think of street railways and electric railway supplies without at the same moment thinking of the Electric Merchandise Co., he will make a good exhibit for the curiosity department of the World's Fair. The mere existence of such an individual would be enough to make Mr. W. R. Mason feel that he had lived and advertised in vain. But in point of fact he doesn't feel that way at all. Some one has said that a good way to succeed is to "strike the note of distinction," and Mr. Mason sums up his philosophy on the subject in the corollary that the best way is to "keep on striking it."

NEW YORK NOTES.

The Fitch Battery & Electric Co., of Oneida, N. Y., have recently issued a very interesting catalogue descriptive of the "Perfect" battery of which they are the sole manufacturers. That this is not a misnomer may be inferred from the many gratifying letters received, a few of which they have published, attesting its merits. In the latter part of the book some pages have been left blank for memoranda.

Waite & Bartlett Manufacturing Co., of 143 East 23d street, recently furnished a large Holtz machine for Dr. Rockwell's lecture on the physiological effects of electricity before the electrical section of the Brooklyn Institute. It was of the latest and most approved form. They also exhibited a Wimshurst influence machine and some excellent Leyden jars.

Arrangements have just been perfected by the Security Insulator Co. whereby they are enabled to fill all orders promptly and at greatly reduced rates.

NEW ENGLAND NOTES.

H. N. Bates and Company, of Boston, have just issued one of the handsomest catalogues, if not the most handsome, ever presented, showing a general line of shafting, clutches, pulleys, and various kinds of machinery for the transmission of power. The book commences with a description of the famed Hunter friction clutch cut-off coupling, for which this company is the sole selling agent, and shows it as applied to varied kinds of work. The Hunter friction quill as illustrated in the Catalogue is particularly interesting to electrical engineers, as it enables them to lay out stations with countershafting, with the main pulleys supported entirely on a quill with independent bearings. The strain of the main belt is thus taken up on independent bearings, and the engine can be started up entirely independently of the shafting. The catalogue contains numerous cuts of Hunter friction clutch pulley, single and double armed, and a comprehensive price list from 18 inches diameter to 116 inches diameter. There is also a valuable set of tables of whole and split iron pulleys from 6 inches to 108 inches diameter, and split wood pulleys from 9 inches to 108 inches diameter. Besides these the catalogue contains numerous illustrations of various kinds of pulley and belt drives, belt tighteners, adjustable belt carriers, iron and steel shafting, couplings, gearing, hangers and all kinds of shafting brackets and pillow blocks. The floor stand with adjustable pedestal and loose pulley bracket attached, is worthy of special mention, as being used largely in connection with dynamos, and is used to relieve the dynamo from the strain of the belt when the belt is shifted on to a loose pulley. The book concludes with a valuable treatise on the dimensions of hangers, pillow blocks, floor stands, couplings, &c., and will be found to be an extremely useful and necessary addition to the library of every engineer who is engaged in designing plants for any kind of machinery. The book is handsomely bound, and is profusely illustrated, and reflects great credit on Messrs. Bates & Company, and a copy should be in the hands of every electrical and mechanical engineer.

The Berlin Iron Bridge Co., of East Berlin, Conn., are just completing a new machine shop for the Bridgeport Machine Tool Co., at Bridgeport, Conn. The building is made entirely of brick and iron, divided into two parts, each 40 feet wide, the total length being 96 feet. One portion is two stories high, the roof and floor being designed for light work, while the opposite half of the building is of the same height but the second floor is omitted so that it may be used as an erecting shop. The erecting shop is controlled by a traveling crane. The building when completed will be one of the most perfect and best designed machine shops in the New England States.

The Tripp Manufacturing Company of 180 Summer St., Boston, recently shipped 19 of their standard roller bearing trucks to the Central Electric Railway, of Sacramento, Cal. Mr. Lewis, the general manager of the road, spoke so highly of these trucks that the Oakland, San Leandro & Haywards Road, of Oakland, have ordered 12 similar ones on his recommendation.

Mr. J. Bradford Sargent, of Boston, agent in New England for the Cooper Corliss Engine Company, of Mount Vernon, O., has secured the contract for three 500 h. p. Cooper Corliss compound condensing engines, to be installed in the new station of the Lowell and Suburban Street Railway Company at Lowell, Mass. These engines have a very high reputation, and will be similar to the 450 horse power engine recently installed by Mr. Sargent in the plant of the Leicester and Spencer Street Railway Company, near Worcester, Mass.

Perry and Demeritt, of Montpelier, Vt., are meeting with marked success with the "L. P. and D." system of transmitting power to dynamos. This system can be applied either direct to the engine flywheel, or to the pulley on a countershaft, and saves all the space occupied by long belt drives. Perry and Demeritt have established agencies in the West, with parties who are well pleased with the system, and their business has grown so large, that they are now making arrangements to extend their manufacturing facilities.

Albert and J. M. Anderson, of Boston, have recently received orders from the West End Street Railway Company of Boston, for several thousand pieces of their well known Ætna insulating devices for electric railway work. They are also in receipt of some large orders from the Newark Passenger Railway Company, of Newark, N. J., the extension of the Paterson Street Railway Company, Paterson, N. J., and the Trenton Passenger Railway Company, of Trenton, N. J.

The Chester Pipe and Tube Co., of South Chester, Penn., have placed the contract for their new building with the Berlin Iron Bridge Co., of East Berlin, Conn. The building will be 52 ft. in width by 170 ft. in length and constructed of iron, no wood work being used about the construction.

ST. LOUIS NOTES.

Mr. W. L. Arnold, St. Louis, agent of the Thomson-Houston Electric Co., has lately made the following sales: The City Electric Street Railway Co., Little Rock, Ark, 20 arc lights; Iowa Iron Works, Dubuque, Iowa, for the U. S. Government torpedo boat No. 2, 20,000 c. p. search light and 100 incandescent; Missouri Malleable Iron Works, East St. Louis, 50 arcs and 450 incandescent. Construction of the plant in the Wainwright Building is now under way. The installation will consist of three 50,000 watt and one 15,000 watt generators driven by four Westinghouse compound engines.

Mr. G. Pantaleoni, Western representative of the Westinghouse Electric Co., reports the following sales: Leggett & Meyers Tobacco Co. 1,600 lights; Westlicher Post Association 700 lights; D. Crawford 250; Geo. Fowler Sons & Co., Kansas City, 1,600 lights; Salisbury, Mo., 750 lights.

The Short Gearless Motors are now in successful operation on a thirty-foot car of the Lindell Railway Co. The Short single reduction motors are also being given a trial on one of the Lindell Railway Co's. thirty-foot cars.

The Edison General Co. are fitting up spacious quarters on the ground floor at 728 Locust street.

WESTERN NOTES.

Mr. S. F. B. Morse, the inventor of Morse's lightning calculator for electric light circuits, which is meeting with a large sale among electrical people generally, has completed and copyrighted a similar calculator for motor circuits, motive power and street railway service and available efficiency of water-powers, which will be placed on the market in due time by Edward Lasell of Kansas City, Mo.

Vulca Ducts.—Among plants equipped with Vulca ducts by the New York Insulated Wire Co., through Mr. G. H. Meeker, their Western manager, may be mentioned the Wausau Court House, Wausau, Wis., Pabst Hotel, Milwaukee, and Maus Office Building, Indianapolis.

George Cutter says that he can sell the new interior conduit "Buildite" quicker than the factory can ship it, but still has hopes of having a stock at Chicago soon.

Mr. P. C. Ackerman, agent of the American Electrical Works, No. 10 Cortlandt street, New York, spent some time in Chicago last week.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

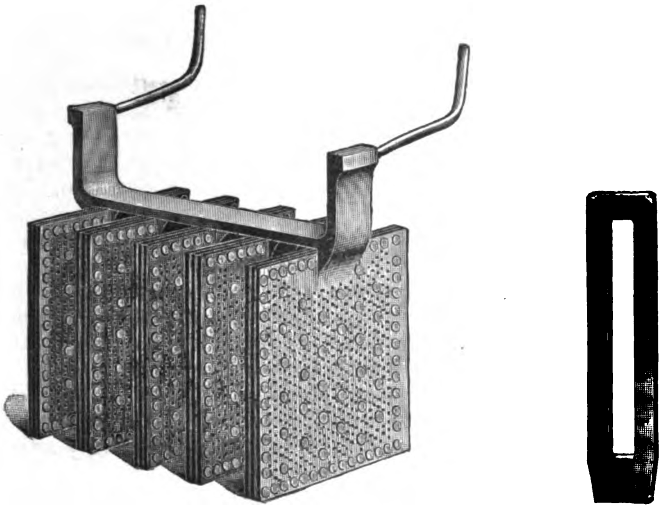
THE
Electrical Engineer.

Vol. XIII. FEBRUARY 24, 1892. No. 199.

THE "MAIN" HIGH VOLTAGE STORAGE BATTERY.

THE ordinary types of storage batteries in which the active elements are lead and oxide of lead, respectively, are known to give a working difference of potential of about 2 volts; their construction, also, has involved the employment of lead, one of the heaviest metals. In order to obviate both these drawbacks and to obtain a cell which should give an increased working E. M. F. with diminished weight, the use of zinc was early advocated, and M. Reynier, among others, has devoted considerable attention to the lead-zinc battery. Up to the present, however, this type of cell cannot be said to have met with much success, due principally to the great solubility of the zinc in sulphuric acid and also to the lack of a permanent backing upon which it could be redeposited.

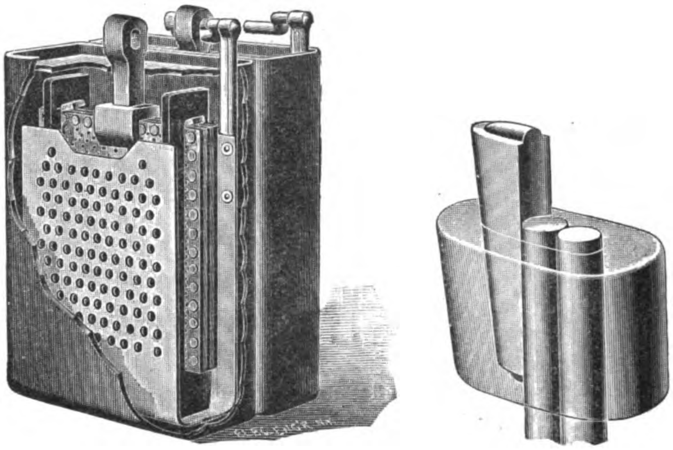
It was with these defects principally in mind that Prof. Wm. Main some time since began experimenting on this type of cell, and the results of his labors are now embodied in a storage battery just brought out by the Union Electric Co., of this city, who are manufacturing under the patents of the River & Rail Electric Light Co.



Figs. 1 and 2.—Positive Electrode of Main Cell, and Separator.

The manner in which Prof. Main has accomplished these results will be understood from the engraving, Fig. 1, which shows the positive electrode of a single Main cell of the type known as F 5. It consists of five lead plates connected by a cross-bar, also of lead, to which terminals are secured to connect with the negative electrode of the adjoining cell. Each of these plates is made of a number of thin sheets of lead, enclosed between two stout outer sheets. These are all perforated simultaneously in a press and secured together by numerous leaden rivets. Sometimes, as shown in the illustration, there is also a centre sheet of the thicker lead.

The plates built up in this manner are then "formed" by the prolonged action of a charging current, which converts the thinner inside sheets completely into peroxide of lead, leaving the thick ones, which are but superficially affected, as permanent retaining walls and supports. The transverse holes which remain open give free access of current and fluid to the interior of the plate. The working surface thus obtained is much greater than the outer flat sides would afford; no peroxide can drop out, and the plate, however thick, is discharged uniformly throughout.



Figs. 3 and 6.—Main F 1 Cell, and Connector.

Fig. 2 shows the hard rubber separator employed, two of which are slipped over each lead plate, serving both as supports, and preserving the space between electrodes, which is greater than in that usually allowed for in storage cells.

The cells of different sizes are designated F 1, F 2, F 3, etc., according to the number of plates in the positive electrode, but the plates themselves are all of the same size, viz., a little over six inches square. Each plate will yield 100 watt-hours under a moderate rate of discharge, so that an F 5 cell has a capacity of 500 watt-hours, the number indicating the number of hundreds of watt hours to be expected.

Fig. 3 shows the interior of one of the F 1 cells, and Fig. 4 the method of connection. The negative pole or electrode, in all of these cells, differs even more widely than the positive in its construction from the usual methods. It is made of an amalgam of zinc and mercury, deposited electrolytically upon a copper plate.

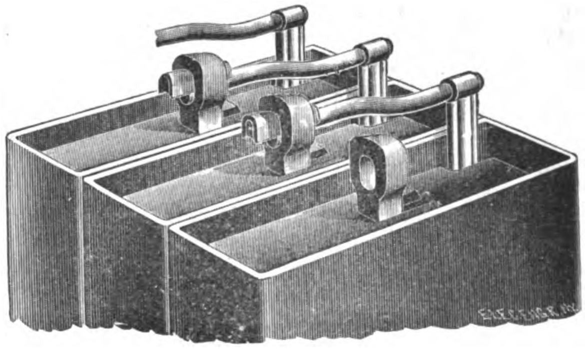


Fig. 4.

Zinc gives a higher electromotive force than the spongy lead usually employed, and but little of it is required. It is partly dissolved during the discharge of a cell and redeposited upon the copper plate by the charging current, so that there is no loss. The copper support gives permanence and high conductivity to what would be otherwise a perishable plate, while a small amount of mercury suffices to prevent local action, as it spreads by capillary action over the whole surface. The copper sheets are of No. 22 gauge, but the deposited zinc amalgam, with which they are coated, alters their form but very little, although, of course, making them somewhat thicker and rougher than they would be otherwise. Each copper sheet has a number of large perforations through it, giving a better hold to the soft amalgam, and it is long enough to bend into a U form, so as to come opposite to both sides of the lead plate. These sheet copper U's are riveted together in numbers corresponding to the lead plates. A complete F 5 cell is shown in Fig. 5.

The method of connecting the elements of the cells is one of the most simple and effective which we have yet noticed. The connecting wires are of copper, solidly coated with lead. The clamp which is shown in Fig. 6, is an oval collar of hard lead alloy, slightly tapered in one direction to correspond with a key wedge of the same material, which is lightly rapped into place, or pressed in with pliers. The inner face of the wedge is hollowed to fit the wire, so that a considerable surface is driven firmly into contact. Rapping the collar downward, with a light, quick stroke, or the application of pliers to the small end of the key and the upper face of the collar, loosens it in a moment.

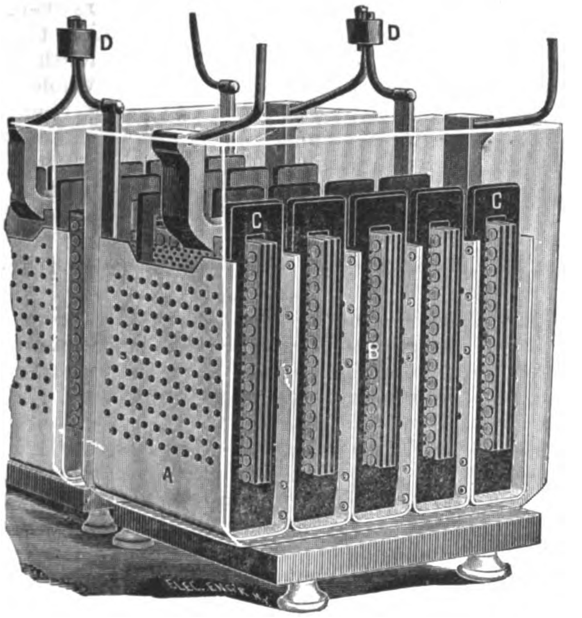

Fig. 5.—High Voltage, Main F 5 Cell.

This connection exposes no brass or copper to the action of acid, is made wholly of conductive and non-corrodible material, and has proved reliable under the most trying conditions. All cells except the types F 1 and F 2 have double connections, ensuring a high degree of conductivity. Single plate cells are connected as shown in Figs. 3 and 4, the lead-coated wire from the negative plate being passed into an eye in the solid lead terminal of the next positive and keyed fast.

All of the cells may be taken apart by simply lifting out the positive electrode.

From the fewness of the plates and their distance apart, it might appear to some that the internal resistance of these cells would be higher than desirable. This is not the case, for it will be found upon calculation, and has been proved by experiment, that the battery fluid can cause but a small part of the internal resistance of storage batteries, which is due mainly to the *character of the surface* of the plates employed.

In this case the peculiarities of construction all favor conductivity, for the surface of a negative plate remains the same throughout the discharge, and the positive shows no visible formation of sulphate of lead at any time. For this reason the positive plates may be thicker, fewer and more widely spaced; this affords a more solid and simple construction, while the internal resistance remains as low as in cells of corresponding capacity, but carrying a large number of closely set plates of the common "grid" pattern.

It will also be noted that, in contradistinction to the usual grid form of plate, in the plates of the Main battery the absorbent material, instead of filling an extended series of cavities opening outward is solidly enclosed between continuous sheets, so that it cannot work out.

These cells have an increased voltage of 20 per cent. over that of the "lead" batteries and possess the property of discharging at high rates without buckling or disintegration or injury of any kind whatever.

NOTES ON ELECTRIC STREET RAILWAY CONSTRUCTION.—II.

BY

A. K. McCay.

CAR CLEANING AND CAR INSPECTING.

The one branch of electric railroads which demands system, constant care and faithful work is the inspecting and cleaning of the motors. On the result of this being well done will depend the life of the motors, the size of the repair bill and even the success of the whole system. The motors should be inspected once a day by a competent, regular inspector, who should instruct the motor man at the same time what faults are likely to arise.

This point, the instruction of motor men, should be impressed on managers, a motor man should know every fault his motors are liable to, he should not only be able to start and stop the car like an automaton but should be able to remedy any small defect, at least to replace a brush or to know if his armature is flashing sufficiently to cut it out. This instruction will pay and I strongly advise it.

This inspection should take place preferably at the end of a route, boarding the car a short distance from the end, and inspecting the motors WHILE THE CURRENT IS ON THEM. The traps in the floor being raised the inspector should observe the action of the motors running together; if the car be fitted with double motors. Then each motor should be cut out, and the action of the other carefully noted. Very often the inspector finds that there is a blaze or a bubble of sparks at end of the brush, the motor apparently running all right, but a perfect ball of fire at end of brush. This is usually caused by the brush being worn away and having become fastened in the brush-holder, the spring not pushing it up against the commutator. Again, the inspector will find that there is a purplish, bluish spark which appears to follow around the commutator in the direction in which the armature is revolving; this means a broken wire or a loose connection; this motor should be *cut out at once* and the trouble remedied while in its incipiency, as oftentimes can be easily done. On cutting in one motor by itself it may be found that when the platform switch is thrown in the armature may turn a quarter turn and then remain at a standstill; this shows a short circuit in the coils of the armature and as it is always good for the repair man to know where it is, both motors should be cut in, and operated a short while together till the commutator bars are "marked" opposite the coil in question. This "marking" will generally take place in the mica just between commutator bars, it being eaten away quite rapidly by the spark which ensues on the brushes passing the short-circuited coil.

Another fault which will probably be detected before the inspector arrives is the grounding of an armature; this is usually manifested, if it is a leak more than a ground, by a violent jumping or "bucking" of the motor in question; very frequently rising up against the bottom of the car in a manner more marked and positive than agreeable. This motor should be cut out at once. Excessive sparking not following the commutator or amounting to a ball of fire beneath brush is usually caused by a dirty commutator. If very bad it should be cleaned at once; to do this a piece of No. 2 sandpaper, tacked on a block which is shown in Fig. 1, must be held tightly against the commutator while revolving, but having no brushes on the same, it being driven by the other motor. This will soon give a bright glossy color and when the brushes are reset it will be found that all trace of sparking has disappeared.

The inspector having carefully looked over the electrical conditions of the armature and brushes should then place his hand on the field coils, noting their temperature and comparing the two motors; for if one set is unduly heated and the set in the other motor is comparatively cool, one motor is doing all the work. In the same way the different coils of the individual motors should be examined to see that none is short-circuited and doing no work. After looking over the fields the inspector should turn his attention to the bearings, feeling them and seeing that they are properly lubricated. A glance at the gears is usually sufficient to satisfy him, and his inspection is properly over, unless the motor man call his attention to the lamp circuit, fuse box, or platform switches. Then the inspector should look generally over the car to see that no glasses are broken, that the windows are clean, and the car has been properly swept and cared for. Then he should fill out his inspector's blank, a form of which is given in Fig. 2. These blanks are turned in to the superintendent after the inspection for the day is over. The superintendent then issues his orders to the night inspector and cleaner who begins work on the cars when the cars are run into car house at night.

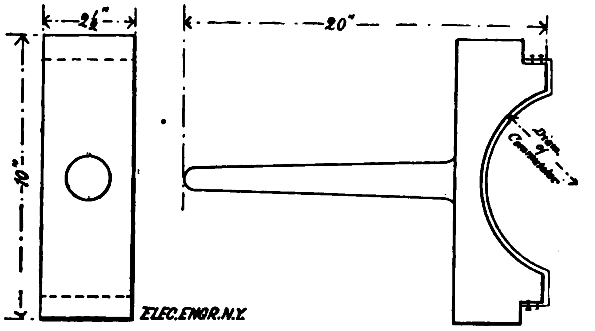

Fig. 1.—Sandpaper Block for Cleaning Commutator.

The cleaning and repairing which is necessarily done at night should be entrusted to careful, conscientious men; as this portion of the work is both tedious and monotonous. One man can thoroughly clean a car in the space of half an hour, and at least that time should be devoted to cleaning, irrespective of any small repairs on the cars. Both covers of the platform switches should be taken off and the switch nicely cleaned and polished. Then the brushes should be taken from the holders to see if they need renewing, and all the dirt and grease carefully wiped from the brush-holder, as the failure of a brush-holder causes considerable trouble sometimes. Then all the oil and grease should be wiped off of bearing and out of pans beneath the motors, and the lower and upper fields wiped dry from any flying oil. Then the orders issued by the superintendent for that car should be noted and immediately executed, so that the particular car is ready to go out in the morning with the exception of oiling. This oiling should be left till just before the car starts in the morning; for if the boxes be filled with oil or grease, being warm when they stop work, the grease will melt and run through the boxes without appreciable lubrication and be wasted. I have found grease of the type of Albany compound gave excellent results on all bearings except armature bearings, where a good engine oil answers every purpose. The night inspector should also varnish the field coils of every car under his care once a month, until a thoroughly waterproof cover is over the whole. This should be done with any good varnish, costing from $2 to $3 per gallon. When the motors are sent from the factory they only have one coat of varnish on them; after they have had repeated coats wet umbrellas running a small stream on them from the car above will have no effect whatsoever. This varnishing should be extended to the armatures also, as their life will be prolonged and dangers from burn-outs be decreased. The car should then be swept and dusted, and the windows wiped and cleaned. The dashboard and outside of car should receive special attention being wiped down with a damp sponge and dried with a chamois skin.

Inspector's Report '92.

Line.	Car number.	Remarks.
		Signed

Inspector.

Fig. 2.—Car Inspector's Report Blank.

This system of thorough inspection and cleaning can be carried on by small roads as well as large ones; the inspection on a small road will probably occupy some two hours and can be assigned to a man who has other duties to perform and yet has the time to attend to this one. It is much preferable to have a different inspector from the repairer and cleaner, as the work of one checks the work of the other. I have laid down the general outlines of the system, mentioning, in passing, some of the faults to which a motor is subject to, and know, if this system and practice were followed, a satisfaction and regularity of service, not reached by some roads, would be obtained.

ELECTRICITY FROM WIND POWER.

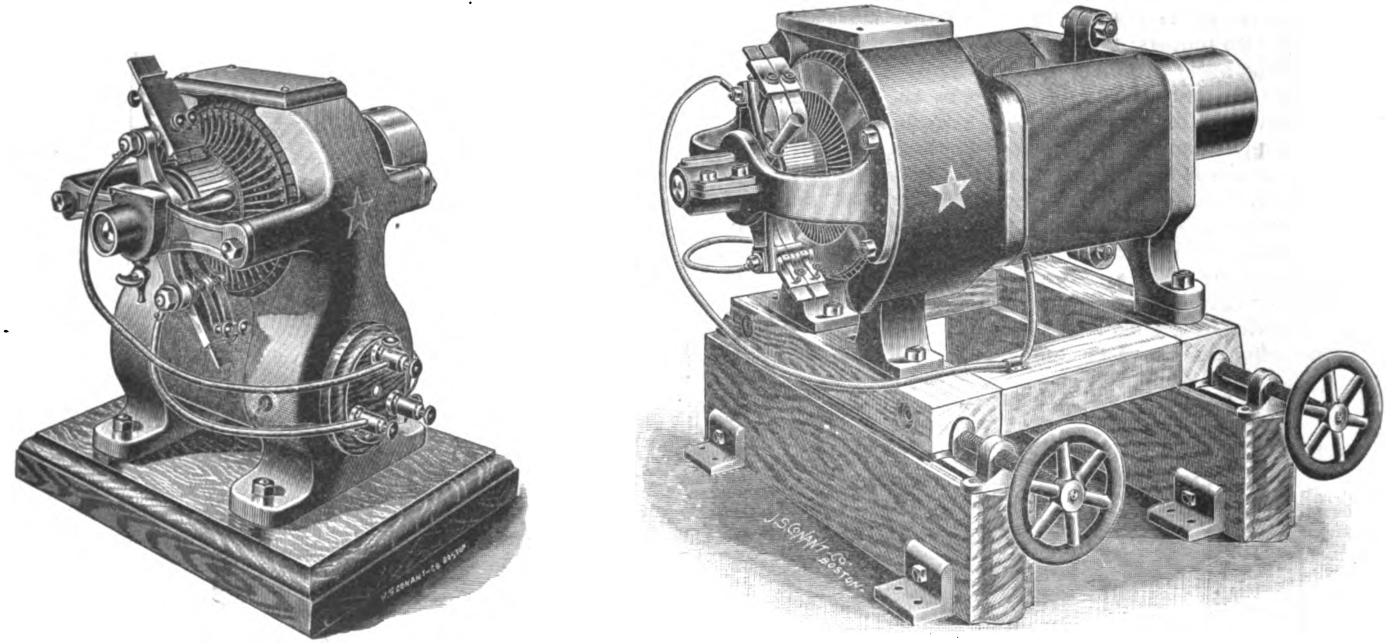
At the last meeting of the Royal Scottish Society of Arts, Prof. Blyth, of the Anderson College, Glasgow, read a paper on the "Utilization of Wind Power for the Generation of Electric Light." After alluding to his previous experiments, Prof. Blyth stated that last summer he had used a machine on the principle of the Robinson anemometer, with hollow cups, rotating horizontally. It worked satisfactorily, and in a fair wind gave out 4 E. H. P. Even in a gale it ran satisfactorily.

ELECTRIC TRACTION IN BELGIUM.

The Belgian Minister of Railways has caused a report to be drawn up on the results obtained on the electric lines at Vevey-Montreux, Moedling-Hinterbrühl, Blackpool, and other places, with the object of seeing what advantages could be obtained by the adoption of electric traction on railways.

THE JENNEY STAR MOTOR AND DYNAMO.

We illustrate in the accompanying engraving the new motor recently introduced by the Jenney Star Electric Company of New Bedford, Mass., whose office is at 196 Summer street, Boston. The engraving represents their regular 1½ h. p. motor and has several new features about it which render it interesting, and which are calculated to make a very substantial and efficient machine. The pole-pieces are of cast iron and are bolted to the horizontal wrought iron magnet. The bearings are made of brass, bolted to iron projections on the pole-pieces, and are self-oiling, having a loose ring in the shaft which revolves constantly in a bath of oil. By the arrangement of the bearings, the armature can readily be got at and removed in a very few miuutes by simply withdrawing the bolts which hold the bearings to the pole-pieces. The armature is of the Gramme ring type, but has no brass spider, being supported on fibre discs ⅜-inch thick at either side, and perforated for purposes of ventilation. The amature core is built up as usual of laminated iron. Carbon brushes are used, and there are four separate carbon blocks in each brush holder, the blocks being kept in contact with the commutator by spiral springs, the tension on which is regulated by four screws as shown. It is claimed that this type of motor will run quite cool when working up to full load. These motors are built in sizes of from ¼ to 20 h. p., and are wound for 110, 220 or 500 volts. This type is also used for incandescent dynamos up to 200 light capacity.



Figs. 1 and 2.—The Jenney Star Motor and Dynamo.

Fig. 2 shows the style of their arc light dynamo, of 10 light capacity, and of their incandescent dynamos of over 200 light capacity. The machine is, as shown, in two halves, bolted together at the pulley end, and is also provided with self-oiling bearings. The armature is of the Gramme type, and is supported in the usual way on brass spiders. The machines are well finished, and of first-class workmanship, and have attained a good reputation in actual service.

ELECTRIC MINING IN ENGLAND.

Considerable interest, says the *Newcastle Journal*, is being evinced in mining circles generally as to the result of an important electric mining installation at one of the Earl of Durham's collieries, which, when finished, will be the largest and most complete electric mining plant as yet erected in England. The operations to be effected consist of electric haulage, winding, pumping, lighting, etc.

THE ISOLATED PLANT IN THE EDISON GENERAL ELECTRIC CO.'S BUILDING, NEW YORK.

BY

Robert P. Dobbie

The new lighting plant of the Edison General Electric Co., recently installed in their own building, is probably as nearly as possible an ideal plant, and one in which everything pertaining to economy, convenience and mechanical refinement is to be found. Commencing with the boilers, there are four in all, two Heine of 125 h. p. each, and two Babcock & Wilcox of 125 h. p., aggregating 500 h. p. Any two will run the steam plant of the building. The latest devices for economy and comfort are used. Locke Bros'. damper regulator controls the draught, and all pipes, etc., are carefully covered. Two exhaust fans, each operated by a 3 h. p. motor of standard Edison type, ventilate the basement, and these are rendered more effective by partitions which cause the air to circulate on a principle similar to that used in mines to attain the same result.

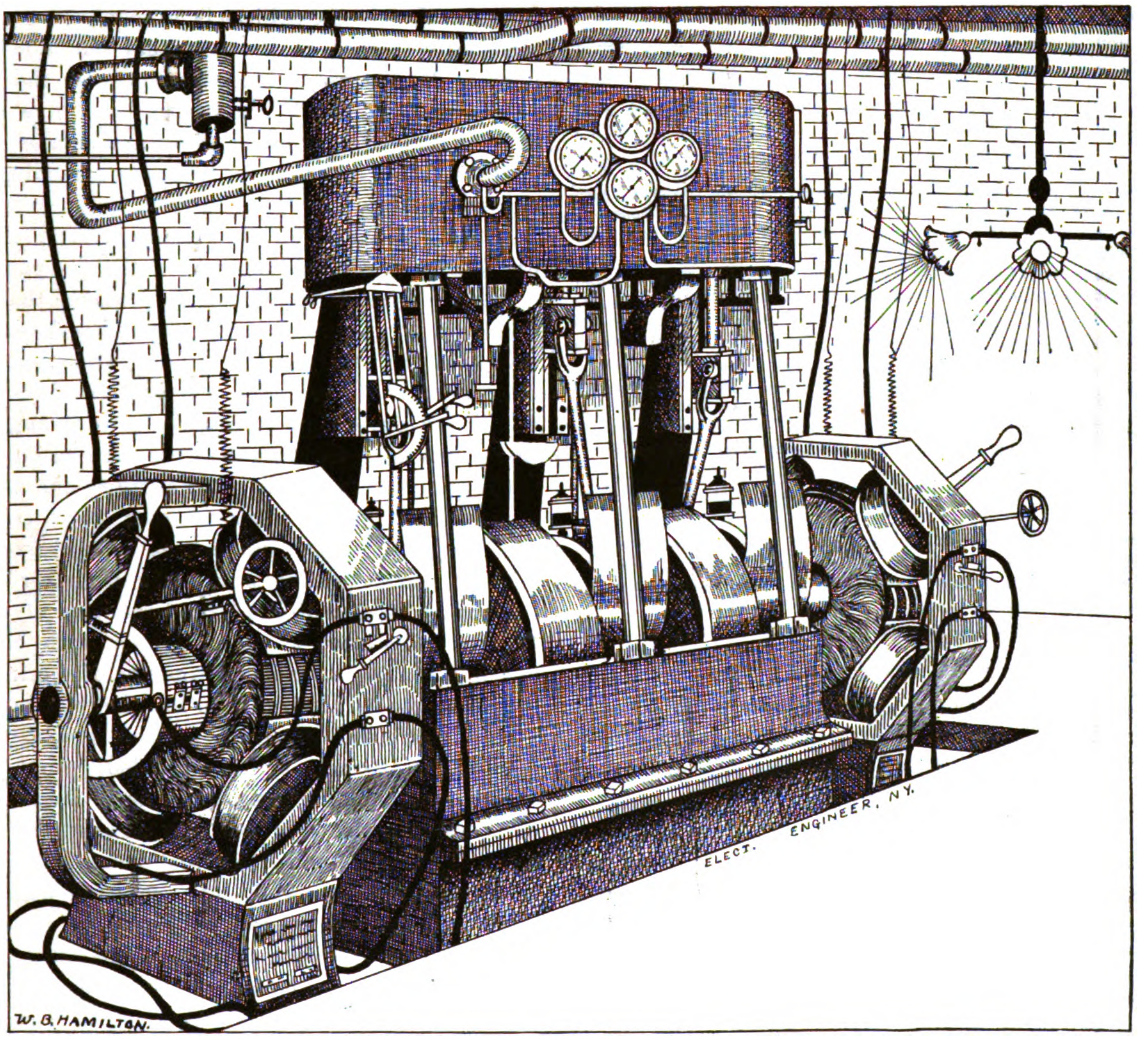
The system of duplication seen in the boilers is carried out through the whole plant, including engines, dynamos, elevator machinery, etc., down to the smallest pump.

The motive power consists of two engines each turning two 25 K. W. dynamos. The engines used are of the triple expansion inverted type so familar on the great Atlantic liners but, as may be expected in an engine for the exacting requirements of electric lighting, great attention has been paid to the question of governing. This is effected by having each eccentric operated by its own independent governor so that the point of cut-off in each cylinder is changed with the load. By this means the speed, 300 revolutions (600 feet per minute piston speed), differs less than 2 per cent when the load is changed from full load to no load.

This is not by any means a usual performance. I saw the engines running the South London Electric Railway last summer, and as they had a governor on the high pressure cylinder only, enough steam was in the receivers, valve-chests, etc., to cause the engine to race badly, if the load fell off to any great extent.

Each engine and pair of dynamos is capable of lighting the entire building which is wired on the 3-wire system throughout. Positive counters and facilities for indicator diagrams, gauges, etc., are always ready for use, and De Rycke straight line separators ensure dry steam. Unforunately, owing to locality, it was found impracticable to obtain a supply of water for condensers, but this was unavoidable. The dynamos, as will be seen, are of the multipolar Gramme ring type (4 pole). The armatures, fastened directly to each end of the crank shaft, revolve at 300 revolutions per minute, and being 2[illegible] inches in diameter, the peripheral speed is about 2,200 feet, which is very moderate, and suggests small wear and tear.

The current is taken from the commutator by four pair of brushes placed 90° apart. The field consists of a massive casting forming the yoke, while the cores over which the exciting spools are placed are castings of mild steel of such high magnetic permeability as to be practically equal to wrought iron.



ELECT. ENGINEER, N.Y.
W. B. HAMILTON.

THE EDISON 50 K. W. COMBINED ENGINE AND DYNAMO IN THE EDISON BUILDING, NEW YORK.

The method of attaching the cores to the yoke is to fit them into holes passing through the yoke. By this means an exceedingly good joint is made which is far better than merely butting the cores on a plane surface. They are compound wound with the series coils outside and are connected with equalizers in the usual way. The armature is built up of thin sheets and is mounted upon a massive bronze spider keyed to the crank shaft of the engine and having a commutator of large size. The brush-adjusting and raising devices are very complete. A worm gear arrangement moves the rocker, and, by means of a convenient lever, all brushes can be raised or lowered simultaneously. The switchboard is constructed of porous terra cotta faced with King's plaster. It presents an appearance equal to marble and can be very easily worked and repaired. Upon this are placed the numerous switches controlling dynamos and service, and a large switch connected with the Edison Illuminating Co.s' street mains renders a total shut down a very remote possibility.

THE REPULSION AND ROTATION PRODUCED BY ALTERNATING ELECTRIC CURRENTS.

In a paper on this subject, communicated to the Royal Society in December last, Mr. G. T. Walker, of Trinity College, Cambridge, gives some expressions for calculating the intensities of the force and couple respectively experienced by a ring of metal placed over, and by a ring of metal pivoted over, an alternating electromagnet. He also investigates the well-known experiment of Professor Elihu Thomson, in which a sheet of copper is placed so as to half cover an alternating magnetic pole, and a hollow copper sphere is laid upon the plate; the electromagnetic action producing a couple sufficiently powerful to overcome friction and to spin the sphere round. According to Mr. Walker, the sphere spins round in virtue of the fact that the currents induced in the copper plate "do not coincide in phase with those of the magnet, and not (as has been stated) because it acts as a screen, and renders the field unsymmetrical. Were the plate a perfect conductor it would be a perfect screen, but there would be no couple."

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, FEBRUARY 24, 1892. No. 199.

The class of men who were intended to be encouraged by our patent system are the most meritorious and useful ever found in any age or country. They have created all the wealth of which the law gives them the limited enjoyment.—Charles Mason.

THE BUFFALO CONVENTION.

IT might well have been supposed that coming so soon after the meeting at Montreal, the convention this week at Buffalo would find the enthusiasm and energy of the members of the National Electric Light Association flagging, so that in many respects the high level of former gatherings would hardly be attained. But the facts are quite otherwise. Not only has a good programme been prepared—already announced, with a further prospect of a trip to inspect the grand engineering work on the Niagara water-power—but the attendance already at this moment, five days before the opening, promises to be very large. Part of this is probably due to the fact that a long recess is to be taken until next year, but it must also be credited in no small measure to the deserved popularity of President Huntley and to the zeal of Secretary Porter. These two gentlemen, seconded by Mr. C. O. Baker, the master of transportation, have gone at their work in a manner beyond admiration, with the result that the central station element will be strongly represented.

That, after all, is the main thing. The Association exists for the benefit of central stations, and if the men who are interested in that very important field of work do not get together under its auspices, it fails of its purpose. Once or twice it has looked as though the Association would be lured or diverted from its fundamental objects, and each time trouble has threatened; but so long as the Association works in its chosen field, it gathers weight, influence and numbers. We know of no industrial interest more alive and progressive than that of electric light and power; and as its representative organization the Association has an indefinitely long career of usefulness before it.

COMPOUND ENGINES AND ELECTRIC LIGHT STATIONS.

THE discussion on the relative types and sizes of engines best suited for electric light stations which has been carried on in our columns has attracted general attention and has served to bring forward a number of considerations of the highest importance to central station managers. The interest taken in the subject is not confined to this country alone as evidenced by the fact that our London contemporary, *Engineering*, recently reprinted the articles by "Carleton" and Mr. W. L. Church, and in a recent issue devotes its leading editorial to a discussion of this subject. Thus, it points out, that the difficulty attending the use of non-condensing compound engines, as is well known, decreases as the initial pressure is raised, but that it does not necessarily follow that the use of the compound non-condensing engine is uneconomical, provided that the power unit is properly chosen. If the engine has the same unit provided both for the light and heavier service, waste must occur; but if the engine power be divided, as it now usually is, into several units, it is easy to arrange it so that there shall never be more than one running unloaded.

Carrying the argument still further, our contemporary expresses its doubts whether, under these circumstances, the compound engine has any advantage over the single engine in street railway work, as in the latter case it very frequently happens that a large proportion of the cars are stopped and started at once. Under such circumstances not only is there an immense amount of work to be done in setting the cars into motion but the electric motors also give a decreased efficiency, putting a vastly augmented load on the engines. This is a decidedly novel point in this controversy, and it remains to be seen whether the results of actual practice bear out this assumption. In the absence of data by which the coal consumption of two stations equipped—one with the compound engine and the other with the single—can be compared, it is as yet too early to form a definite opinion on this subject.

Engineering also points out that the reason that light loads are so detrimental to steam engine economy was admirably brought out by Mr. Willans in the discussion before the Institution of Civil Engineers on Mr. Crompton's paper on the "Generation and Distribution of Electrical Energy," read last year. Experiments show that the amount of steam used per indicated horse power in an engine regulated by a throttle valve is constant for all powers; or, in other words, it requires the same additional steam to raise the power from 20 to 30 h. p. as it does to raise it from 90 to 100 h. p.; but this does not hold good for very light powers. From the results of other tests by Prof. Kennedy and Mr. B. Donkin, Jr., *Engineering* believes that it is not far wrong in assuming that it requires 100 lbs. of coal per hour to run an 80 h. p. dynamo, light loaded. This amounts to 17 cwt. a day and does a good deal to explain the disadvantage of operating a station equipped with one or two large engines only. As a curious result of this state of affairs it is also pointed out that the reproach leveled at the advocates of the low tension distribution system against the method of working with transformers placed on the consumers' premises is largely removed, for when this plan is adopted the light load line remains constantly at a fairly high level. We must, however, remark that the remedy of one evil by the introduction of another, can hardly be considered good practice.

Our contemporary also believes that although the economy of fuel in electric light stations is of great importance, it is very possible to purchase it too dearly, and that if extra money is spent on an engine to make it more economical of fuel, then to render this cost profitable the improvement must be so great that the saving on a few hours' working per day will pay interest on the depreciation of its cost. When coal and land are dear, a small economy in the consumption with its attendant gains in boiler space and storage capacity may amount to a very respectable sum in a year. Where coal and land are cheap, money spent in complicated valve gears will, says *Engineering*, generally be wasted, and while the coal consumption in electric light stations remains at from three to six times its theoretical amount, there is plenty of scope for economy in other ways than matters of engine construction.

ELECTRIC INSTRUMENT MAKING IN AMERICA.

THE demands which the rapid growth of electric lighting made upon the manufacturers of electrical apparatus of all descriptions, especially in this country, were such that, for some time, they were unable to keep pace with it, and as a result, many of the measuring instruments employed in daily practice were, of necessity, imported from abroad. It was not to be wondered at, therefore, that the erroneous impression existed at one time that American manufacturers were unable to produce instruments of the desired quality. But if such an idea still lurks in the minds of some it must be dispelled on the perusal of the description which we give this week of one of the largest establishments in this country devoted to the manufacture of fine electrical instruments. The apparatus manufactured by Messrs. Queen & Company, both in variety and quality will, we think, stand favorable comparison with those from abroad, and they, together with other American instrument makers, deserve credit for having raised the standard of American manufactures in this department.

Advanced Central Station Engineering.

THE account we publish this week of the manner in which the Edison Illuminating Company of this city is proceeding in the design of its newest and latest station, will not fail to impress the readers with the change which is gradually taking place in the engineering of central stations. But a short while ago the installation of the enormous engines contemplated and the application of the high steam pressures to be employed, would have been considered contrary to the canons of good practice. But the adoption of the means described, by which it is hoped to attain the highest economy is, we think, not only justified but entirely feasible. Mr. John Van Vleck, the engineer of the company, is deserving of much credit in having inaugurated a practice which, we hope, will be followed by others in the equipment of electric central stations.

High-Tension Experiments.

THE interesting experiments described by Prof. Elihu Thomson in our last issue cannot have failed to arouse the interest of our readers, considering especially the fact that the apparatus employed is so simple and easily constructed. In this issue Prof. Thomson gives further details of his experiments, all of which are of an interesting character and will not fail to give stimulus to investigation in this direction.

THE HEAT RADIATION OF RAREFIED GASES UNDER THE ELECTRIC DISCHARGE.

Herr Angstrom, says *Nature*, has been lately engaged in examining with a bolometer the heat radiation of various rarefied gases under the electric discharge. He confined himself to the stronger positive light, using cylindrical glass tubes, with lateral electrodes, and rock-salt plates at the ends. An accumulator of 800 Planté elements was the source of electricity. Briefly stated, the results are these: With a given pressure the radiation is proportional to the intensity of the current. With constant current, the radiation does not vary while the pressure varies between 0.1 and 1.5mm., but at higher pressures it increases somewhat. With the same gas and pressure, the composition of the radiation is constant, and does not depend on the intensity of the current. With varying density of gas, the ratio of the intensity of radiation of shorter wave lengths to that of the whole decreases with increase of pressure. (This ratio varied, *e. g.*, from 46 to 15 per cent. in carbonic oxide between the above pressure limits.) Thus this ratio, at low pressures, reaches much higher values than in our ordinary light sources. The intensity of total radiation varies considerably in different gases, and stands in no simple relation to the molecular weight, nor to difference of potential in the gas; nor does it seem to depend on absorption of gas at ordinary pressure and temperature.

LAW OF THE MAGNETIC CIRCUIT.

IT is curious that nearly all electrical engineers think that magnetism follows Ohm's, or an analogous law. It really does not follow any such law. Ohm found by experiment that $\frac{E}{C}=R$. That is a definite law, R depending on the ratio of E and C, and not on their absolute value. The analogous magnetic "law" merely amounts to a definition. It is not a statement that the resistance is equal to the ratio of the "magneto-motive force" to the flux, as that is not the case. The resistance depends on the values as well as on the ratio of these quantities so that we have only a definition left, with no underlying law whatever. Some say, "When there is a magneto-motive force and a flux we will call their ratio the magnetic resistance." The ratio of any two quantities may be given a name, but that does not provide any analogy to Ohm's law. Of course, it must not be forgotten that current and induction are both solenoidal, but solenoidal distribution is met with in so very many branches of physics that it affords no special analogy between current and induction in particular.

THE PLANT IN THE NEW HOTEL BROEZEL, BUFFALO, N. Y.

The design and construction of isolated plants for hotels has wisely been made a specialty by some electrical engineering firms, prominent among whom may be mentioned F. P. Little & Co., of Buffalo. One of their installations of this nature was illustrated and described in The Electrical Engineer not long ago, and another shown on this page in Figs. 1, 2 and 3 will afford a good object lesson for visitors to Buffalo during the Convention week. We refer to the plant in the new Hotel Broezel. This installation comprises two Thomson-Houston spherical dynamos of a capacity of 500 and 600 lights respectively. The engines, which were also furnished and set up by F. P. Little & Co. are Rice automatic high-speed, built by the John T. Noye Manufacturing Co., of Buffalo, and are of 50 h. p. and 30 h. p. respectively. Underwood cotton leather belting is used with much satisfaction. The engines and dynamos are set on solid brick foundations, which are tied together to the floor level. The foundations extend 10 feet below the floor surface, and are built free from the foundations of the building itself. Owing to the adoption of this method no vibration is perceptible at any point in the hotel.

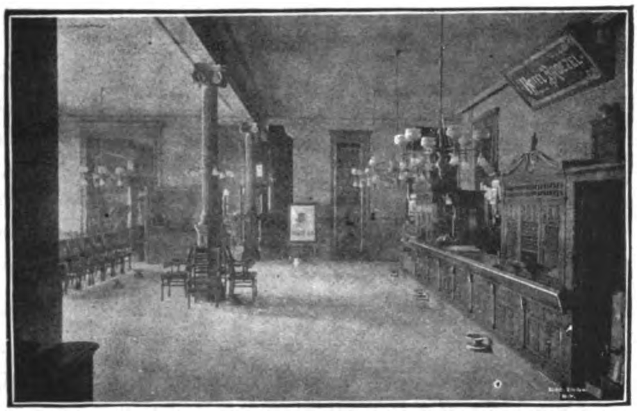

Fig. 1.—Electric Lighting in the Hotel Broezel, Buffalo, N. Y.

The building is wired for 800 lights, 500 being of 16 c. p. and 300 of 20 c. p. There are two arc lights provided for outdoor use. These are of the well-known "Mosher" type, run on the incandescent circuits, and give excellent results. The wiring is concealed throughout the building beneath the floors, and nothing but the "Grimshaw" of the New York Insulated Wire Company is used. The wiring is done in such a manner that there is practically no difference in potential between any two lights in the building. In order to avoid any risk, moreover, ample space between the wires is allowed, and no two wires of opposite polarity are anywhere nearer together than 4 inches. All safety devices are of porcelain. There is a separate cut-out for each separate group of lights; also a separate cut-out for each circuit, grouped together, placed so as to be conveniently got at on any floor. It may be noted that there is an entire absence of wires in the dynamo-room. The feed-wires are brought to the switchboard through the walls, and are not visible. The wires from the dynamos to the switchboard are carried in a conduit under the brick flooring.

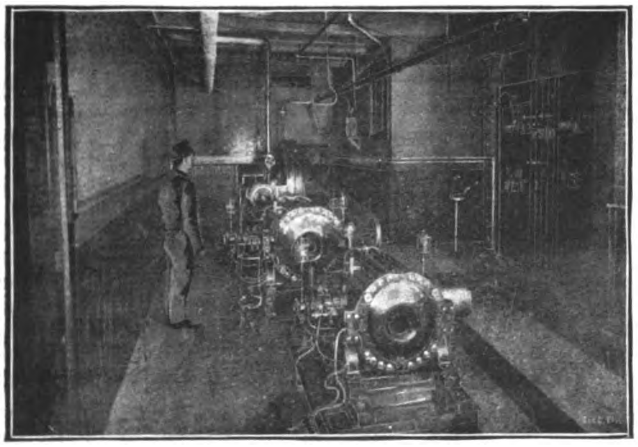

Fig. 2.—Dynamo Plant of the Hotel Broezel, Buffalo, N. Y.

Motors are becoming an essential feature of hotel plants, and this installation proves no exception, as F. P. Little & Co. have received an order for two Crocker-Wheeler motors, one of 4 h. p. and one of 2 h. p. They promise to become a strikingly valuable addition to the outfit of this altogether modern hotel, where efficiency of operation is studied equally with the comfort of the guests, and where electricity is relied upon to supply no small part of the conveniences.

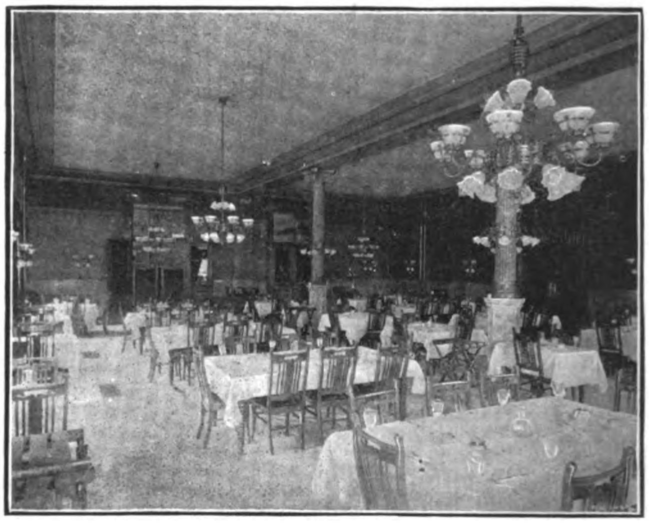

Fig. 3.—Electric Lighting in the Hotel Broezel, Buffalo, N. Y.

The firm who have put in this plant have lately been very busy in their own locality, their recent installations including a 100-light plant for the Wells Elevator at Buffalo, a plant for the W. H. Walker & Co. Building, Buffalo, and a $15,000 contract at the new Capitol, Albany. It must certainly be regarded as one of the most hopeful and encouraging features of electrical engineering that concerns of this high professional grade are establishing themselves in different localities to secure and undertake contracts requiring expert ability and skilled experience for their satisfactory execution.

COPPER.

Although the stock of copper in England and France and afloat was smaller at the end of January than it had been at the same date for three years previously, the price is considerably lower. According to Messrs. H. R. Merton & Co.'s statistics, the stock on January 31, 1892, was 57,462 tons, as against 61,396 tons in 1891, 95,714 tons in 1890, and 109,528 tons in 1889. Yet the price this year was £44 12s. 6d. per ton, as compared with £52 12s. 6d. per ton, £48 17s. 6d. per ton, and £77 10s. per ton on the same day in the three preceding years.

THE MANUFACTURE OF FINE ELECTRICAL INSTRUMENTS IN AMERICA.

BY

Jos. Wetzler.

I.

RAPID as the advance in electrical application was in this country during the last decade, it was not evenly kept up all along the line. American dynamos and lamps and motors and "systems" not only proved successful at home but were in demand abroad; yet when comparisons were made with Europe, as to fine instruments of precision, it was found that we were almost wholly dependent upon the foreigner. Some people, in fact, took it for granted that such conditions must prevail indefinitely, and that, for some occult reason, the manufacturers of England, France and Germany would long enjoy a control of the market as the result of the absence of competition. It is needless to say that these ideas, so little creditable to American skill and enterprise, have been rudely upset, and that though domestic occupation of this field has been tardy it begins to be pretty complete. In spite of the prestige and influence of long years of monopoly, and of the remarkable strides made by some of the younger builders of instruments in England, the American manufacturer has now practically made this market his own, while the profession has never had better or cheaper apparatus at its command.

It has seemed to us that this technical revolution is one worthy of a little notice at our hands, as a leading feature of contemporaneous American electrical industry; and it is but natural that the career and work of the old house of Queen & Co., of Philadelphia, should furnish us with some unusually interesting material for a brief survey of the subject. This firm serves to demonstrate the fact that age in business, contrary to the accepted laws of nature, may often be marked by growing vigor and activity; and in its special domain of work it has done not a little during the last quarter of a century to confirm the high reputation that was won for Philadelphia by Franklin in his various apparatus, by Rittenhouse with his ingenious planetarium, or by the Harrisons in expert chemistry. The history of any art is largely the history of representative individuals or firms, and the study of what has been done by them, as well as their way of doing it constitutes a valuable course of instruction.

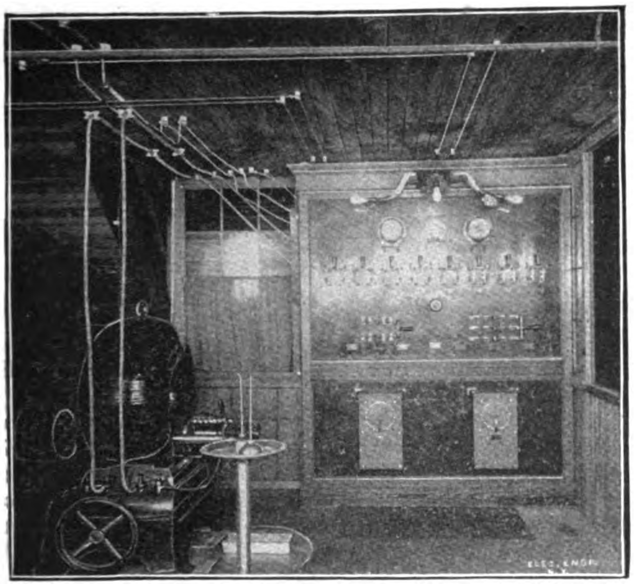

FIG. 1.—MATHER DYNAMO AND SWITCHBOARD.

In 1853 Mr. James W. Queen started an optical business at No. 924 Chestnut street, Philadelphia. The business grew very rapidly, and in 1858 Mr. Queen associated with him Mr. Samuel L. Fox. Under this new management the firm throve wonderously and extended the scope of its trade with great rapidity. In 1870, Mr. Queen retired from business, and Mr. Fox has since conducted the business alone, taking into the firm with him in 1881 his son, Mr. Edward B. Fox. Exclusively an optical business at first, the firm has gradually enlarged its scope so as to include optical instruments of all kinds, and from optical instruments to scientific instruments in general, until now the firm probably keeps in stock, handles, manufactures and sells a larger number of scientific instruments and instruments of precision than any one firm in the world.

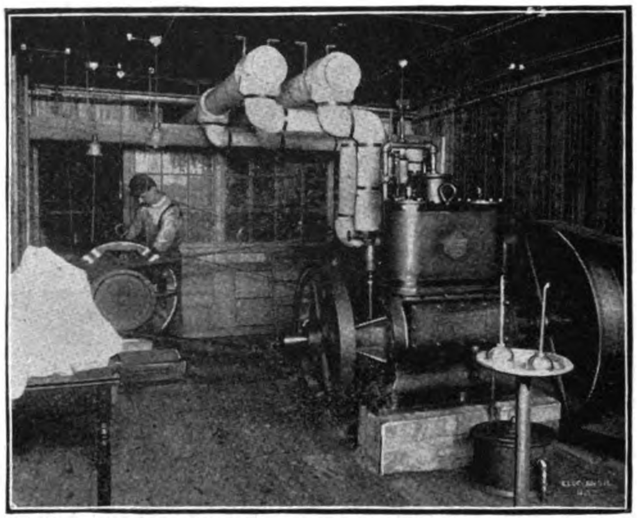

FIG. 2.—EDDY 4-POLE POWER GENERATOR.

For many years the firm was located at No. 924 Chestnut street, the site originally occupied by Mr. Queen; but the business grew with such rapidity that this building, though five stories high, exclusive of basement, proved quite insufficient for it; and a number of other buildings in the vicinity were obtained for storage and other purposes. In 1888 the building was greatly enlarged and improved and it was then hoped that sufficient space would be afforded for all. This hope, however, proved delusive, and it was deemed necessary last fall to look about for other and more commodious quarters. These were soon secured at No. 1010 Chestnut street, and extensive alterations were immediately put under way to adapt the premises to the varied needs of the business. These alterations were practically completed by the 1st of January last, and the firm moved into and took possession of its new building.

This building has a frontage of 23 feet, and has three floors and a basement extending 230 feet in depth clear through from Chestnut to Sansom streets. Another story in front and two in the rear complete the building. The total floor space in this building is 27,000 square feet, being 6,000 square feet more than in the old building at 924 Chestnut street.

II.

The new store of Messrs. Queen & Co. has been built exactly according to their designs for the express purpose of adequately accommodating the peculiar and varied interests of their vast business which is among the largest of its kind in the world. In it may be bought everything of the most remote scientific interest and importance from a magnifying glass to a steam engine.

A complete system of speaking tubes passes through the building, all tubes connecting to a central board at which an operator is stationed who makes different connections so as to render communication possible from any one part of the building to another. Each department also has a district messenger service by which messengers, police, fire or carriage service may be quickly obtained. The optical shop is connected with the repair desk of the optical deptartment by pneumatic tubes, so that repairs and work may quickly be passed to and fro. With these tubes a package may be sent from the third floor rear to the ground floor front, a distance of 325 feet and an answer received within 10 seconds.

The entire building is heated and lighted by a private plant located in the rear of the basement and is entirely satisfactory in every sense of the word. The plant consists of two 40 h. p boilers made by the Coatesville Boiler Works; injector and pumps for same; one 35 h. p. Westinghouse engine; one 25 h. p. Westinghouse engine.

The heating is done by steam at a pressure of but 3 lbs. during the coldest weather and the plant was put in by the Onderdonk Steam Heating and Ventilating Co. of No. 19 North Sixth street, Philadelphia. A Spencer damper regulator is used, and by its means the steam pressure is kept constant within a variation of but ½ lb. The entire plant was put in under the supervision of M. R. Muckle & Co., engineers and contractors, of Philadelphia, and was planned by Mr. M. R. Muckle and Mr. E. G. Willyoung, of Queen & Co.

The dynamos are a 400 light Mather 110 volt machine and a 20 h. p. 220 volt Mather 4-pole generator; the 220 volt generator furnishes power to the front passenger elevator which is run by an Eddy motor, and also to the optical shop on the third floor rear, where there is installed a 10 h. p., Mather 4-pole motor. Our engraving, Fig. 1, shows the Mather machine together with the switchboard, which was specially designed so that the plant can be directly connected to the Edison street mains by throwing over a switch. Fig. 2 shows one of the Westinghouse engines driving the Mather 4-pole generator.

The wiring throughout the building, as also the actual installing of the engine and dynamo plant, was done by Messrs. W. S. Griffiths & Co., the Mather agents for Philadelphia. The rear elevator is run direct from one of the engines, both being very close to each other.

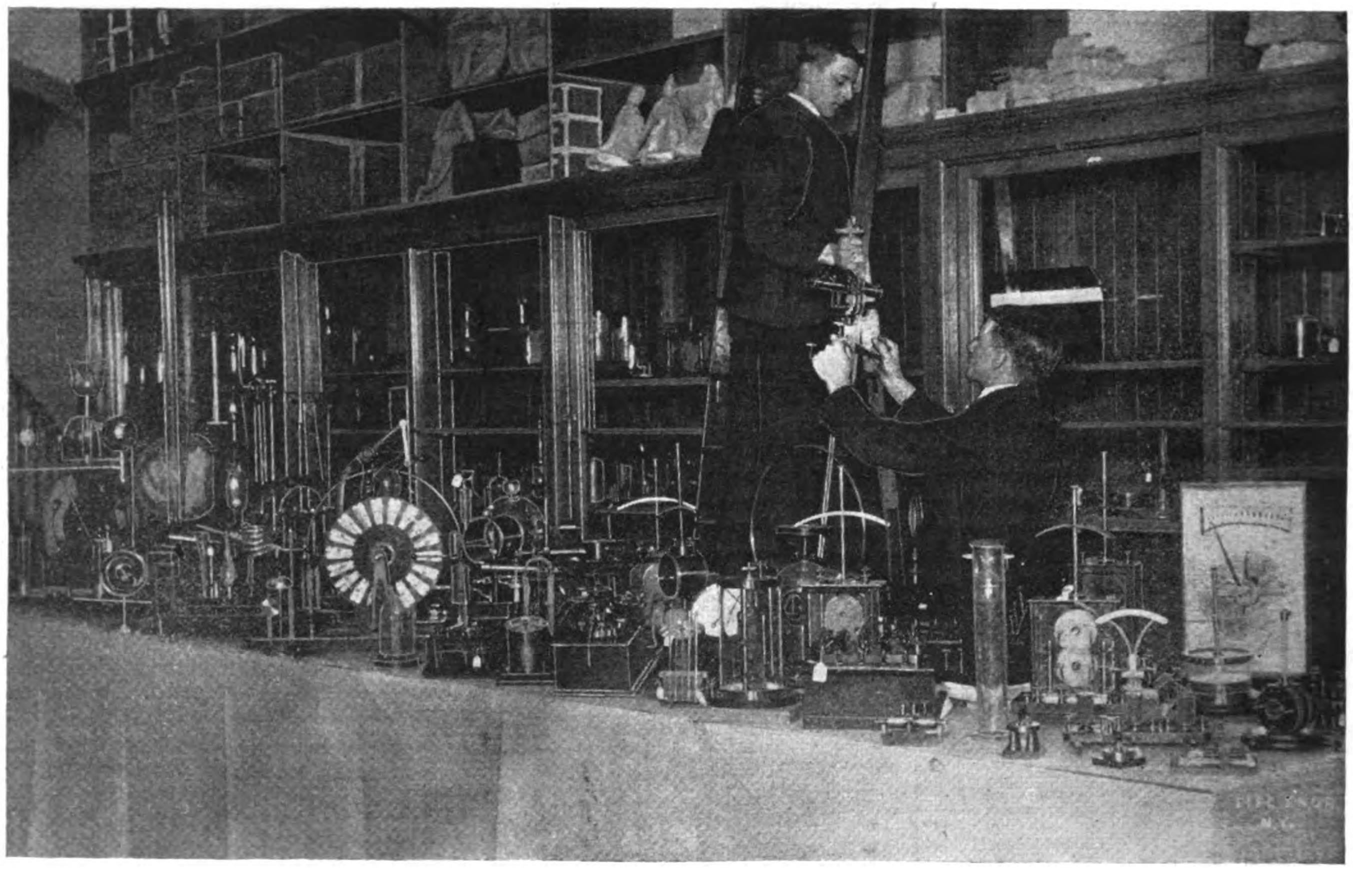

FIG. 3.—A VIEW IN THE ELECTRICAL INSTRUMENT DEPARTMENT.

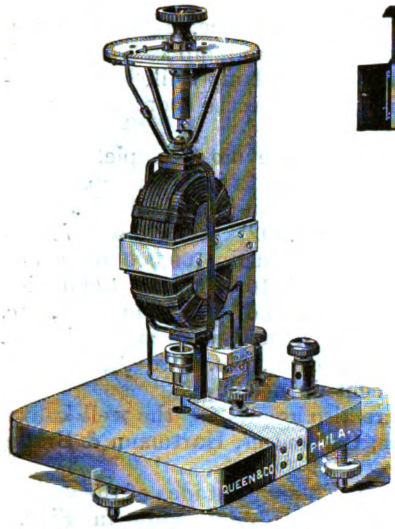
III.

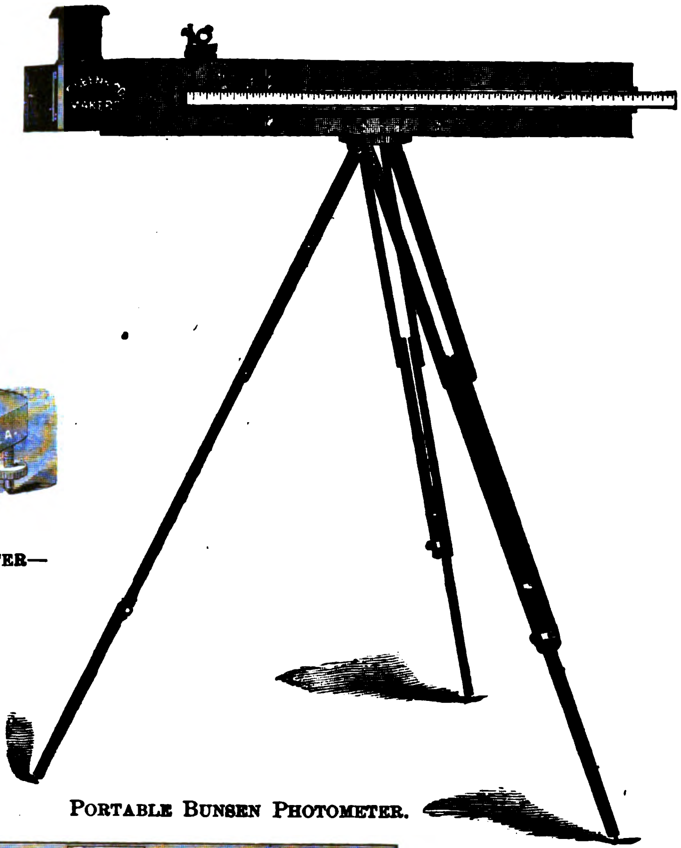
There are now seven departments to this immense establishment, each under the management of men who have had special training and experience in the particular line under their charge.

These departments are: 1. Optical. 2. Engineering and mathematical instruments. 3. Microscopic. 4. *Electrical Test Instruments;* Electrical and philosophical instruments and apparatus. 5. Magic lanterns, stereopticons, astronomical telescopes, etc. 6. Meteorological instruments. 7. Photographic apparatus and accessories. 8. Chemical.

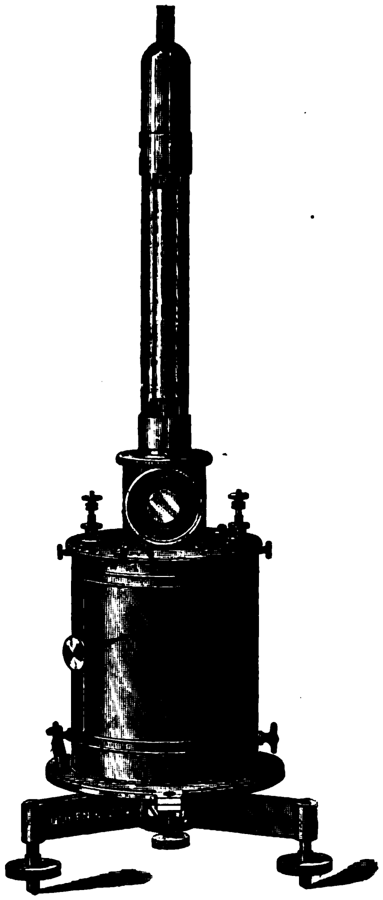
The limits of this article prevent us from entering into the details of all these departments which could be made the subject of several interesting volumes, but a good idea of the varied character of the apparatus handled by Messrs. Queen & Co. can be gathered from the bound catalogue of the firm combining the catalogues of all the departments. This is probably the largest catalogue published by any house in the world. It has over 1,200 pages and lists over 30,000 distinct articles. When it is remembered that



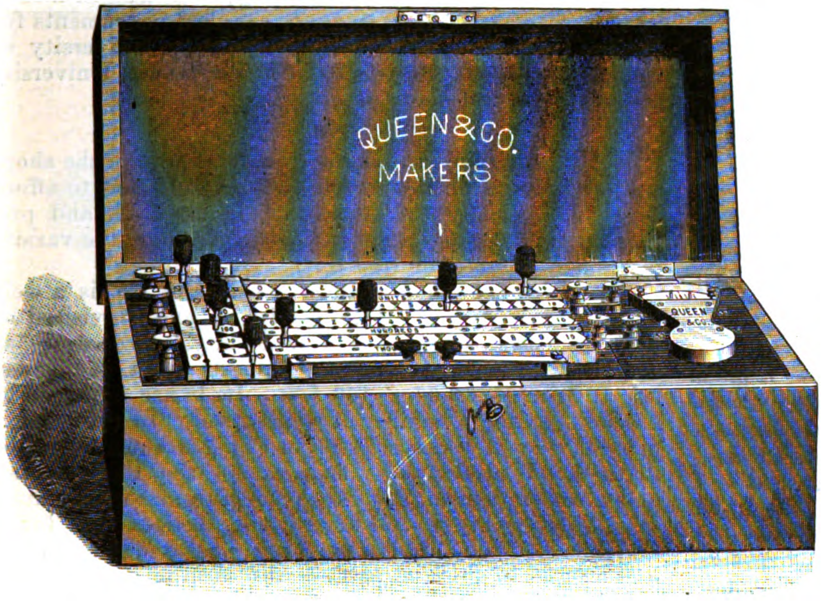
SIEMENS ELECTRO-DYNAMOMETER—
"OPEN FORM."



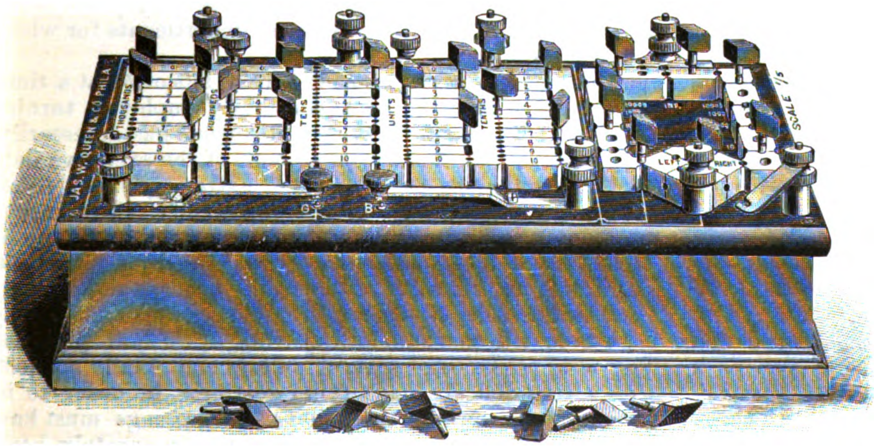
PORTABLE BUNSEN PHOTOMETER.



MASCART ELECTROMETER.

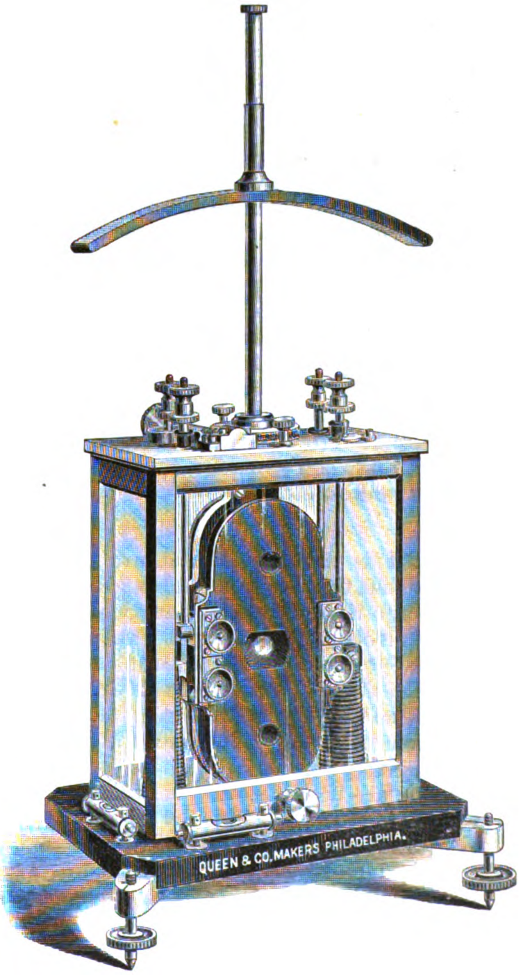


PORTABLE TESTING AND RESISTANCE SET.



STANDARD RESISTANCE BOX AND WHEATSTONE BRIDGE, No. 1.

FIG. 4.



QUEEN & CO. MAKERS PHILADELPHIA.

NEW THOMSON GALVANOMETER.

almost every one of these articles is of scientific importance, some idea of the vast scope of the business may be obtained.

We must, however, confine ourselves to the Electrical Instrument Department, one of the largest and most flourishing of the establishment, and one which is known all over the country wherever fine and accurate instruments are used.

IV.

For purposes of management the work of the Electrical Instrument Department has been divided into three parts, namely, General Oversight and Finance, Correspondence and Advertising, and Manufacturing.

Mr. Wm. Biddle, the business man of the department, has been with Messrs. Queen & Co. for many years and has in succession filled most of the various positions in the department and has had, therefore, a large experience. His brother, Mr. Jas. G. Biddle has also been with the firm for a number of years and has made a special study of the marketing of scientific instruments and apparatus; all quotations are made by him, a work of no small magnitude when it is remembered that the number of distinct pieces catalogued by this department alone is over 4,000, while at least 2,500 pieces made by other makers (most of them foreign), and none of these pieces duplicates, are sold every year. To assist in the work of correspondence with foreign makers a translating clerk is attached to this department. Mr. Jas. Biddle also has charge of the advertising of the department.

The manufacturing of this department has been for the past two years in charge of Mr. Elmer G. Willyoung, a graduate of Michigan University, and formerly assistant in physics and electrical engineering in that institution. The manufacturing of this department embraces both that of electrical instruments and apparatus and of physical apparatus. This department publishes the largest physical apparatus catalogue that is issued in America, about 4,000 pieces being listed, most of them being manufactured in the shop of the firm.

All the instruments and apparatus manufactured by this department are designed in the draughting-rooms of the department, skillful draughtsmen being employed. To supervise the manufacturing of physical apparatus as distinguished from electrical, Mr. Willyoung has an assistant who gives his whole time to the work.

This department has dealings with nearly every college in the country and with a majority of the schools. Probably three-fourths of all the scientific instruments and apparatus sold to schools and colleges for the purposes of class or laboratory work in physics goes from Department 4 of Queen & Co. Among the instruments manufactured and sold may be mentioned air pumps, sirens for determining the rate of vibration of tuning forks and other musical bodies, Atwood's machines for determining the laws of falling bodies, etc.

V.

But it is in the manufacture of fine electrical instruments that this department has grown most rapidly. Three years ago it was thought practically impossible to secure a good electrical instrument except from abroad. Now it can be positively asserted that most of the instruments made in the shops of Queen & Co. are fully as good as any for the same purpose that can be obtained from English or continental makers if, indeed, they are not superior. Among the leading specialties for which Queen & Co. are famous are their Cardew voltmeters, the American patents for which are owned by them; portable testing and resistance sets; standard resistance sets, etc.

This department also manufactures Thomson tripod and double-coil reflecting astatic galvanometers, as well as a large number of other types of galvanometers, together with the telescopes, scales and lamps to be used with them. Among the products of the firm, also, are large photometers for either arc or incandescent measurements and fitted with all appliances, such as candle balance, Methven screen, socket for using a calibrated electric lamp as a standard, socket for carrying an incandescent lamp while being measured so as to present it to the "grease spot" at any desired angle, etc.

In addition to these, probably the most complete line of standard resistance boxes in the world is manufactured by Messrs. Queen & Co., including the Standard No. 1 Set of Prof. Anthony's design, "P. O." pattern of Wheatstone bridge and rheostat combined, 100,000 ohm box (long) in 10 sections, subdivided 10,000 and 1,000 ohm boxes, Standard 1 ohm, $\frac{1}{10}$ ohm, and $\frac{1}{100}$, ohm coils, etc. All of these are wound with platinoid wire and adjusted, the No. 1 from $\frac{1}{50}$ to $\frac{1}{100}$ per cent., No. 2 to $\frac{1}{20}$, and the others from $\frac{1}{10}$ to $\frac{1}{20}$ per cent. in accuracy.

Messrs. Queen & Co. are also agents for the well-known foreign makers, Edelmann, Carpentier, Hartmann & Braun, Sir Wm. Thomson, etc.

Our illustration, Fig. 3, gives but a faint idea of the variety of apparatus handled in this department, while in Figs. 4 and 5 there are illustrated some of the more important of the instruments above referred to which afford an interesting object lesson in electrical measuring instruments, embracing, as they do, instruments for the most refined measurements as well as for every-day commercial work.

During the past few years Messrs. Queen & Co. have equipped most of the new electrical laboratories which have gone up about the country. The new electrical laboratory of Princeton College, built about three years ago, was equipped with over $5,000 worth of the finest electrical instruments by Queen & Co. A large part of the equipment of the Massachusetts Institute of Technology was also furnished by this firm, who have similarly supplied instruments for Purdue University, Ohio State University, University of Michigan, Cornell, University of Pennsylvania, University of California, and many others.

VI.

We propose, now, to take our readers through the shops and laboratories of Messrs. Queen & Co. and thus to afford them an opportunity of inspecting the methods and processes which are applied in the manufacture of the various instruments above referred to.

The instrument shop of Messrs. Queen & Co. is a well-known establishment of Philadelphia, and is visited by most scientists coming to or near the city. It occupies an entire floor at Nos. 817 and 819 Filbert street, and covering a floor space 60 x 150 feet. In in are employed 70 hands including a number of apprentices. In this shop, a general view of which is given in Fig. 7, are manufactured all the goods made by the firm except the thermometers and spectacle lenses. The shop is equipped with all kinds of special machinery and labor-saving devices. As far as possible the hands in this shop are separated into groups and located in different parts of the shop to conform with the division into departments for which they are executing work; this has the advantage of keeping work of the same nature together and of making it more readily accessible for inspection by the heads of those departments for whom it is being done.

Cardew voltmeters are made here in lots of 50 at a time, and one set of men is kept constantly employed turning them out. The work on these instruments has, necessarily, to be of a very high order on account of the excessive delicacy of the moving parts and the extremely small forces involved in the working of the instrument. The instrument depends for its action, as is well known, on the linear expansion of a very thin wire when heated by a current. Depending upon heat effect alone, the instrument is equally valuable for either direct or alternating currents and has long been accepted as a standard instrument for both purposes. This wire passes over several pulleys and finally connects with a very delicate magnifying gearing. In order to insure accurate working the pulleys and gearings must have finely polished pinions and the jewels be accurately bored and set. The gear teeth, jewels and pinions are all carefully

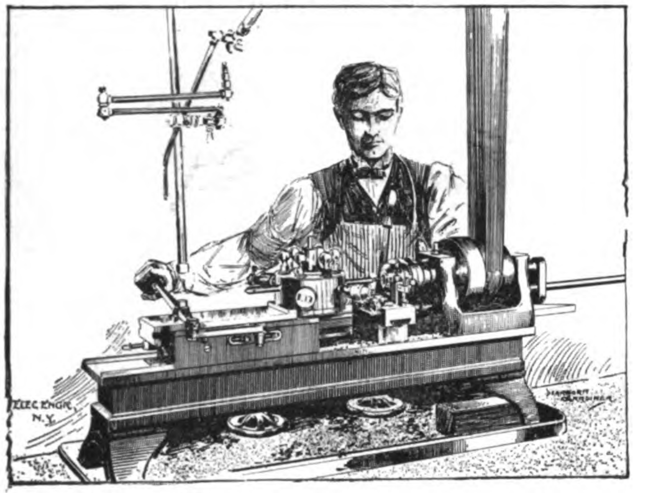
examined with a magnifying glass before using and the slightest irregularity or roughness is the cause of their rejection. All the other parts of this instrument, also, are made exactly to gauge and hence all parts of completed instruments are mutually interchangeable. Wherever possible, the smaller parts are stamped out with very accuately cut steel dies.



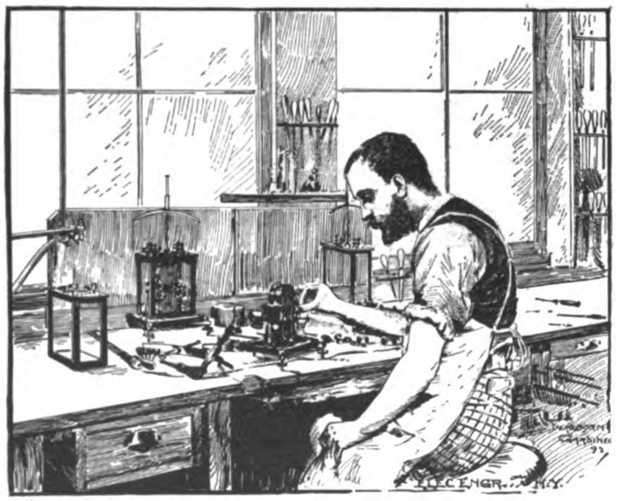
ELEC. ENGR. N.Y.

FIG. 9.—MAKING BINDING POSTS IN SCREW MACHINE.

In making these instruments Queen & Co. have greatly improved upon them as made by foreign makers, both in appearance and quality. One very valuable modification which will be appreciated by all, is the great diminution of weight. In a lot of instruments just completed by Messrs. Queen & Co. almost the entire instrument is made of aluminum, with the result that the weight of the instrument is but 4 lbs. as against 7½ lbs. in the English make. The effect is, also, to considerably add to the beauty of the instrument.

VII.

The adoption of aluminum in the construction of electrical instruments may be said to constitute one of the most important advances in this art made in recent years. In this direction Messrs. Queen & Co. have probably accomplished as much as any other firm, if not more, in the determination of certain of the more important mechanical properties of aluminum and its alloys. They have expended a great deal of money in working out the practical problems connected with its use and have attained results amply satisfactory. As a result, they can now cast an alloy containing over 85 per cent. of aluminum and an exceedingly small amount of copper which has the rigidity of cast brass, turns as easily and smoothly as any other metal, and in which the most delicate tapping and threading can be accomplished with entire success.



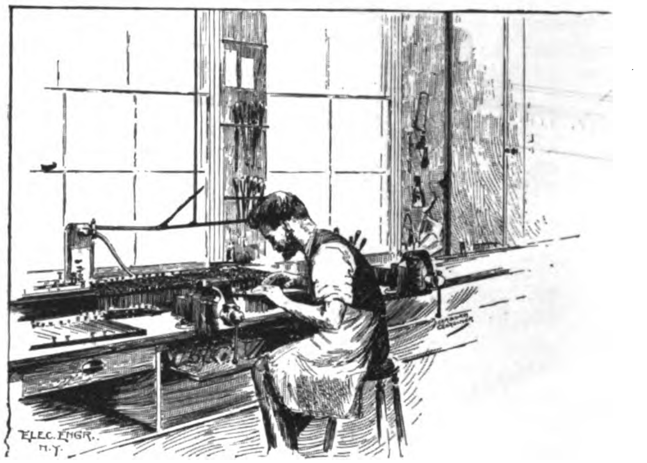
ELEC. ENGR. N.Y.

FIG. 6.—ASSEMBLING A THOMSON DOUBLE COIL GALVANOMETER.

Many have given up in despair all hopes of ever securing a hard, firm casting; others, again, of ever putting a delicate thread in aluminum on account of its porosity. These difficulties are now so lightly regarded by Queen & Co. that they are now making aluminum transits regularly as a market article. A number of ammeters and voltmeters, parts of galvanometers and electrometers have also been made of the metal as well as portions of leveling rods, etc. Opera glasses with aluminum cases have also been made and are very popular. A method has also been invented in the shop of Messrs. Queen & Co. by which seamless aluminum tubing up to 2½ inches in diameter and 3 feet long can be easily obtained; this, up to two months ago, had been thought quite impossible, and is still thought to be so by many.

VIII.

In another part of the shop Queen & Co.'s well-known "Portable Testing and Resistance Sets" are made; these, also are made in lots of fifty at a time, special tools having been made for many of their parts so that they may be turned out quickly, accurately and cheaply. For example, all the hexagonal blocks on the top of the set are made by one set of men, all the rubber plugs by another, the binding posts by another, the rubber tops are cut and polished by another, etc. These sets are sold either combined with a galvanometer, or without, and are capable of measuring with an error of but one-fifth of 1 per cent. resistances ranging from $\frac{1}{10}$ ohm to 10 megohms.



ELEC. ENGR. N.Y.

FIG. 6A.—ASSEMBLING PORTABLE TESTING SETS.

A little further along we find a set of men engaged in making the new Wagner-Queen direct and alternating current voltmeter, recently brought out by Messrs. Queen & Co. This instrument is said to be the lightest voltmeter in the world, weighing but 22 ounces. It is made almost entirely of aluminum, and the engraving, Fig. 8 shows it in the course of assembling, the instrument complete being shown in Fig. 5 group.

Still a little further along we find a number of workmen engaged in manufacturing the well-known "Magnetic Vane Ammeters and Voltmeters." The same subdivision of labor is practised here as in other parts of the shop, one man, or set of men, making all the backs, another all the bodies, another all the binding posts, etc. All the smaller parts of these instruments are stamped out by accurately cut dies and heavy machinery, so that all parts are exactly alike and inter-changeable.

Twenty-three different forms and ranges of these instruments are catalogued, the instruments being made in several sizes for either large or small plants and both in brass and iron. Ammeters of this type can readily be made to include as high a range as 2,000 or 3,000 amperes, and volmeters as high as desired. These instruments have come into very extensive use; they are great favorites, especially on ship-board and form an essential part of the magnificent plants put in by the Edison Company on the Sound line of steamers.

In the manufacture of fine galvanometers, Queen & Co. believe they have attained a success in two years fully equal to that secured in tens of years by the best European and English makers. The Thomson double-coil and tripod galvanometers, in particular, manufactured by them, they believe to be superior to any other made anywhere in the world, in regard to beauty of finish, high insulation and great sensibility. These instruments are now made in several different ranges so as to be suitable for any kind of high grade work. A large variety of other forms of galvanometers is also made in this shop, both for commercial and for laboratory work, and embracing the reflecting, ballistic, dead beat, etc., types. A large quantity of control and reversing keys of orthodox and special design for all kinds of testing and cable work are also made here. Figs. 6 and 6A show two views in the assembling department.

IX.

Among the special machines used by Messrs. Queen & Co. in their manufacturing department we find milling machines, punching machines, shapers, etc. The screw machines are very interesting, these being largely automatic in their action and used in the manufacture of binding posts, screws, etc. The largest of the machines now owned by Queen & Co. and illustrated in Fig. 9, takes rod up to $\frac{3}{4}$-inch in diameter. All that is necessary in this machine is to keep it supplied with rod, special tools shaping the post or screw, drilling and tapping it, cutting it off, etc. in quick succession; on one of these machines several thousand complete binding posts may be made in one day.

In the rear of the shop will be found the lens grinding and glass cutting machinery which is also very interesting. Here bevel edged glasses for "Magnetic Vane" and Cardew instruments are made; small lenses for magnifying scale readings are ground, shades are cut, etc. An interesting process is the cutting of holes in the top or sides of bell shades; holes can be cut in any portion of these shades up to 2 inches in diameter, and this, no matter upon what part of the shade or what its curvature.

In the rear of the shop also is one of the large dividing engines, a view of which is given in Fig. 10. On this engine are graduated many of the glass or metal scales used on various instruments; divisions can be placed accurately at any distance apart on circles or parts of circles up to 18 inches in diameter. A second dividing engine of a much finer kind is used on the best grade of graduating; this engine is kept in a special room built for it on top of the instrument shop, the adjuster working here alone, perfectly undisturbed. This engine will graduate circles up to 36 inches in diameter. In this room the final adjustments are made of the finer transits, points for setting being located over a mile away in each direction.

Attached to the instrument shop is the foundry. This occupies the bottom floor of a small detached building just back of the main shop while the pattern-room is located just above. Expert molders are employed in this foundry, in which are made nothing but the finest castings, all rough iron castings being obtained from outside; aluminum and aluminum alloys, phosphor bronze, brass, etc., are all cast here.

Queen & Co. are now making extensive alterations on the floor just above the foundry for the purpose of placing

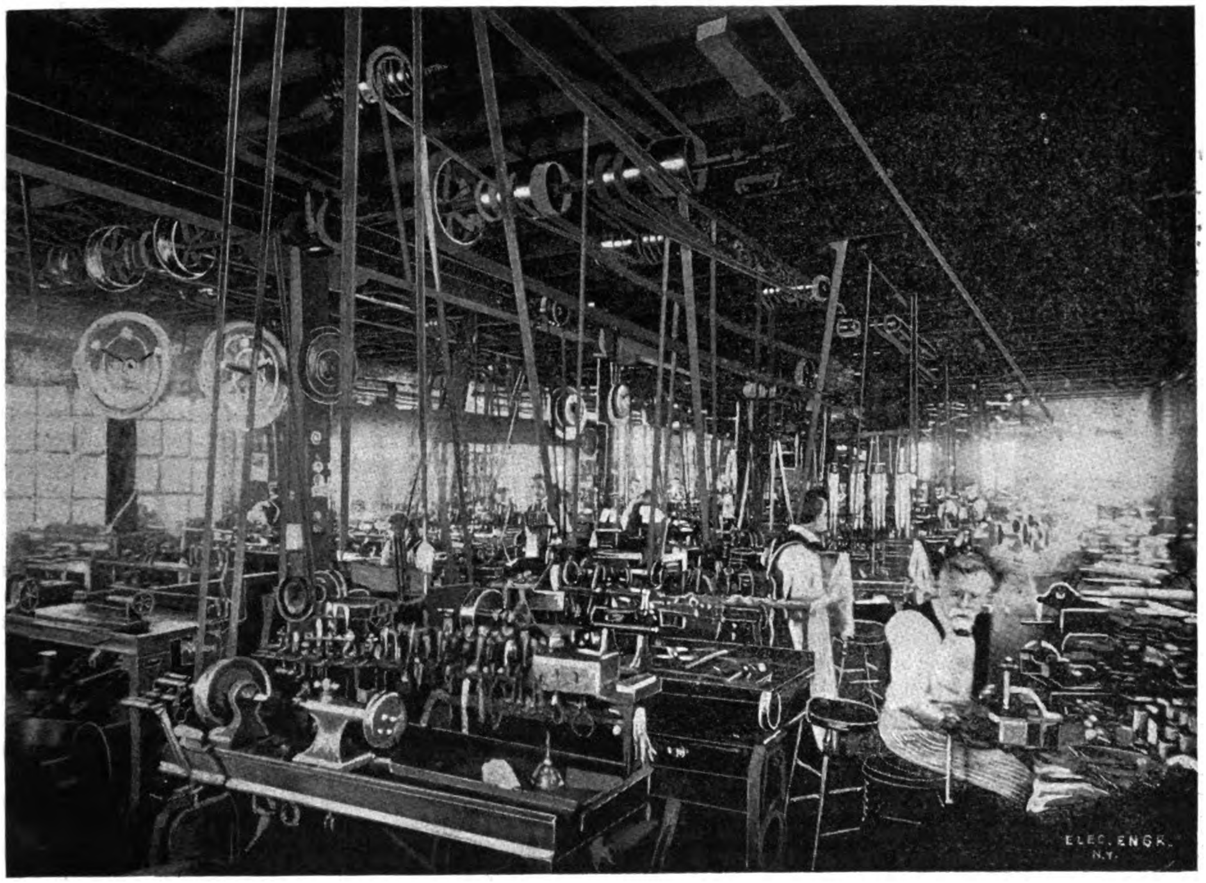


FIG. 7.—GENERAL VIEW OF MESSRS. QUEEN & CO.'S INSTRUMENT SHOP, FILBERT ST., PHILADELPHIA.

there, their cabinet and wood working shop, and will equip it with the most improved wood working machinery.

X.

An important part of electrical instrument manufacturing is the testing and calibration, etc., including special tests of wire for insulation and conductivity; tests of batteries for efficiency, output, etc.; tests of galvanometers for sensibility; experimental work on new instruments; calibration and standardization of standard and commercial ammeters and voltmeters; adjustment of standard resistance boxes and coils, etc.

Realizing the necessity for work of this kind, Messrs. Queen & Co., about two years ago, at just about the time they began to actively push their electrical business, made a contract with the Mather Electric Co. of Manchester, Conn., which had just secured the services of Prof. Wm. A. Anthony, then leaving Cornell University, as electrician, by which the Mather Co. was to do all the finer standardizing and adjusting for them under the supervision of Prof. Anthony. Operating under this contract the business rapidly developed until it necessitated almost the running of a special and separate plant by the Mather Co. for the doing of this work. Under this contract Prof. Anthony designed several new instruments, which were manufactured by Queen & Co. and adjusted by him.

As time went on the business assumed such proportions that it seemed to be very desirable that it should be concentrated and done under one management, especially as the growing business of the Mather Co. demanded more and more of Prof. Anthony's time. It was therefore decided that the contract, expiring Jan. 1st, 1892, should be discontinued on that date. Hence Messrs. Queen & Co. immediately set to work to equip for themselves a laboratory suitable and adequate for their work. It should be stated here that during 1891 a large part of Messrs. Queen & Co.'s work was done by themselves at their old place, No. 924 Chestnut street, the Mather's Co.'s facilities, owing to other calls, not being sufficient to turn out the large quantity of work needed. This work included the adjusting and standardizing of Cardew voltmeters, of school resistance sets, galvanometers, etc.

Looking about for larger facilities, it was decided to be quite impossible to secure the requisite stability and freedom from magnetic disturbance within the city proper. After considerable prospecting a property was found at Ardmore, Pa., which seemed to answer all requirements.

XI.

Ardmore is ten miles out from Philadelphia, on the main line of the Pennsylvania R. R. to Pittsburgh; it is just below Haverford College and two stations east of Bryn Mawr. The property secured by Messrs. Queen & Co. is 50 feet wide and 275 feet deep and has upon it a large frame house containing ten rooms, Fig. 11. This house has been fitted up to do all but the very highest grade of work; for the latter a separate magnetic house was built, which will be described later.

In the house the office is the second story front. Here are situated the desks of the electrician and of the bookkeeper. A fine reference library of the best American, English, French and German works on electricity and cognate science, dictionaries, etc., is here for the use of the staff. There is also a table upon which are the current numbers of the principal American and foreign periodicals. The laboratory staff is encouraged to read these books and periodicals, and each member is allowed to take not over two of them home overnight at any time. All completed work is brought to this office for inspection and approval before shipment.

In the second story front is also the draughting-room. In this room is a large case in which are kept the working drawings used in construction; these drawings, hundreds in number, are all carefully classified and arranged so that any one can be immediately referred to without the slightest loss of time. Four draughtsmen are employed continually, and even then the work can hardly be done rapidly enough. In this room is done all the scale draughting, original designing, etc., and the making of working drawings and tracings.

Just back of the draughting-room is one of the inside testing-rooms. This room, illustrated in Fig. 11, is fitted up with a complete equipment of instruments for the measurement of resistance and the adjustment of resistance coils and boxes; several galvanometers are used, of various resistances and of the D'Arsonval type. Almost all the galvanometers used on the premises are of this kind, it being possible to make them exceedingly sensitive and yet practically uninfluenced by magnetic disturbances or ordinary mechanical vibration, while their dead-beat qualities render them very quick in use. In addition to the testing instruments is a work table well equipped with small tools, etc.

XII.

Stepping across the hall we come to the winding-room and upper workroom. In this room is done all of the winding of spools needed for the "Portable Testing and Resistance Sets." To wind spools for these sets requires the steady labor of one man. A small lathe is used for winding, run by a 110 volt Perret $\frac{1}{8}$ h. p. motor; a special resistance box is used by means of which the speed of the motor is under perfect control and may be varied from one revolution to fifty per second; with this box, also, the direction of motion can be changed at will.

The winding of these coils, which is illustrated in Fig. 12, is done very systematically and can be done with an exceedingly small waste. Before beginning to wind a lot of coils of any kind, each spool of wire, as it comes from the makers, is tested in order to see how many centimetres run to the ohm. The amount needed to make up a given resistance is then calculated and about $1\frac{1}{2}$ per cent. added. One half of this amount is then wound off on a reel exactly one meter in circumference and placed behind the winder as shown in the engraving. The other half is then wound off on the reel at the side of the first. The reel being about two feet long there are usually several dozen pairs of such lengths wound off; this supplies enough wire for as many spools as there are pairs.

The outside ends of two adjacent wires are now taken and carried through two small holes in one end of the spool and the two wires wound upon the spool (which has been chucked in the lathe) side by side; when, finally, the two ends are reached they are soldered together. The other two ends are then clamped in the testing bridge and the resistance of the spool measured. The adjustment is secured by altering the position of the joint; if the resistance is too high a little solder is run between the wires so as to make the total joint length shorter. By testing every tenth spool or so, to allow for any non-homogeneity of the wire, the spools can be so closely adjusted in the winding that not over $1\frac{1}{2}$ per cent. of the wire is lost.

Part of this room, also, is used as a workshop for the upper floor. A fine Hill instrument lathe with divided head stock, taper cutting attachment, slide rest, etc., complete, is placed here with a complete set of metal and wood turning tools. A heavy carpenter bench fully equipped with carpenters' and cabinet makers' tools allows the doing of any incidental woodwork which may be necessary.

Just across the hall from this room is the other inside testing-room. This latter room is equipped very much as is the first testing-room described, except that the instruments are of a somewhat higher grade for the doing of a somewhat better class of work. In addition to the apparatus for resistance adjusting there is, in this room, a switchboard connected with the electrical system of the house,

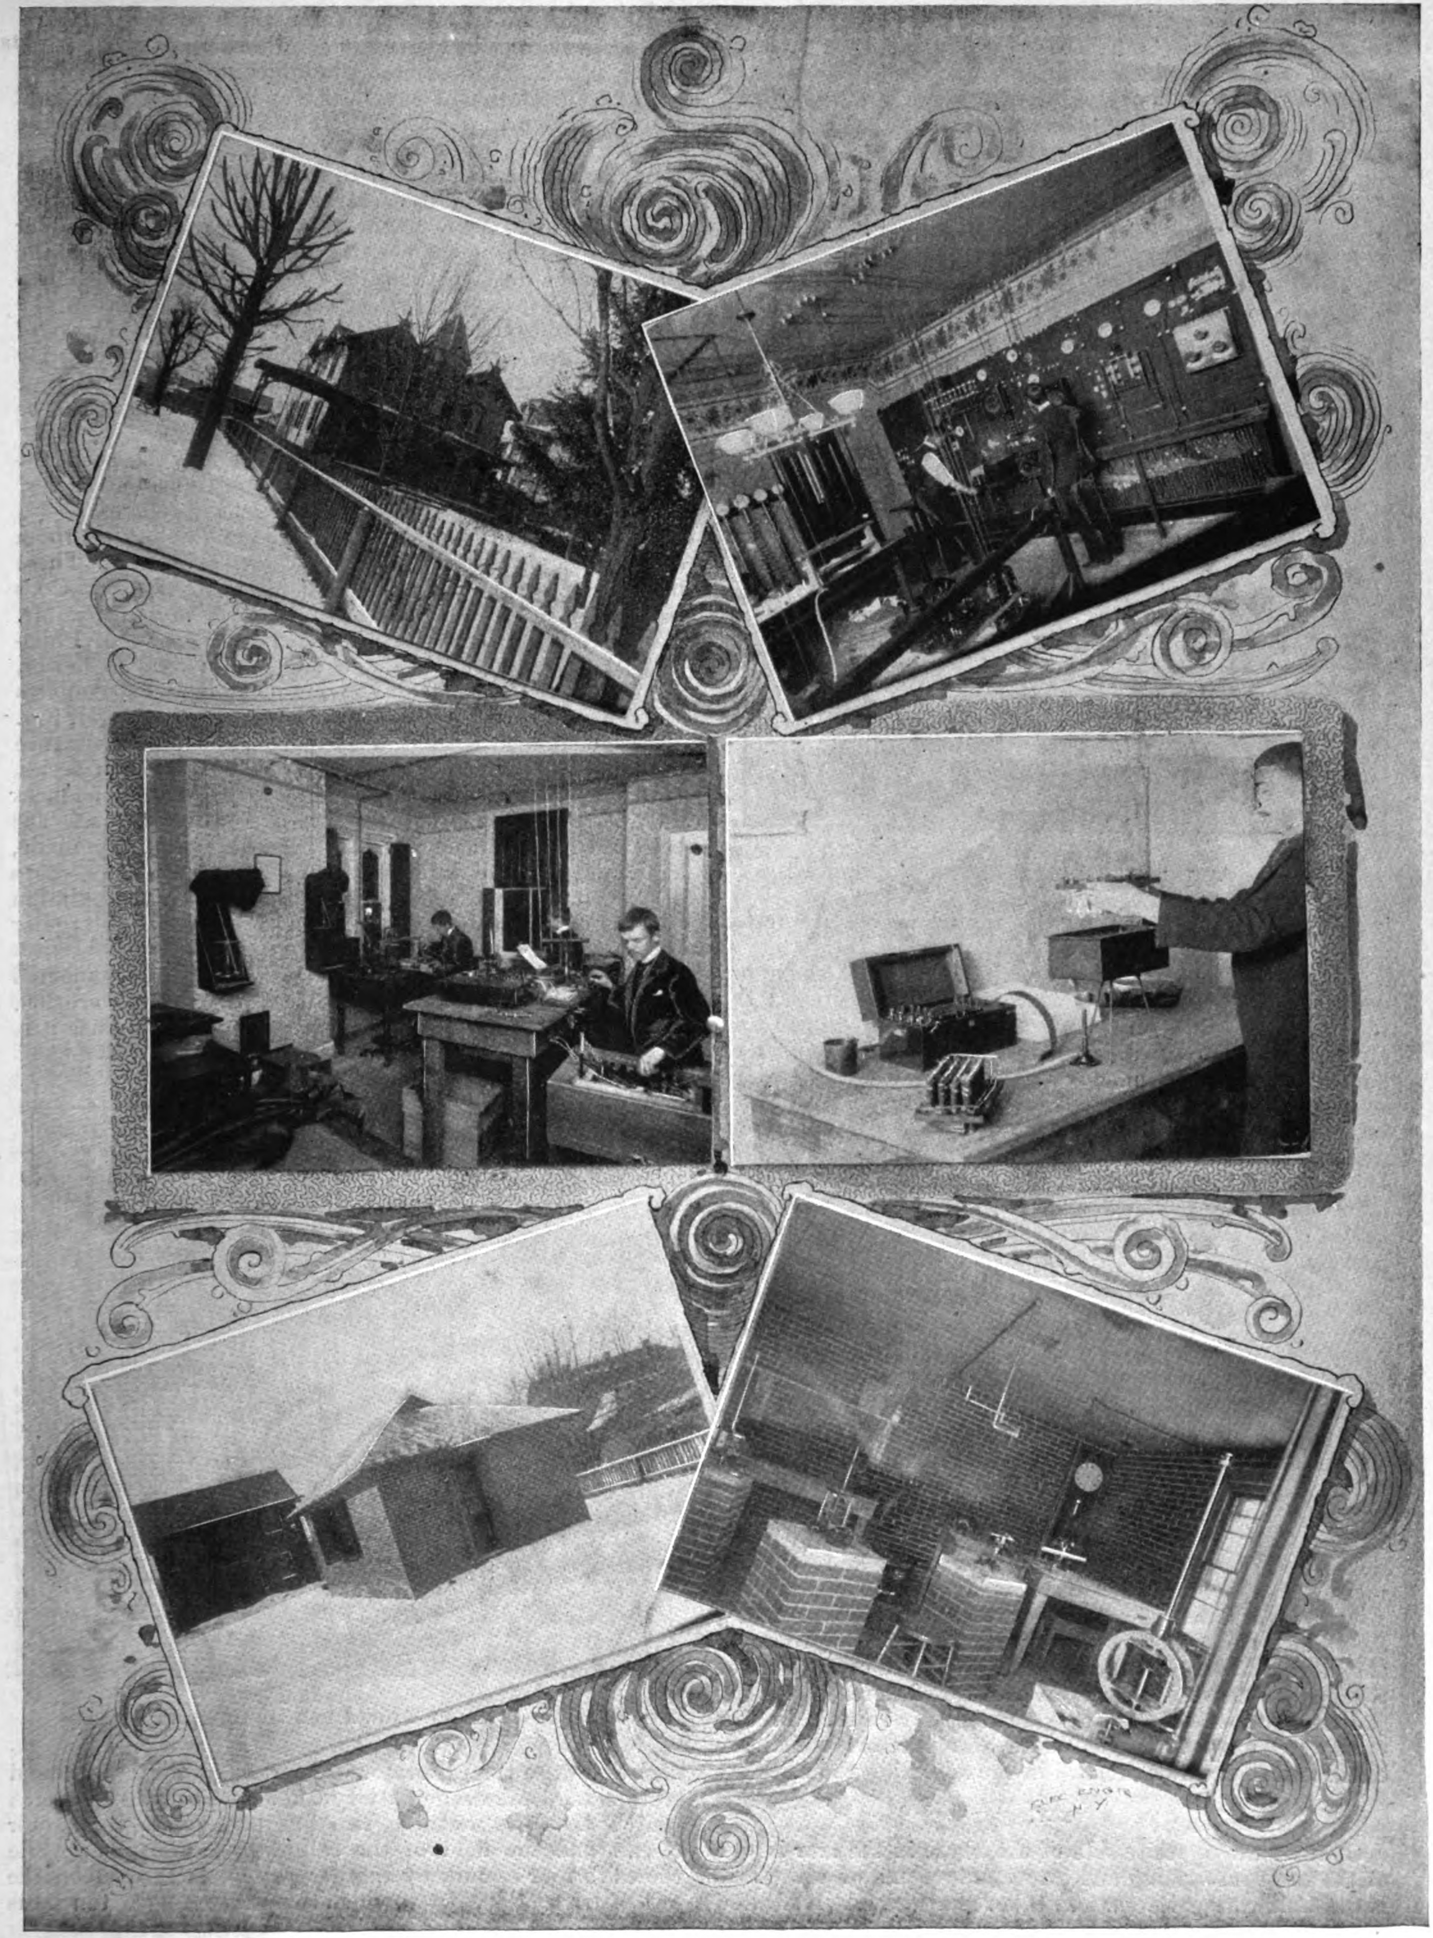

FIG. 11.—ELECTRICAL STANDARDIZING LABORATORY AND MAGNETIC ROOM OF MESSRS. QUEEN & CO., AT ARDMORE, PA.

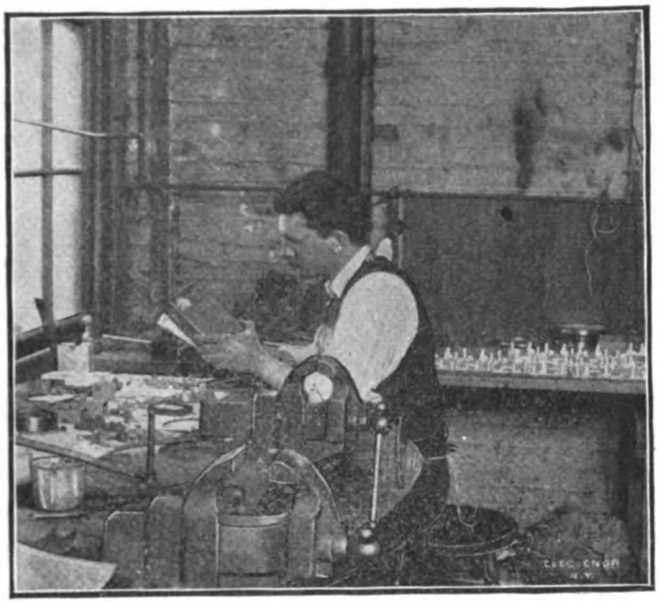
designed for the calibration of low range ammeters and voltmeters and any other odd uses requiring E. M. F. or current. This board gives voltages from 0 to 100 and currents from 0 to 100 amperes. In this room, also are wound all the high grade galvanometers, ammeters, shunts, etc., which are then taken to the magnetic-room for careful testing. All the electro-dynamometers made are also standardized here. In this room also the wound spools are tested and put into place in the resistance boxes.



ELEC. ENGR. N.Y.

FIG. 8.—ASSEMBLING WAGNER-QUEEN VOLTMETERS.

The rear of the centre corridor just outside of the room described has been converted into a paraffining-room; the illustration, Fig. 11, shows a testing set being dipped and already well coated with paraffine. A number of pairs of pans are used to accommodate the various sized resistance sets made; one pan is supported within another with water between the pans in order to prevent the paraffine from getting too hot and decomposing—decomposed paraffine being almost a *conductor* of electricity. Just back of the office is a coat, wash and lunch room in which are hot and cold water, tables for lunching, etc.

XIII.

On the ground floor, the right hand front room is the store-room and packing-room. A series of deep, glass doored and locked closets have been built around two walls of the room, and in the closets is kept all wire not needed for immediate use, as well as all other stock supplies such as screws, galvanometer mirrors, lenses, etc. Here also are kept all the fine instruments used by the laboratory only occasionally. Work not yet issued to the hands is also stored here, as well as all extra tools, etc., kept in stock against breakage.

Back of the store-room is another work and winding room; in this room all of the winding for ammeters and voltmeters is done. For this purpose a lathe and Perret $\frac{1}{8}$ h. p. 110 volt motor are used as in the winding-room on the upper floor. A work bench and full equipment of tools, grindstones, etc., may also be found here.

Just back of this room is the battery-room. In this room are set up 60 large Julien accumulators which are connected to the switchboard in the adjoining room.

XIV.

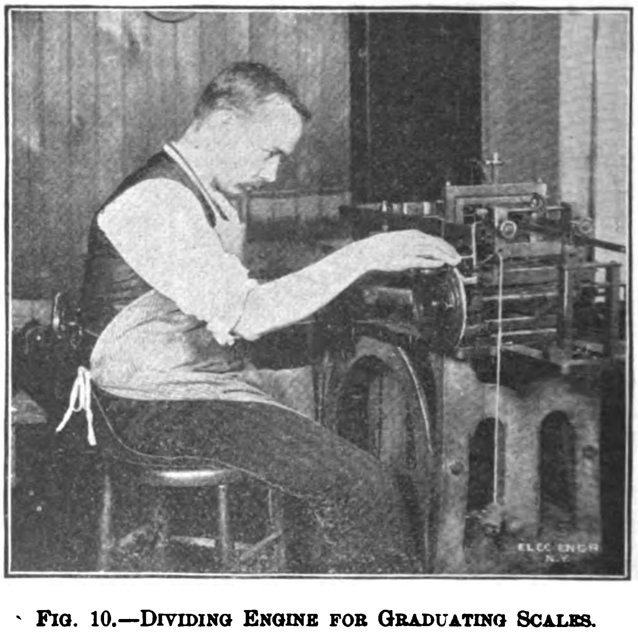
Over on the opposite side of the house in the rear is one of the most interesting and important rooms of all. This is the Calibrating Room. In this room which is illustrated in Fig. 11, is the switchboard from which potential or current, either direct or alternating is distributed to all parts of the plant. This switchboard measures 16 feet by 9 feet. At the right of the board and about 2 feet from the floor, as will be seen, there is a shelf attached to the board.

In this shelf are held four rows of iron cups filled with mercury, while next to each row of cups is a trough filled with mercury. Two of these rows contain 60 cups per row, one row being the positive terminals of each of the 60 accumulators, the other the negative terminals. These accumulator terminals are each wired to the cups on the switchboard by No. 8 copper wire. The other two rows of cups form the terminals of resistances, 60 in number. By the use of these cups it is evident that any combination of batteries and resistances, either series or multiple can be made.

Just above this shelf of mercury cups may be seen the two copper bus bars. In all combinations whatever, these two bus bar are made the distributing centres.

In front of the switchboard and the middle of the room are seen the dynamo machines used for calibration. These machines were specially built for Messrs. Queen & Co.'s laboratory according to specifications furnished by Mr. Willyoung, by the La Roche Electric Works, of Philadelphia. There are three machines in all; a 2 h. p. motor, a small alternating machine giving 60 volts and 20 amperes and a direct current calibrating machine. The latter, Fig. 12, has combined with it a special switch and resistance box by which the two fields may be connected in series, multiple, or used singly or in any of these circumstances have extra resistance included in one or both fields. The belts used in the machines have been very carefully made, and this machine will deliver voltage from 0 by steps of $\frac{1}{10}$ volt, or even less, to 1,200 volts, giving a maximum current of a little over one-half ampere at this voltage or below it.

The bus bars are put up in sections which are connected together by heavy copper strips of the same cross section. The switches are so arranged on the board, that in case it is desired to run the calibrator, for instance, the right hand section has the storage battery connected to it in series; a switch then throws these two bus bars on to the motor circuit and the field of the calibrator in multiple; while the calibrator circuit, by another switch, is thrown on the left hand section, from which this calibrating potential is



ELEC. ENGR. N.Y.

FIG. 10.—DIVIDING ENGINE FOR GRADUATING SCALES.

distributed to all parts of the premises. All the power used on the plant is secured through the medium of the storage batteries which are charged from the mains of the Haverford Electric Light Co., situated just above Ardmore.

XV.

In this room special racks have been provided for the calibration of Cardew voltmeters, many hundreds of which are sold yearly; on these racks which are illustrated in Fig. 13, twenty-five instruments may be standarized at once. A voltage of about 10 per cent. greater then the maximum working potential of the instruments is kept on for from 48 to 60 hours before the instrument is finally standarized; this is partly to "season" the working wire and partly to discover any defects which may exist in it and which might cause the instrument to break down. After this preliminary seasoning process, a scale is separately determined for each individual instrument by making a table of the readings in degrees on a special scale used for the purpose. These tables are then sent to the dividing engine and the separate dial of volts engraved. This method is greatly superior to the old one of compelling all instruments to read to the same scale, and has resulted in a great saving of labor with additional accuracy.

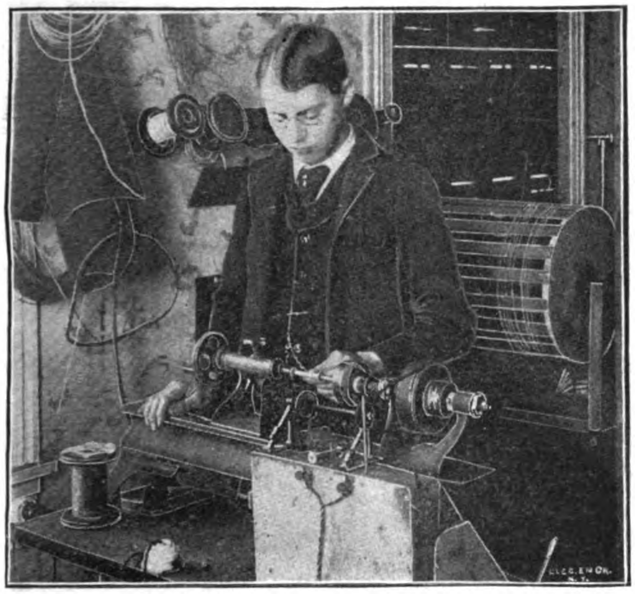


FIG. 12.—WINDING SPOOLS FOR PORTABLE TESTING AND RESISTANCE SETS.

XVI.

The Magnetic Room, an exterior and an interior view of which are given in Fig. 11, is considered to be one of the finest rooms for high grade electrical work to be found anywhere in the country, being superior to anything else of its kind except perhaps the magnetic rooms of Cornell and of the Worcester Polytechnic Institute. The room is a detached building, built of pressed brick, and 60 feet away from the nearest building, which is a small barn. The walls of this room are double and filled in with sawdust to prevent any sudden change of temperature. Not a grain of iron or other magnetic material can be found within 25 feet of the building, copper nails, etc., being used throughout. The windows and doors are also double. The window weights, catches, locks and gutter are all brass or copper, as are also the gas pipes and fixtures. The room is heated with hot water from a boiler located in the barn in the rear. The heating is done with but 2 lbs. of steam up to 65 degrees or 70 degrees F. and can be kept there within half a degree all day long, even in the coldest weather. This heating plant was put in by the Onderdonk Steam Heating and Ventilating Co., of Philadelphia.

Inside the room are five square piers each 2½ feet square, and capped with a heavy slate slab. These piers are hollow and filled in with conglomerate and extend down three feet into the ground; the floor has a clearance around them of about half an inch while weather strips make the cracks impenetrable to air currents. Three of these piers are in one straight line, being the line of the meridian, while about 40 inches opposite to the centre pier is a fourth pier at right angles to the line of the three.

On the two end piers are two standard Helmholtz-Gaugain tangent galvanometers, while on the fourth pier are a pair of telescopes and scales for observing them. One of these galvanometers can be used for measuring potentials from 0 to 1,000 volts and the other for measuring currents from 0 to 1,000 amperes. These two instruments are permanently fixed and are never disturbed. They have been carefully standardized and readings may be taken instantly to check the secondary standards used in ammeter and voltmeter calibration.

At one side of the room, on a slate slab let into the wall, is a Thomson centiampere balance, with extra resistance, and working up to 1,000 volts. This is merely intended as a check against the indications of the tangent instruments. Near to the Thomson balance is a delicate analytical balance sensitive to $\frac{1}{10}$ milligram and weighing up to 200 grams. On the wall is a standard chronometer with sweep seconds attachment and made specially for the laboratory by the Seth Thomas Clock Co.

Upon the fifth pier is placed the galvanometer used in adjusting the highest grade resistance sets. This galvanometer was specially designed for this laboratory and is said to be one of the finest instruments ever made by Messrs. Queen & Co. The instrument is of the dead beat bell magnet type and has a 1¼-inch mirror. The suspension tube is 30 inches long and the suspension a single cocoon fibre. There are three sets of coils with the instrument, of low, medium and high resistance. These coils may be quickly interchanged in conformity with changes in the character of the work. Upon the telescope table used in working with this galvanometer are permanently mounted all the keys, connections, etc., needed for quickly taking up any character of work.

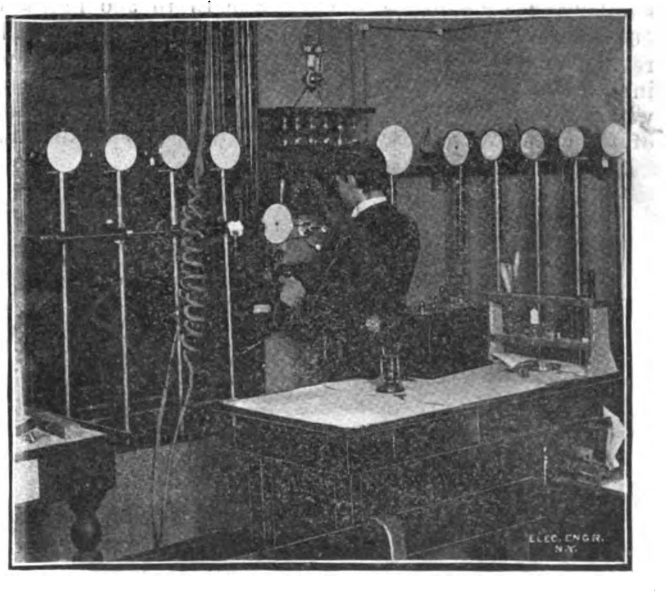

FIG. 13.—CALIBRATING CARDEW VOLTMETERS.

Just to the left of the electrician is mounted the standard set of coils used in most of the work. This set is one of the celebrated No. 1 sets, designed by Prof. Anthony, and is correct, as compared with original Cavendish standards, within $\frac{1}{100}$ of 1 per cent. Several ultimate single coil standards are also at the laboratory; these last were adjusted and were certified to by Prof. Glazebrook in charge of the Cavendish laboratory, at Cambridge, England. A table just to the right of the electrician is arranged to receive the standard slide wire bridge and apparatus used in adjusting ultimate standards. Shelves, etc., are about the room to receive work in process of adjusting.

In this room is done all the standardizing of resistance coils and boxes which require an accuracy of over $\frac{1}{4}$ per cent.; also the exact standardizing of the secondary standards used in the calibration of ammeters and voltmeters; and the adjusting of high grade shunts, determination of galvanometer constants, special tests, etc. The entire plant is amply equipped with gas and water and all conveniences.

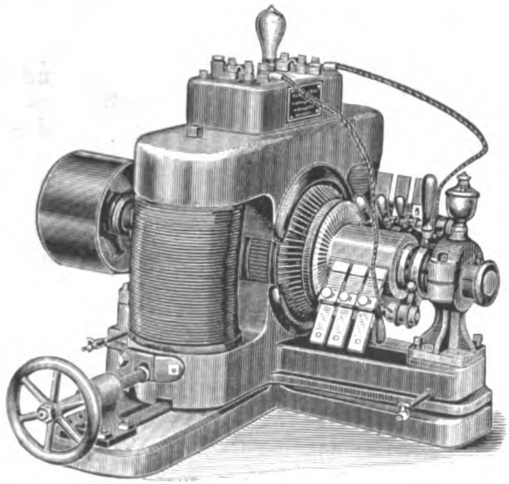
XVII.

The laboratory and its equipment were planned by Mr. E. G. Willyoung, of Messrs. Queen & Co., and have more than given satisfaction. Mr. William Young, who has been with the firm for several years, is assistant electrician and has charge of the laboratory under Mr. Willyoung. The laboratory at present employs 16 assistants, all of them having had special training in practical and theoretical electricity. One of these assistants is a graduate of the University of Pennsylvania; one of Amhurst and Cornell; one of the Philadelphia High School; two of other schools, and eleven of the Philadelphia Manual Training School. It is interesting to note how largely the Manual Training School graduates are employed by Messrs. Queen & Co.; indeed, it has been said in jest that this School is run for their benefit and that they take the entire output as soon as the youths are graduated.

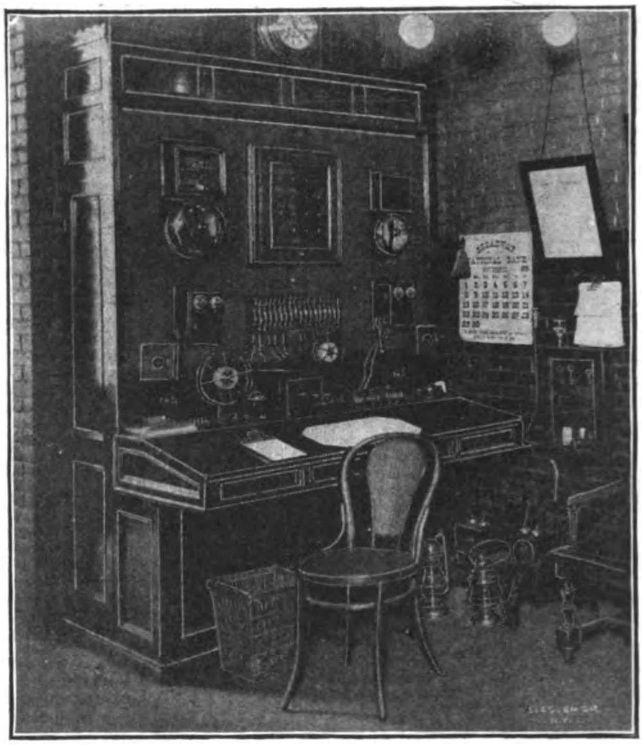
In conclusion the writer desires to acknowledge his indebtedness to Mr. E. G. Willyoung for the many courtesies extended and information volunteered during a recent visit to Messrs. Queen & Co.'s various establishments.

THE INCANDESCENT GENERATOR OF THE DUPLEX ELECTRIC CO.

The generator illustrated here has a capacity of 6 h. p., and is made by the Duplex Electric Co. Ltd., of Corry. Pa. The incandescent machines made by this company are very similar to their motors and vary from 15 to 500 lights of 16 c. p. They sit on a sliding base with belt-tightener. The regulation is accomplished automatically. They are simple in construction, self-regulating, thoroughly automatic, without the use of wasteful rheostats or appliances outside of the generator. They run quietly without sparking and without any change in the position of the brushes under any possible change of load and have a very low temperature at full load. The armature used in this generator is a modification of the Gramme. Its core is a drum, built on a brass spider of the best charcoal wire wound on an iron frame having a cross-section, which divides the core into four parts. The armature is carefully balanced both before and after winding. The air space is reduced to a minimum, bringing the field magnets, the cores of which are of best wrought iron, close to the armature and forming a highly efficient magnetic field. The commutator segments are of tempered copper, insulated by mica and firmly held in place by a fibre collar which renders it impossible for them to fly out. The brushes are composed of thin copper strips fastened together at one end. They do not require shifting and are free from sparking under extreme variation of load, thus ensuring their long life. The brush holders are simple in construction, of brass and thoroughly insulated. The bearings are made of the best anti-friction metal, while the boxes are attached to the pedestals by means of a ball-and-socket joint which secures perfect alignment.



THE DUPLEX INCANDESCENT GENERATOR.



INSPECTOR'S SWITCHBOARD, EDISON STATION, BOSTON.

A CENTRAL STATION INSPECTOR'S SWITCHBOARD.

BY

B. B. Hatch

THE inspector's switchboard in the Boston Edison station contains scarcely anything new or unusual to the electrical fraternity, but as it has attracted considerable attention from central station men who have visited us, a description of it seems in order, so that other stations may be benefited by the same, if it should contain any features new or worthy of consideration.

The Edison Illuminating Co., of Boston, maintains a corps of inspectors whose duty it is to care for all complaints, make small repairs and look out for the welfare of their customers generally, both day and night. It is in their room on the fourth floor of the Head Place station that the board is located. The board is built of oak and combines both a switchboard and desk, the upright portion consisting of a polished slate front. On this are mounted the fire-alarms, telephones and annunciators. On the desk are placed a watchman's register and automatic telegraph apparatus communicating with the various hotels and theatres so that they may call an inspector without delay. In the base of the board are located the batteries and cable terminals of the bell system for the entire station.

The board presents a very neat and compact appearance, and has received much favorable mention from central station people who have seen it. It was built in the company's shops and was designed by the writer, their chief inspector.

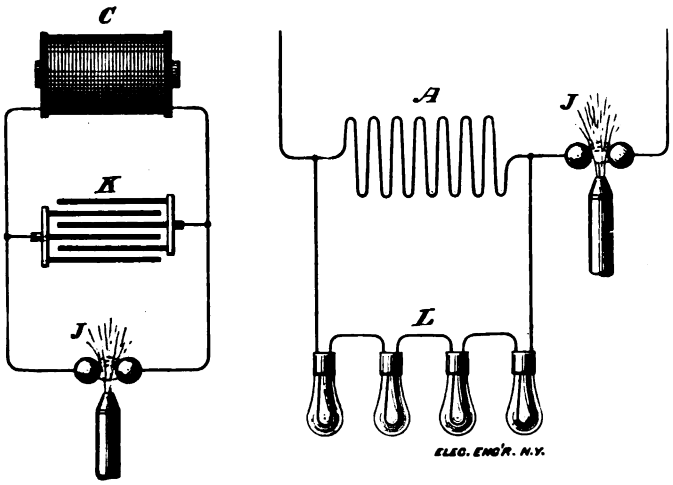
FURTHER EXPERIMENTS WITH CONDENSER, SPARK AND AIR JET.

BY

Elihu Thomson

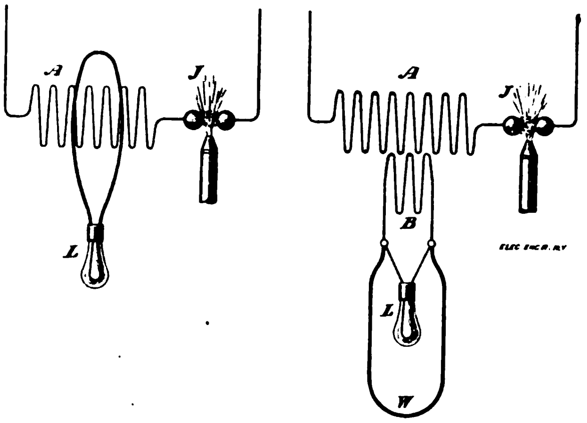
In a prior communication[1] I described some effects which were obtained by the induction of Leyden jar or condenser discharges passing through coils or helices upon other coils or helices placed in inductive relation with the former, and the effects of the use of an air jet or blast upon the spark discharge of a condenser as acting to enhance the inductive effects of the discharge were alluded to. It is my purpose in the present paper to still further emphasize the novel actions brought about by allowing a stream of air to play upon the discharge obtained from a condenser connected to the terminals of a high potential coil, such as a secondary whose primary is fed by alternating currents of any frequency.

Fig. 1 typifies this arrangement. C represents a coil which may give from 10,000 to 20,000 volts as a secondary to a suitable primary fed with alternating currents of suitable voltage. The terminals of this coil are connected to the condenser K, as indicated, and the discharge of this condenser is effected by means of terminals at J, and an air jet is allowed to play upon the discharge at J for the purpose of making use of discharges of very high frequency. In other words, the inductive effects of the discharge passing across the gap J, which without the presence of the air jet would be quite feeble, may be enormously enhanced, and represent in fact the passage of currents of extraordinary frequency.



FIGS. 1 AND 2.

Thus, in Fig. 2, if a coil A of a few turns of heavy copper wire, even as large as a quarter of an inch in diameter and, say, 15 to 20 turns, wound to a diameter of about 6 inches, be interposed in the path of the discharge, or in series with the discharge terminals at J, the self-inductive effects of this coil are such that a number of incandescent lamps in series are lighted in shunt to it; without the air jet at J the lamps do not incandesce. This experiment shows the presence of enormous self-induction in A as its actual resistance can be but a very small fraction of an ohm. The presence of such high self-inductive actions in A naturally suggests that it may be used as a primary and produce strong inductions in a parallel circuit. Thus, in Fig. 3, if a single turn be taken around the coil A and an incandescent lamp L, demanding 25 volts and two amperes of current, be connected across the terminals of the single turn, as shown, the lamp at L is lighted by the inductive effects, but this does not occur without the air jet at J.



FIGS. 3 AND 4.

Another demonstration of the extremely high frequency of the discharges is indicated in Fig 4, where two or three turns of conductor are placed in inductive relation to the coil A, such as are indicated at B. In the figure they are indicated as being separated, but it is to be assumed that they are wrapped around the coil A and perfectly insulated therefrom. Several turns in B are sufficient to illuminate the lamp at L, depending upon its voltage and its resistance, even though its terminals are solidly shunted by a heavy copper wire W several feet in length. This experiment is somewhat similar to one of Mr. Tesla's experiments in that it depends upon the enormous frequency of the discharges in B. The effects are practically *nil* without the air jet playing at J.

If, as in Fig. 5, the coils A and B be employed as a simple induction coil without an iron core, it is found that at a distance of a quarter of an inch, at J, with the air jet passing at J, very heavy, thick sparks pass at D, which space may be made three-quarters of an inch in length, the sparks resembling Leyden jar discharges, although the number of turns in B is only 20 and in A about 10. Both coils are constructed of very heavy copper wire and the turns kept apart, the average diameter of the coils being six inches.

In Fig. 6 is shown a modification in which the outer coil, consisting of about 20 turns of copper wire about a quarter of an inch in diameter, and the inner coil about 12 turns of somewhat similar gauge, are connected together so as to form, as it were, a closed circuit with each other through the lamps at L. The discharges are sent through the system as before by the air jet spark at J from the condenser K fed by high potential alternating currents of 10,000 to 20,000 volts. The lamps at L are brilliantly lighted in this experiment. Variations of the effective length of the single coil A, which is made of bare wire, can be obtained by a sliding contact, as indicated in the figure. This contact may be made to include more or less of the turns of A.

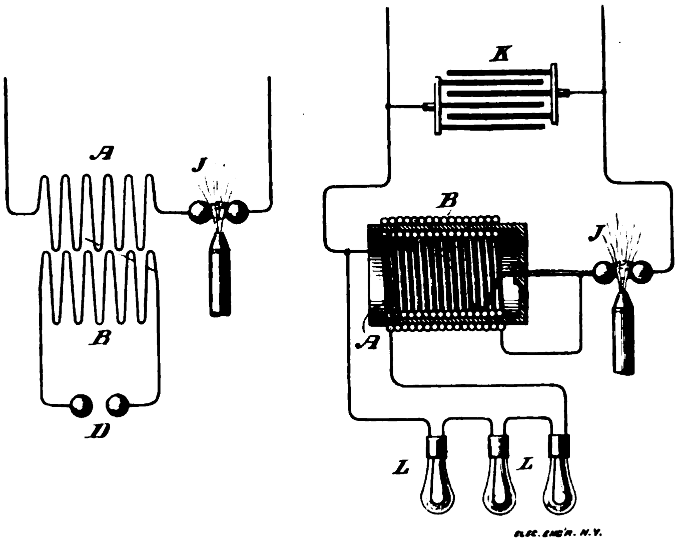
---

[1] THE ELECTRICAL ENGINEER, Feb. 17, 1892.

A modification of the experiment Fig. 6 is shown in Fig. 7 in which two coils A and B are connected in multiple, but the coil A is connected through the lamps, which are brought to high brilliancy on the passage of the discharges at J with the air jet playing thereon. The coil B has the greater number of turns in this experiment and probably feeds its lamps through the coil A by a sort of local current flowing through the two coils in series, though this is very difficult to determine. If on the passage of the discharges across J there are unequal inductions in the coils A and B, which set up currents local to the lamps, we would have an action analogous to the flow of currents locally to the coils connected in multiple arc when they are in unequal positions with respect to a changing magnetic field, causing an inequality of electromotive forces to exist.

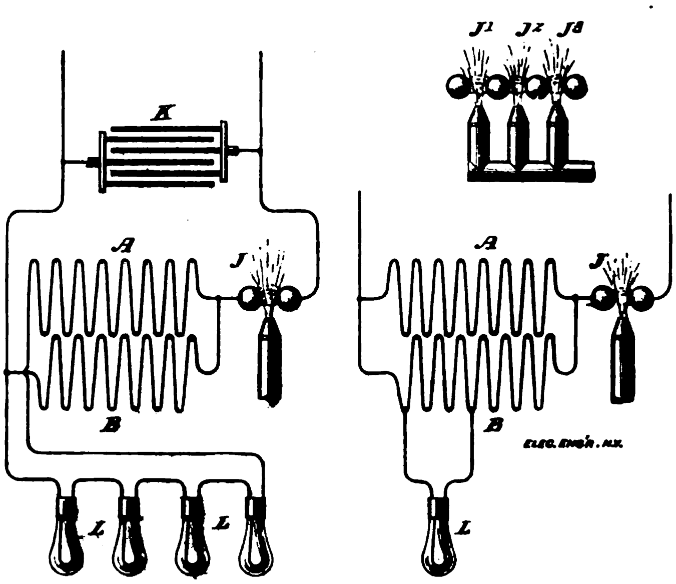
Fig. 8 shows that with the coils connected in multiple, even though their turns be unequal, it is easy to light a lamp L which spans a few of the turns in the outer coil. The lamp used in this case was a 100 volt lamp. The vigor of the self-inductive actions is certainly remarkable, and with the ordinary periodicities of alternating current, namely, 125 or 250 alternations per second initially used, effects due to very high frequencies are very readily obtained. The actions appear to be more vigorous the larger the condensing surface in K, the longer the spark at J, and the more vigorous the air jet used. The air jet hitherto employed by me has been of very moderate pressure and I expect to increase its force with the construction of a much larger apparatus for getting these inductive effects.

It would appear that we have in the air jet and the spark discharge a partial solution of the problem of obtaining very high frequencies in a fairly continuous manner. Fig. 9 shows an arrangement which may be found more effective when working with very powerful apparatus; that is, a series of spark gaps J^1, J^2, J^3, are each of them provided with air jets blowing therethrough. A much higher potential will be required to leap these combined spark gaps while the extinguishing action or the blowing action of the jets will be equally vigorous in each space. The apparatus is so simple and of so little cost to construct even for obtaining, by inductive actions of this character, sparks of great length and extremely high voltage, that it is contemplated to construct a much larger apparatus than that which has hithorto been used.



Figs. 5 and 6.

The coil B in these experiments while made of a few turns of heavy, coarse wire, was in my former communication described as constructed of a much larger number of turns of fine wire immersed in oil, and it was shown that torrents of long sparks could readily be obtained therefrom. The ratio of inductions between the coils A and B seems to be approximately those in an ordinary transformer, and while it is very difficult to estimate from the length of spark alone the actual voltage existing, yet it is certainly true that very many thousands of volts potential difference exist between the terminals during the passage of such sparks as 7 inches and 8 inches in length. The striking distance, however, appears to increase much more rapidly than the potential, and if the law holds good it would appear to be easy to secure sparks of very great length by extending the scale of my experiments.



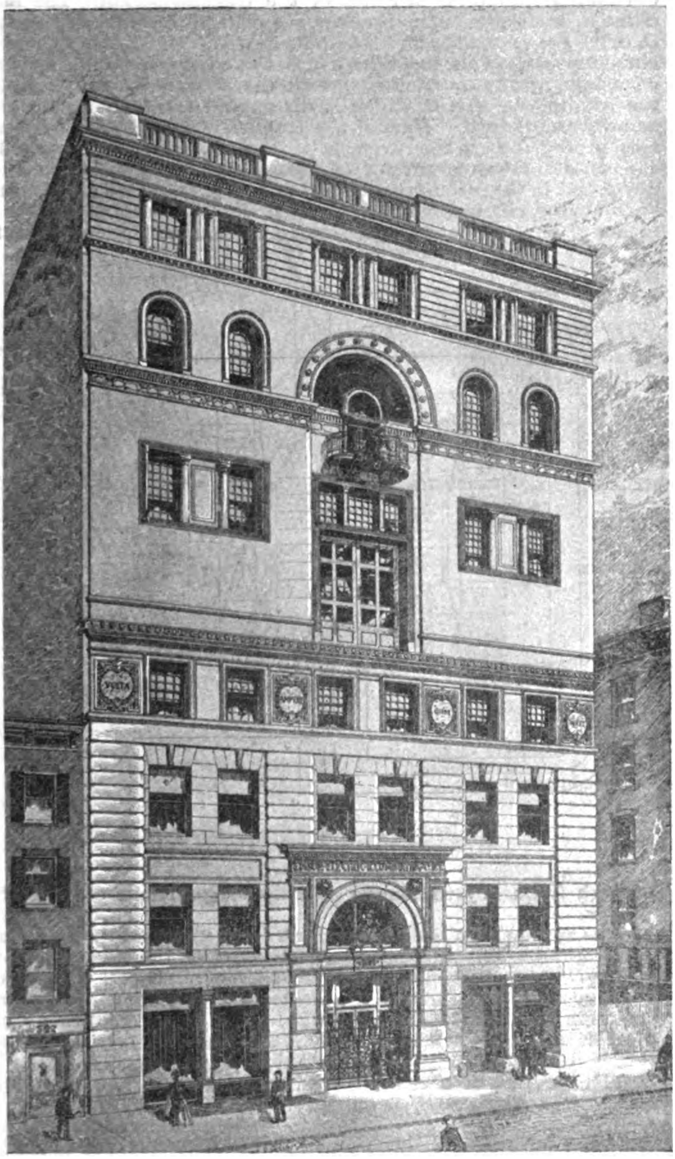
Figs. 7, 8 and 9.

It may be remarked here that in reference to striking distance, it is a question whether there is not a certain potential which from a certain sized terminal will strike at any distance. It would appear that in order to prevent the discharge from passing into the air either in the form of a brush or a discharge connecting the terminals, the terminals themselves should be made in the form of larger and larger poles kept perfectly smooth the higher the potential worked with, and that for voltages as high as 200,000 or 300,000, terminals tipped with small balls would act practically as points and allow discharge into the air in the form of a brush discharge, if this potential could not actually cause a leap between the terminals.

THE NEW STATION OF THE EDISON ELECTRIC ILLUMINATING COMPANY, NEW YORK.

The credit of having installed the first central station in the world for the distribution of current for incandescent lighting is, as our readers are aware, due to the Edison Electric Illuminating Company, of New York City. Started in 1882, this station has been in continuous operation ever since, and the success early obtained in its working soon induced the company to erect other stations, with a result that during the past few years stations at Twenty-sixth street and Thirty-ninth street, New York, have come into operation. The old station in Pearl street, however, has long since ceased to meet the demand made upon it, so that the company some time ago resolved to erect a central station which should be able to meet fully all requirements, both as regards capacity and economy of operation.

The new station which is situated at the corner of Pearl and Elm streets, may be said to be growing gradually, the plant at present installed being merely temporary in its nature. Thus, during the past year the company have been developing the most economical type of engine to employ, and believe that they have secured this in the Van Vleck disconnective engine, described in our issue of January 20, and now in daily operation in their Twenty-sixth street station. They are now constructing under the supervision of their engineer, Mr. John Van Vleck, a similar type of engine, intended to work up to 1,600 h. p., which is to form one of the set of small units for the new station. As the load on the station increases, larger units will be required, and provision is being made for six or eight of these of from 4,000 to 5,000 h. p. each. Thus it will be seen, while affording an ample number of large units, the error will not be made of placing the station in such a position that a break down in any one member would seriously affect its working.



New Edison Station, Elm St., New York City.

When fully equipped to carry 200 pounds steam pressure and over, quadruple expansion engines will be employed. Owing to the peculiar day load which obtains in this district and which reaches a maximum between 10 and 11 o'clock a. m., it will admit of almost 12 hours' operation at full capacity, and hence this high load factor will permit of the economical employment of quadruple expansion engines.

The contemplation of quadruple expansion naturally necessitates the employment of high steam pressures, and in the matter of boilers the company are not yet quite decided as to the type they will employ, as they are of the opinion that better results can be obtained in the matter of evaporative power than can be obtained with the present type of water-tube boilers. Their object is to get a safety boiler with an evaporative capacity equal to that of a first-class marine boiler; the latter type, of course, cannot be used on the score of safety.

The steam piping also is receiving its due measure of attention and is designed throughout to withstand 300 pounds pressure. Mr. Van Vleck has devoted considerable study to the construction of the steam piping which will be on what is known as his "Cannon" System. This is a multiple pipe system, consisting of a number of pipes 8 or 9 inches in diameter placed in a row and expanded into headers with flanges. These flanges will probably be 4 inches thick and bolted with 2½ inch bolts. No duplicate or cross-over piping will be used as it is believed that the method of construction here adopted will make all repairs unnecessary and avoid all the trouble usually encountered with high pressure steam piping.

It is contemplated to operate the boiler furnaces under hot blast, and for this purpose, the engine and boiler-room will have closed doors, these rooms being slightly under pressure, and supplied with fresh air forced in through ducts below the floor. This air, on rising, accumulates all the radiant heat from the engine, piping, boilers, etc., and in the hot rooms above will attain a temperature of 100 to 150 degrees. From these hot rooms, again the air will be exhausted and sent through heaters in the stack, where it will be further heated up to 300 to 350 degrees. From these heaters it will find its way to the ash-pit of the boilers, the whole forming what is now called the hot-blast system, which has been very successfully applied on many English steamers and is now being introduced on American vessels.

With the arrangement as here outlined, energy can only find its way out of the station through three channels; first, in the form of electrical energy, conveyed through the conductors; second, as heat contained in the heated air escaping through the stack, and which has been reduced to as low a limit as possible by the feed-water heaters and hot-blast heaters; and third, as heat contained in the water flowing from the condensers which will also be reduced to the lowest practical limit by heating the feed water and by the employment of quadruple expansion engines.

In the matter of the electric generators to be employed, the company has also gone to work very deliberately, and favors a series-wound disc dynamo, and the indications are that such a type of machine will be used.

The system of electrical apparatus within the station will also be of an exceedingly novel character. Among other things, the output in amperes on each feeder will be so indicated as to automatically form a curve on the side wall, showing the distribution of the load on the entire system. The pointers of the ampere-meters will all terminate in black dots, which will move vertically up and down through slots. The pressure at the ends of the feeders will also be shown in a similar manner and will form a straight line when the pressure is normal all over the system. Any abnormal pressure will thus evidently be indicated by a break in the straight line, and will thus immediately attract attention. The main voltmeters to be employed will be constructed on the principle embodied in Sir William Thomson's engine-room voltmeter specially adapted for the present purposes by Mr. Van Vleck. These voltmeters will be two feet in diameter and are now being constructed by James White, of Glasgow.

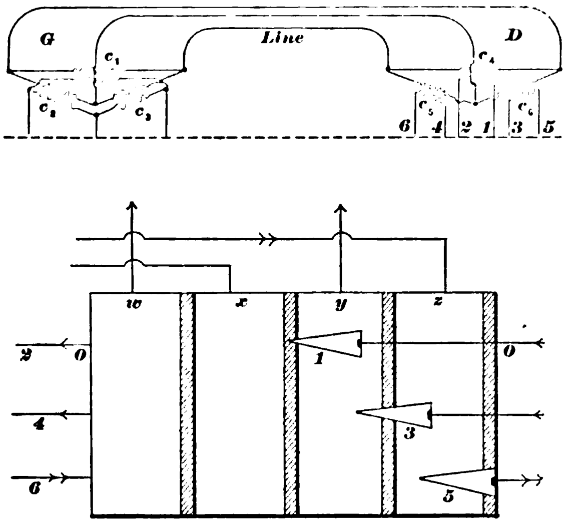
The station being designed for 500,000 lights, the main ampere-meter will be constructed to measure 200,000 amperes. It is also proposed to use Sir William Thomson's electrostatic voltmeters on the common pressure wires. These voltmeters, as is well known, require no actual current for their operation, and hence they will not deflect the comparative indicators, and will thus make it unnecessary to run the common pressure wires to the ends of the standard feeder.

It will, of course, require some time to put all these ideas into actual practice, but the work is steadily going on and will be pushed with all possible speed. It must be considered a subject for congratulation that so large and important a company as the Edison Electric Illuminating Co., of New York, is under the management of one so intelligent and far-seeing as Mr. R. R. Bowker, the first vice-president of the company, who has done much to place the company in its present splendid condition.

A PROPOSED SYSTEM OF ALTERNATING DIRECT CURRENT TRANSFORMATION.[1]

BY F. JARVIS PATTEN.

THE lecturer described several devices affording the means of transforming a single alternating current of short wave length or high frequency into triphased alternating currents of long wave length or low frequency, and also a means of transforming a single alternating current into a continuous direct current of uniform E. M. F. The requirements of practice would probably be met by two independent armature windings carried on the same core. One winding has a collector directly and reversely connected, and is supplied with a single alternating current. This winding is also connected to the other one at three equidistant points, and the other winding is provided with an ordinary Gramme collector, and, if desired, three rings that are connected to three intermediate equidistant points of this winding.



FIGS. 1 AND 3.

This reduces the machine to a single armature with two windings and two collectors, or at least to two separate armatures and collectors, which form will doubtless be found preferable. The consumption circuit will be connected either to the brushes bearing on the collector or the rings of the secondary winding, according to which function of the machine it is desired to render operative.

Thus a single alternating current of ordinary period may be transformed either to triphased alternating currents of low period or to a direct current of comparatively uniform E. M. F.

If a three-wire system, like that shown in Fig. 1, is used throughout, giving triphased currents at the delivery end *D*, from the secondaries of the three converters, the transformation of these triphased currents to a single direct current of uniform E. M. F. or to triphased currents of a much lower frequency of alternation, can be accomplished on similar lines. It is well known that multiphase motors give better results with currents of comparatively low frequency, 40 to 80 per second being the reported practice abroad. On the other hand, the converters for reducing potential increase rapidly in size as the frequency of alternation decreases; consequently very large converters are required for such systems. These features are antagonistic and render the conversion apparatus costly if low frequencies are essential to the proper working of rotary field machines.

The system shown in Fig. 2 admits of using high frequencies on the line and in the conversion apparatus at *G* and *D*, for raising and lowering potential, while the transformer, Fig. 14, changes these triphased currents of high frequency either to a uniform direct current or to triphased currents of a lower rate of alternation.

At the delivery end *D*, Fig. 1, separate converters c_4, c_5, c_6, (not interlinked) are used, the secondaries having free terminals, as shown, which are taken to the brushes 1, 3, 5 and 2, 4, 6, bearing on the commutator of the ring R_2, Fig. 2, the winding of which is connected at three equidistant points *x*, *v*, *y* of the ordinary Gramme ring and collector R_3, or to three ring contacts, as may be desired, according to whether a direct current or triphased currents required, as a result of the transformation. The machine R_1 is simply a synchronizer, requiring only sufficient power to drive the apparatus and is supplied with one of the triphased currents only. This machine keeps the whole apparatus in synchronism, and the currents from all the secondaries are taken to the winding R_2, Fig. 2, which is direct and reversely connected as before explained. Thus, if the frequency throughout the system in Fig. 1 were 288 reversals per second, and there be, say, 12 segments in the commutator of the ring R_2, there would then be developed in the circuits connected to *x*, *v*, *y*, triphased alternating currents having 48 reversals per second. We have, then, here a means of changing at a single transformation multiphase currents of high frequency to similar multiphase currents of low frequency.

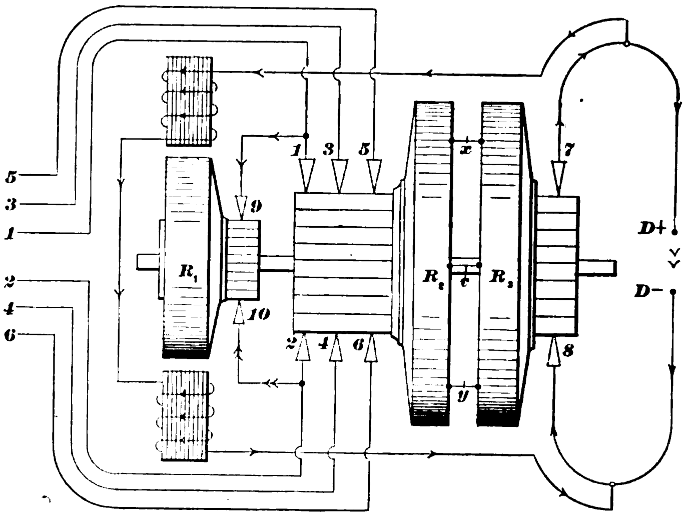


FIG. 2.

This system admits of using high frequencies on the line, and in the conversion apparatus at both ends of the line, and low frequency in rotary motors at the delivery end. If, instead of being connected to three rings, the leads *x*, *v*, *y* are connected, as shown in the figure, to another winding, a direct current of uniform E. M. F. will flow in the circuit *D*+ *D* —. This transformation requires no further explanation here. Fig. 3 shows a developed view of a part of the commutator of the ring R_2 and the relative positions of the brushes.

To prevent short circuiting, the segments are separated, as shown, so that a brush will not bear simultaneously on adjacent segments, and for obvious reasons, the brushes have a lag behind each other of one-third of a segment. The arrows show how the currents are flowing at the time being. Brush 1 has no current; brush 3 has a positive, and brush 5 a negative impulse.

If these transformations can be made on a large scale economically, it will be possible to supply not only alternating current apparatus of every description, including multiphase devices, but direct current apparatus as well, from a single high tension alternating current. When the original source of supply is a water power, and the distance is not too great the losses of conversion may well be brought within commercial limits.

MR. GILBERT WILKES, engineer for the Eastern District of the Edison General Electric Co., has resigned that position and has become the chief engineer of the Detroit Electrical Works, to take charge of their electrical work. Mr. Wilkes will enter upon his new duties March 1.

---

[1] Abstract of a paper read before the American Institute of Electrical Engineers.

Society and Club Notes.

A TRIBUTE TO THE MEMORY OF GEORGE WORTHINGTON.

AT a meeting of the members of the Electric Club held at the club house Friday evening, February 12th, the following minute was ordered to be spread upon the records of the club:

> The Electric Club of New York hereby expresses the profound sorrow felt by its members upon learning of the death of Mr. George Worthington.
>
> His genial companionship, his hearty good will, never failing towards any, his disinterested friendship, his utter unselfishness, endeared him to all who came within the circle of his acquaintance. The memory of these traits of his, as well as of his manly independence and courage, leaves in our minds and hearts the gracious sense of past comradeship to temper the sad knowledge of our friend's departure.
>
> He was one of the founders of this club, and the leading spirit in the work of building it up to usefulness and for the benefit and pleasure of its members.
>
> The secretary is requested to communicate this minute to the family of Mr. Worthington.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

AT the council meeting, Feb. 16th, the following applications for associate membership were made:

Fred Deland, Western manager, *The Electrical World*, 465 The Rookery, Chicago, Ill.
Elisha Gray, Highland Park, Ill.
Adolf Graner, electrical patent agent, 529 North 35th St., Philadelphia, Pa.
John N. James, electrician, Naval Observatory, Washington, D. C.
A. F. McKissick, professor of electrical engineering, the A. & M. College of Ala., Auburn, Ala.
Lee L. Summers, assistant electrician, Western Union Telegraph Co., 18 W. U. Telegraph Bldg., Chicago, Ill.

The following applications for transfer from associate to full membership, approved by the board of examiners, January 12th, were acted upon:

Charles B. Burleigh, electrician, Thomson-Houston Electric Co., 620 Atlantic Ave., Boston, Mass.
Robert Edward Dunston, president, the Connecticut Motor Co., Plantsville, Conn.
Angus S. Hibbard, general superintendent, American Telephone and Telegraph Co., 18 Cortlandt St., New York City.
Charles H. Wilson, general superintendent, Chicago Telephone Co., 203 Washington St., Chicago, Ill.
Park Benjamin, electrical expert and engineer, 32 Park Place, New York City.

The American Institute of Electrical Engineers has decided to hold its annual meeting this year in Chicago.

LOUISVILLE ELECTRIC CLUB.

THE representative members of the different electrical firms in Louisville met in the parlors of the San Carlos Hotel on February 1, for the purpose of organizing an electrical club. Mr. Sidney J. Sproul, superintendent of the Louisville Electric Light Company, was elected temporary president, and Mr. D. W. Sea, of the Edison General Electric Company, was made temporary secretary.

College Notes.

UNIVERSITY OF NEBRASKA.

THE new Electrical Engineering Laboratory is nearly completed. It is 50 x 60 feet, with high roof for good ventilation, and is designed especially with regard to plenty of light.

In this building are being placed two engines, one 100 h. p. tandem compound condensing Gidding's automatic, made by the Sioux City Engine Works, and one 25 h. p. Atlas automatic, made by the Atlas Engine Works, Indianapolis, Ind. Each engine may be coupled to either end of a line of counter-shafting through the centre of building or belted direct to dynamos. The line of counter-shafting is made by the Falls Rivet and Machine Co., Cuyahoga Falls, Ohio, and is a model of accurate workmanship. The driven pulley from the 100 h. p. engine is attached to the shaft through a Van Winkle 100 h. p. spring dynamometer and thus allows accurate power measurements to be made at all times. Only clutch pulleys are used, so that any dynamo may be started or stopped at pleasure without stopping the engines or throwing off belts. By a system of friction clutch couplings the whole line of shafting may be driven from either engine independently, or from both engines working together as occasion may require. To this line of counter-shafting are connected one Westinghouse 500-light 1,000 volt alternator, one 25-light 2,000 c. p. Thomson-Houston arc dynamo, one 25-light 2,000 c. p. Wood arc dynamo by the Fort Wayne Elec. Company, two 15 K. W. Edison dynamos arranged for the three-wire system, and one 100-light 100 volt Weston dynamo, thus representing nearly every type of machine used at the present time and of commercial sizes. The engines are arranged so that they may be run at high pressure, exhausting through improved exhaust heads into the atmosphere, or they may be connected with a 100 h. p. Worthington independent jet condenser and run as condensing engines. Steam is furnished by a 125 h. p. Sterling boiler placed in a separate building in the rear. Besides the Van Winkle dynamometer, a Prony friction brake, a Brackett cradle dynamometer and two dynamometers of special design, one an oil and the other a magnetic dynamometer, are provided for power measurements. Each electric system represented is complete in every detail. Four handsome fireproof switchboards are provided on which are placed the measuring instruments and regulating devices of each system. About $5,000 has been expended in importing standard electrical instruments alone, and a large amount of apparatus, such as current meters, watt meters, lamps, transformers, etc., possessing special features, have been procured from other firms than those named. Sixty-five storage cells of three different types are used to light the building and for experimental work.

The total addition to the equipment in this department this year will amount to over $30,000, which thus will make the department more completely equipped for its work than any other in the West, and equal to any in the whole country. An outline of the course will be given later.

Legal Notes.

ELECTRIC RAILWAY INFRINGEMENT SUIT—WESTINGHOUSE PATENTS.

THE Westinghouse Electric & Manufacturing Company has recently begun an important suit against the Pittsburgh & Birmingham Traction Company for the infringement of its patent No. 442,459 covering a device which has rendered the electric street railway motors both noiseless and durable. When the Westinghouse company began the manufacture of its motors they were confronted by the objection raised by numerous users of electric motors to the noise of those with which they had experienced. The engineers of the company considered the subject very carefully and there was worked out in due time a device for enclosing the gears in such manner as to suppress the noise and at the same time to provide automatically for a proper lubrication of the teeth of the gear wheels.

The company has put out several hundred motors with these gear cases, and they have been successful in their operation from the very start, and have fully demonstrated the fact that street railway motors can be run without noise, with the further advantage that the wear and tear and consequent expense of maintaining them can be reduced to a nominal figure. The successful running of the motor furnished by the Westinghouse Company, has, it is claimed, made this form of device so desirable that nearly all of the other companies engaged in the business have taken the risk of infringing the patent by closely copying the plans of the Westinghouse Company.

The present suit has been brought as a test case.

THE GREEN ELECTRIC RAILWAY PATENTS.

IT is stated that suits will be brought to enforce the rather extraordinary patents on electric railroading methods granted not long since to C. Green, of Kalamazoo, and noted in these pages. Mayor O. S. Kelley, of Springfield, Ill., is said to have a large amount of money he wishes to lose in trying to "demand royalties from every electric railroad using the overhead system."

Reports of Companies.

ELECTRICAL CONSOLIDATION AT ST. JOHN, N. B.

A CONSOLIDATION of the electrical interests in the city of St. John, New Brunswick, has been effected by the organization of a new company known as the Consolidated Electric Co., Limited; this company have taken over the Eastern Electric Co., Limited, the New Brunswick Electric Co., Limited, and the St. John City Railway Co., and it becomes one of the largest companies in Canada. The new company will have a capacity of 6,000 incandescent lights and 300 arcs. They have the contract for the lighting of the city, and anticipate a large increase in both lighting and motor business.

The officers of the company are: John F. Zebley, of New York, president; H. B. Zebley, of New York, secretary-treasurer; Chas. D. Jones, of St. John, manager, backed by a strong board of directors composed of New York and St. John gentlemen.

Letters to the Editor.

THE PERRET MULTIPOLAR FIELD,

In regard to Mr. Perret's reply to my criticism in The Electrical Engineer of Jan. 20, I will say but little, as he seems inclined to beg the question entirely, and I can see no advantage to be derived from a continuation of the controversy. What Mr. Perret *meant* in his original article no one should know better than himself, and I have no desire to enter into an argument as to the advantage of laminated fields.

In order, however, to justify myself before those who have done us the honor to follow us, I will quote from Mr. Perret's original article of Nov. 1890 (which statement also appears in The Electrical Engineer of Jan. 6), as follows:

"Now, if we so dispose the magnetic circuit as to cause the lines of force to enter the armature core at one point, to leave it at another, to *enter it again at a third point and to leave at a fourth*, it is obvious that the conductor will cut all the lines at four points in each revolution, and that it will therefore generate the same E. M. F. at one-half the original speed." "If we increase the number of poles to six, we shall obtain the same effect at one-third the speed, etc," * * "*This, then*," viz., causing the flux to enter and leave at successive points on the armature, "*is the principle of construction by which we secure low speed.*" (The last italics are my own.)

As Mr. Perret admits that "in practice all the lines of force do not enter and leave the armature at the consecutive field poles," and that it would be of no advantage if they did, I can see no need of further comment.

H. R. Wellman.

Cleveland, O.

FORMING AN ELECTRICAL CLUB AT ERIE, PA.

About fifty young men of our city, most of them engaged in our electrical manufacturing establishments, have organized as "The Erie Electrical Club," for the purpose of studying the principles and phenomena of electricity. We have engaged Prof. J. Brownell Rogers, of the High School faculty, to deliver a course of 12 lectures on electricity. We meet each Thursday evening in Prof. Rogers' laboratory at the High School where we have all the advantages of apparatus and the use of the Edison incandescent circuit for experiment.

Member.

Erie, Pa., Feb. 13, 1892.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED FEBRUARY 9, 1892.

Alarms and Signals:—

Repeater for Electric Circuits, M. G. Crane and F. W. Cole, 468,473. Filed July 2, 1889.

A repeater for use in connection with fire alarm signals and the like.

Resetting Device for Annunciators, R. A. Schoenberg, 468,697. Filed July 31, 1891.

A pneumatic reset for electric annunciators (see The Electrical Engineer, Feb. 10).

Conductors, Conduits and Insulators:—

Elevated Electric Conduit, C. O. Newton, 468,388. Filed Dec. 18, 1889.

An elevated support or conduit for a large number of wires or cables, capable of ready access but secure against unauthorized interference.

Electric Cable, W. Vogler, 468,585. Filed March 7, 1891.

A cable having an insulated central core and a return circuit consisting of several surrounding wires held in position by a series of fibrous threads.

Insulating Coupling, L. McCarthy, 468,772. Filed Oct. 19, 1891.

An insulated pipe joint.

Insulating Coupling, L. McCarthy, 468,773. Filed Oct. 19, 1891.

Similar to No. 468,772.

Distribution:—

Electric Lighting System, S. L. Trippe, 468,487. Filed Feb. 25, 1891.

Claim 1 follows:

The combination, with an electric generator and a series of two or more circuits, of a switch and transformer and an electromagnet both interposed between the generator and the circuits.

System for Operating Glow Lamps by Means of Multiphase Currents, J. F. H. Görges, 468,500. Filed Sept. 3, 1891.

Consists of a number of rotation current conductors corresponding to the number of phases of the current, and a number of current introducers to each lamp equal to the number of said conductors.

Electric Governor, J. T. O'Brien, 468,686. Filed Feb. 9, 1891.

Consists in the combination of a curved solenoid and armature, a series of contacts, a circuit closer and opener operated by the said armature, a series of resistance coils and electromagnetic cut-outs.

Dynamos and Motors:—

Dynamo-Electric Machine, G. E. Dorman, 468,416. Filed Dec. 17, 1890.

Relates to improved method of connecting commutator strips.

Ring Armature, J. G. Pool, 468,690. Filed Sept. 7, 1891.

An improved form of closed circuit ring armature for multipolar dynamos and motors.

Electric Motor, J. T. Wilson, 468,716. Filed Aug. 6, 1891.

An electric motor in which continuous rotary motion is converted into effective reciprocating motion.

Heating:—

Electrically Heated Smoothing Cylinder, W. Mitchell, 468,426. Filed May 26, 1891.

An electric ironing apparatus.

Lamps and Appurtenances:—

Carbon Holder for Arc Lamps, S. P. Parmly, 468,411. Filed Sept. 30, 1890.

A double carbon holder provided with a swivel joint and a clamp for simultaneously grasping both carbons.

Arc Light Globe Holder, C. A. Pfluger, 468,412. Filed Apr. 6, 1891.

A combined globe holder and dust guard for arc lamps.

Arc Light Hanger for Inside Use, C. A. Pfluger, 468,413. Filed May 15, 1891.

An arrangement for conveniently raising and lowering an arc lamp.

Electric Arc Lamp, A. G. Waterhouse, 468,711. Filed Aug. 21, 1891.

Consists of a novel arrangement of the automatic cut-out devices for arc lamps.

Miscellaneous:—

Magnetic Toy, G. A. Goodson, 468,338. Filed Apr. 6, 1891.

Electric Alarm Clock, W. S. Burroughs, 468,414. Filed Mar. 25, 1890.

Magneto-Electric Machine, J. Hunt, 468,451. Filed Apr. 24, 1891.

Relates to improved means of generating a single impulse of electric energy and sending it over a circuit, for use in blasting, etc.

Lightning Arrester, E. Thomson, 468,497. Filed May 5, 1890.

Consists of a series of conducting particles supported in a form of plastic insulating material and arranged so as to form a succession of small disruptive spaces in the path of the discharge.

Electrical Indicator, M. A. Deuel, 468,597. Filed July 3, 1890.

A magnetic indicator for showing the condition of telegraph lines.

Magnetic Separator, E. Ferraris, 468,599. Filed Mar. 13, 1891.

Consists of a wheel carrying a number of electromagnets on its periphery connected with one another and with a commutator at right angles to the axis of the wheel, and a rim of magnetic metal on which the ore is carried and separated by the change of current.

Electric Connector, G. Gibbs, 468,654. Filed Nov. 23, 1891.

A connector for use between the different cars of a railway train.

Magnetic Extractor, H. W. Southworth, 468,706. Filed Mar. 11, 1891.

A magnetic separator for removing particles of iron and steel from paper pulp.

Rheostat, A. J. Shaw, 468,752. Filed Oct. 15, 1891.

An arrangement for varying the degree of resistance of a rheostat quickly, uniformly and certainly without danger of injurious heating.

Apparatus for Stopping Engines or other Motors, J. P. Tirrell, 468,753. Filed May 11, 1891.

A power-controlling device for steam railways and an electrically controlled detent by means of which the aforesaid device may be prevented from operating.

Railways and Appliances:—

Trolley-Wire Support, J. P. B. Fiske, 468,336. Filed July 30, 1891.

Claim 1 follows:

A trolley wire support comprising a hanger extending along the top of the wire and a sheet metal clip extending below the wire, and clamped to the hanger at its ends.

Electric-Motor Truck, F. O. Blackwell, 468,492. Filed Sept. 16, 1889.

Relates to special means of mounting and supporting the motor upon the truck.

Motor-Gearing for Electric Cars, E. B. Phillips, 468,526. Filed Jan 6, 1891.

Relates to means of balancing the stress of transmission in a motor the axis of whose armature is coincident with the axle of the truck.

Electric-Railway Spstem, W. J. Ogden, 468,575. Filed Nov. 20, 1891.

A single centrally located conductor supplying current to cars running on both tracks of a double-track road.

Electric Railway, C. W. Thomas, 468,708. Filed Oct. 21, 1890.

A trolley having two contact sheaves journaled in a single rocking frame.

Switches and Cut-Outs:—

Combined Switch and Switch-Box, A. L. Rohrer, 468,474. Filed Dec. 2, 1890.

Has specially constructed joints by means of which the switch is made water-tight and at the same time can be readily actuated from without.

Telegraphs:—

Telegraphy, W. F. Wentz, 468,755. Filed Feb. 14, 1891.

Means for reducing the current in the main line, and apparatus for throwing said means into operation upon the opening of the main circuit.

ELECTRICAL WORK AT DU BOIS, PA.

Great activity has been shown of late in electric light and power enterprises in Du Bois, Pa. The Du Bois Traction Passenger Railway Co. has placed itself very rapidly on an excellent basis, thanks to the efficient management of Mr. C. E. Bostwick. Its plant is at present operating three cars which run through the principal streets of the town. The building is a large frame structure 145 by 30 feet. The station equipment at present consists of one 60 kilowatt Edison generator belted direct to a 125 h. p. Ball engine, steam being supplied from a 125 h. p. boiler. The company contemplates increasing the capacity of its plant in a short time on account of its intention to extend the road through other streets of the city, besides running to Falls Creek, a town rapidly developing two miles distant.

Moreover, the Citizens' Electric Light and Power Co. is to be affiliated with the Traction Co., and in the early Spring a fine lighting plant is to be installed of both the arc and the incandescent system.

FRANKFURTER ACCUMULATOREN-WERKE, C. POLLAK & CO.

This company has just been organized at Frankfurt, a. M., Germany, for the manufacture of accumulators, safety mining lamps and other electrical apparatus invented by Mr. Charles Pollak. These cells, which have been declared by the French courts and by experts to be independent of the Faure patents, are claimed to exceed in efficiency and life the usual form of cells. Mr. Charles Pollak is the general manager of the company.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

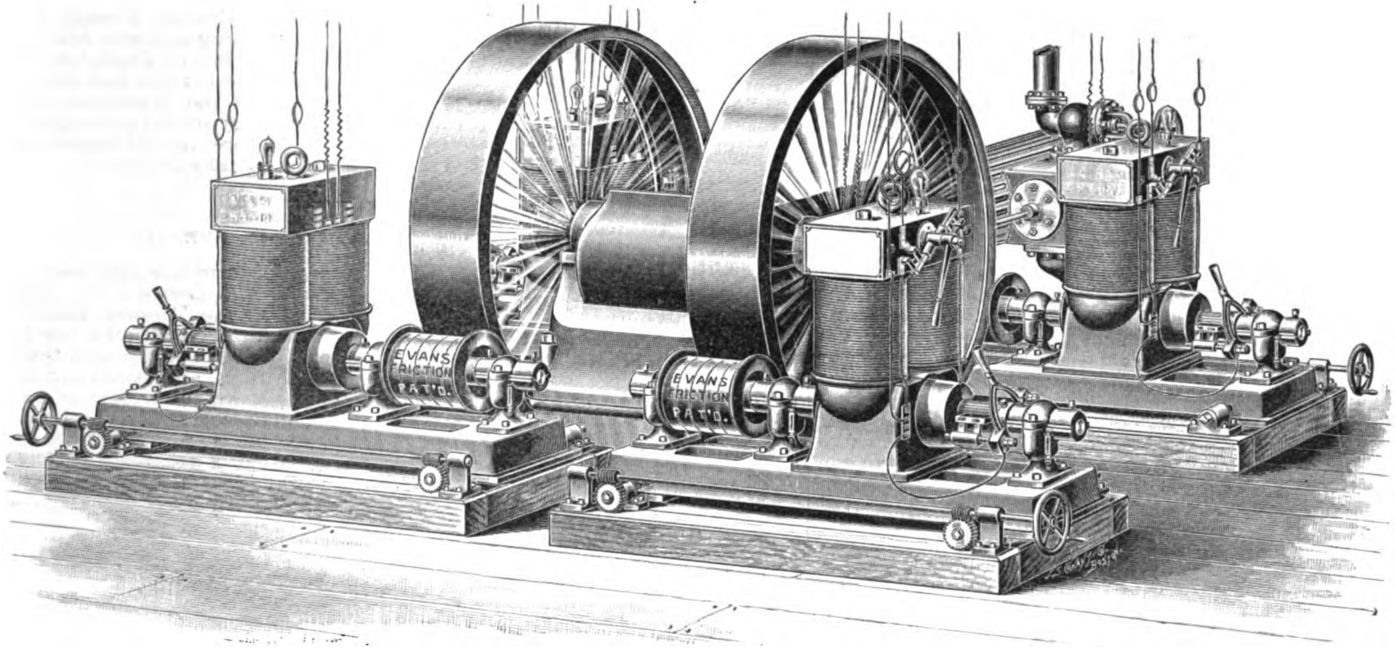
In a good technical journal, the Convention is always going on.

THE CONSOLIDATED ELECTRIC STORAGE CO. SAFETY LAMP.

A portable lamp is manufactured by the above company for the National Transit Co. The case is of quartered oak, 6½ inches high, and 4½ x 2¾ inches in width and depth respectively, and contains the storage battery which may be charged either from a primary battery or direct current. The lamp is of one candle-power, and is hung on springs in the focus of a silver-plated reflector set in front of the case and covered by a bulls'-eye of plate glass. The lamp will burn for six consecutive hours at full candle-power, and the reflector increases the illuminating effect nearly fourfold.

AN EVANS FRICTION CONE DYNAMO PLANT.

We illustrate herewith a plant recently put into the Weeks Building, Boston, Mass., which shows very strikingly the economy in space, and convenience in operation, afforded by the Evans friction cone system of driving, while allowing the use of any dynamo separately. The engraving is so plain as to require little descriptive text. The plant comprises four Edison dynamos driven by the Evans system, in connection with a 200 h. p. McIntosh & Seymour engine.



An Evans Friction Cone Dynamo Plant.

THE EMERSON ELECTRIC MFG. CO.

The first annual catalogue of the Emerson Electric Mfg. Co., illustrating and describing the various specialties of their manufacture, has reached us. Many of the articles shown are entirely new and cannot fail to prove of interest to all users of electrical apparatus. The catalogue has, by way of frontispiece, two excellent half-tone engravings of switchboard installations, while the customary elephant adorns the cover.

THE C. & C. MOTOR COMPANY.

The above company were awarded the contract recently for equipping the large manufacturing building recently erected by J. H. E. Waters, in Denver, with light and motive outfits.

The building is 200 feet square, and at the start will contain a 250 lt. dynamo and a 100 h. p. generator, from which will be operated at once 10 motors of 5 h. p. each, and two of 10 h. p. each.

This will constitute the first large manufacturing plant in Denver.

WRIGHT & STARR ELECTRIC CO.

In the advertisement of the Wright & Starr Electric Company in our issue of February 10, in the sixth line from the top of page xiv, our type made them say that one of the advantages of their system was that "Where the station may be temporarily though totally destroyed it is not necessary to stop travel." By changing the word "destroyed" to "disabled," the true meaning is apparent.

ELECTRIC POWER FOR THE ST. PAUL ROLLER MILL.

Kingsland, Smith & Co., of St. Paul, Minn. write The Electrical Engineer, with regard to the use of electric power in the St. Paul Roller Mill, that they propose to use from 80 to 100 h. p. in all. They expect to use one motor for the rollers, one for the wheat cleaning machinery and one for the bolting and purifying machinery. They have not yet selected their motors.

CHAS. A. SCHIEREN & CO.

The manufacture of leather belting is one of the most important of American industries, not only on account of its magnitude but because its product is in such universal demand in all industries. As is well known the belt is a leading feature in electric light and electric railway work, and the requirements there are often considered to be about as exacting as possible. Leadership in such a field as the electrical is therefore no small thing, but it has been achieved by Chas. A. Schieren & Co., of Ferry street, New York, whose revised and enlarged catalogue, just out, lies before us. Their pure oak-tanned leather belting is in use in electrical plants all over the world, and has won troops of friends, under its name of "Electric" and "Patent Perforated Electric" belting. The new edition of the catalogue is profusely illustrated, and enters in a most instructive and interesting manner into the details of belt manufacture, as practised by this representative house. Readers of The Electrical Engineer will remember the recent able articles by Mr. Chas. A. Schieren on his observations abroad as to European belting, and on reading this pamphlet they will at once perceive how thoroughly the long experience indicated by the articles has entered into every detail of his own work. In addition to the illustrations and descriptions of belt manufacture, there is some valuable information as to methods of power transmission by belts—a section that any central station manager can study with advantage. The catalogue also contains a number of minor features and a telegraphic code.

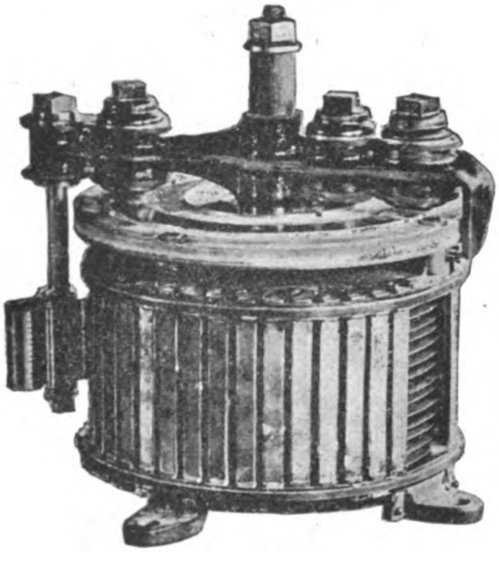
DETROIT ELECTRICAL WORKS.

The Detroit Electrical Works are making extensive preparations in their supply department for this season. A very large addition which they are building to their already extensive factory is evidence that they intend to keep pace with the electrical fraternity.

They are bringing out several new features in this department to be ready for the market in the course of three or four weeks.

NEW EDISON ELEVATOR CONTROLLER.

The Edison General Electric Company have recently designed and are bringing out a new controlling rheostat for use with electric motors running elevators, hoists, and in other places where the conditions require that the motor be started, stopped and reversed continually. The controller consists of a resistance box of special form, as shown in the engraving. By the movement of a lever, resistance can be gradually thrown in or out of the motor circuit as required, thus increasing or diminishing the speed of the motor. The lever also carries the contacts required for reversing the motor. This controller can be employed with either shunt or series wound motors, and possesses the great advantage of an arrangement whereby, before the motor can be reversed the whole resistance is thrown into the armature circuit. By this means the possibility of burning out the armature by too sudden reversal of the motor is prevented, and fluctuations in the voltage of the line wires, by too swift an accession of power, reduced to a minimum. The controller is constructed to carry continuous currents of 15 amperes with all the resistance in circuit, but currents up to 60 amperes can be passed through it, without injury, for a short time, when starting the motor. The contact lever can be worked by a handle or a pulley wheel, as conditions require. For elevator work, it is fitted with a pulley, around which passes the steel rope which, in the hands of the elevator man, controls the movement of the elevator.



New Edison Elevator Controller.

The resistance consists of a continuous series of sheet-iron convolutions with mica insulation between the convolutions, divided into sections, each of which is connected to a vertical brass bar arranged around the iron convolutions, so that a special contact shoe on the lever arm makes a perfect frictional and flexible contact with the brass bars. The lever operating this contact shoe works over a slate table fitted with brass rings for the main and armature connections. Carbon contacts are used on these rings. As iron, brass and mica are the principal materials used in the construction of the controller, it is able to withstand a very high degree of heat, without risk of destruction. A space 2 feet 2 inches and 1 foot 10 inches high is required for the controller.

This controller takes the place of the older motor rheostat, and its novelty of form and many advantages which it offers, should bring it into considerable requisition in places where the older and more cumbersome styles have hitherto been used, and should make it essential in all new installations of electric elevators or hoists.

THE SHORT GEARLESS MOTORS IN SNOW.

It appears to be a curious and interesting feature of the Short gearless motor that it will operate perfectly during snowstorms, maintaining the schedule time, where other motors fall rapidly behind. The only reasonable explanation of this is found in the fact that the weight of the motor is centered directly over the axle, so that maximum traction is attained. In support of this theory, it is noticed that the wheels of the gearless motor rarely or never slip even under the worst conditions of track. Another reason is probably found in the special controlling device used by the Short Co. which prevents a sudden rush of current through the motors, which frequently starts the wheels to slipping and prevents them from taking a good grip on the rail. That this latter explanation has some weight, is proven by the fact that the Short double reduction motors have operated during the past month under conditions of track and weather where other motors of the same type have completely failed. In Braddock, Pa., two 15 h. p. Short double reduction motors are operating cars on 12 and 13% grades during heavy snow and sleet storms, and without missing a single trip. The other road in the town, operating also with double reduction motors, was tied up.

In Cleveland, two Short motors carried a car through 4 or 5 inches of unbroken snow, over a disused switch and started up without difficulty under the same conditions. The gearless cars in Cleveland are the only ones which can keep on time, and the same is true of the long double truck gearless motor car which has now been running for nearly three months in St. Louis, Mo.

In Jamestown, N. Y., the Short double reduction motors have operated right through the heavy snowstorms over a succession of grades varying from 6 to 10% with sharp curves, and the railway people are surprised and delighted at their performance.

CROCKER-WHEELER MOTORS IN ENGLAND.

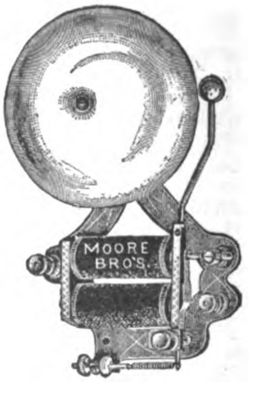
The Crocker-Wheeler Electric Company, New York, has just shown a full line of motors, fan and pumping outfits, automatic switches, etc., at the Crystal Palace Exposition through their agents, the General Electric Company, Ltd., of London, and have come off with flying colors. The General Electric Company now have in writing from Messrs. Crompton & Co., makers of the excellent English dynamos and motors, that their various attempts at making small motors have been failures when compared with the machines put upon the market by the Crocker-Wheeler Electric Company. They have also made arrangements with the General Electric Company to publish a list of Crompton and Crocker-Wheeler motors. One part of the list will deal entirely with the Crocker-Wheeler motors and on the frontispiece they state that they have taken up their sale by special arrangement with the General Electric Company, who are the sole representatives of the Crocker-Wheeler Electric Company in London.

ELECTRIC CONSOLIDATION ABROAD.

Under the firm of Union Electric Co. there has just been organized in Berlin a company consisting of L. Loewe & Co., Thyssen & Co., Mulheim-on-the-Rhine; and the Thomson-Houston International Electric Co., of Boston. The new concern has acquired all the patents and rights of the Thomson-Houston International Electric Co. for Germany, Austria and Northern and Eastern Europe. The company does not intend to erect its own factories, but will have its entire manufacturing done by Loewe & Co. The capital stock of the new company is 1,500,000 marks, equally distributed between the three contracting parties. The company will devote special attention to the introduction of Thomson-Houston apparatus, both for lighting and power purposes.

THE MOORE ELECTRIC BELL.

The Moore Electrical Manufacturing Company, of 652 Hudson street, New York, are introducing a special type of electric bell of which our illustration is a good representation. This bell is an exceedingly sensitive one, fitted as it is with a pivoted armature it is possible to produce a positive vibration of a large bell having a 10-inch gong with the current of one cell of Leclanche battery. The bells are made up to a gong of 20 inches diameter and are so constructed that they will work on either an arc or incandescent circuit if desired. This company issue a neat descriptive catalogue illustrating the specialties manufactured by them.



The Moore Electric Bell.

THE COWLES WATER-TUBE BOILER.

Recent progress in engine design for large stationary power plants calls for double the steam pressure now ordinarily in use and creates an absolute necessity for some well-designed form of water-tube boiler which will meet the very trying conditions presented. Both ashore and afloat the engine-room is now far in advance of the fire-room. We have excellent triple and quadruple engines in regular commercial use calling for 160 to 200 lbs. of steam and the efforts to furnish the steam for these machines with the old types of boiler are very far from satisfactory. The tendency now is to duplicate the modern steamship plant in the large electric lighting and traction stations of the country, and to do this it becomes more and more necessary, as the pressures increase, to use water-tube boilers.

The Cowles water-tube boiler represents, perhaps, the latest successful attempts to meet this increasing demand for progress in the safe and economical generation of steam for high pressures.

The accompanying engravings show plainly the design and construction of this boiler. Special attention has been paid to strength and safety and to a perfect circulation, not only of the water and steam in the boiler, but of the gases passing around the tubes. The very important question of accessibility for cleaning, inspection and repairs has also been given thorough attention. For stationary work the boiler is enclosed in masonry, and for marine or portable work it is jacketed throughout with a steel shell casing lined with a non-conductor and fire tile supported by the tubes. The boilers are built in several sizes ranging from units of 500 h. p. and three inch tubes, for large shore plants and steamship work, down to 25 h. p. and 1½-inch tubes for light work, such as yachts, and for portable use. The tubes are of the best boiler tube manufacture, bent cold to easy curves in a special machine and expanded in; the shells are of the best mild steel, and the heads and manhole plates are of hydraulic-pressed steel. The heavy pipe and malleable fittings are so designed and arranged that they are in no part exposed to the fire or heated gases. The tubes can be thoroughly swept outside and cleaned by a flexible scraper or brush inside. Any tube can be plugged, or entirely removed and replaced without injury to another tube, and access for this work can be had entirely through the uptake, furnace doors and manholes.

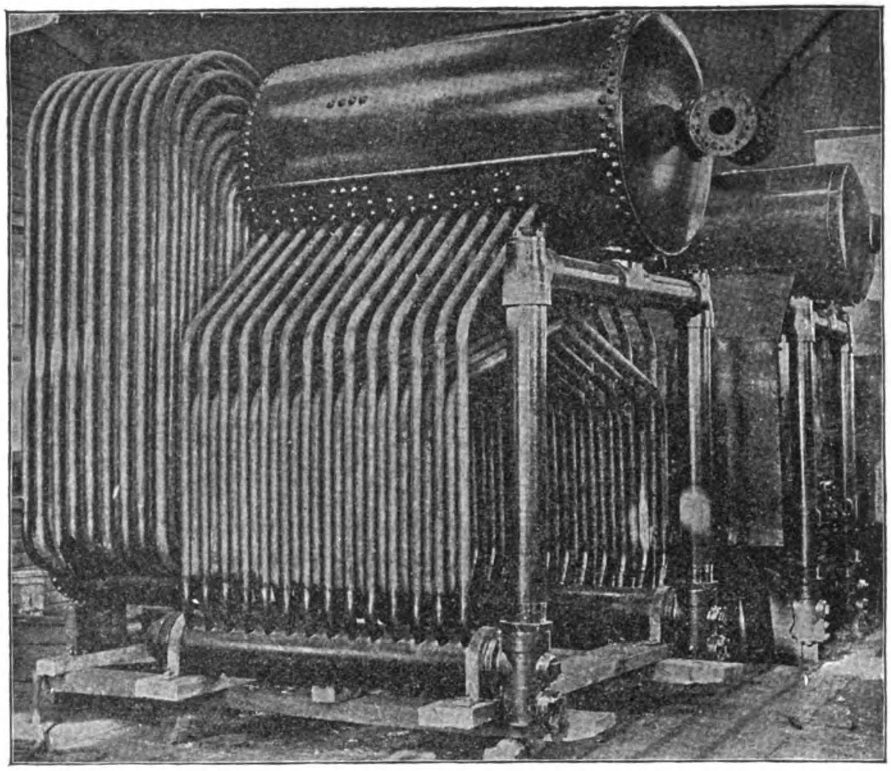


Fig. 1.—The Cowles Water-Tube Boiler.

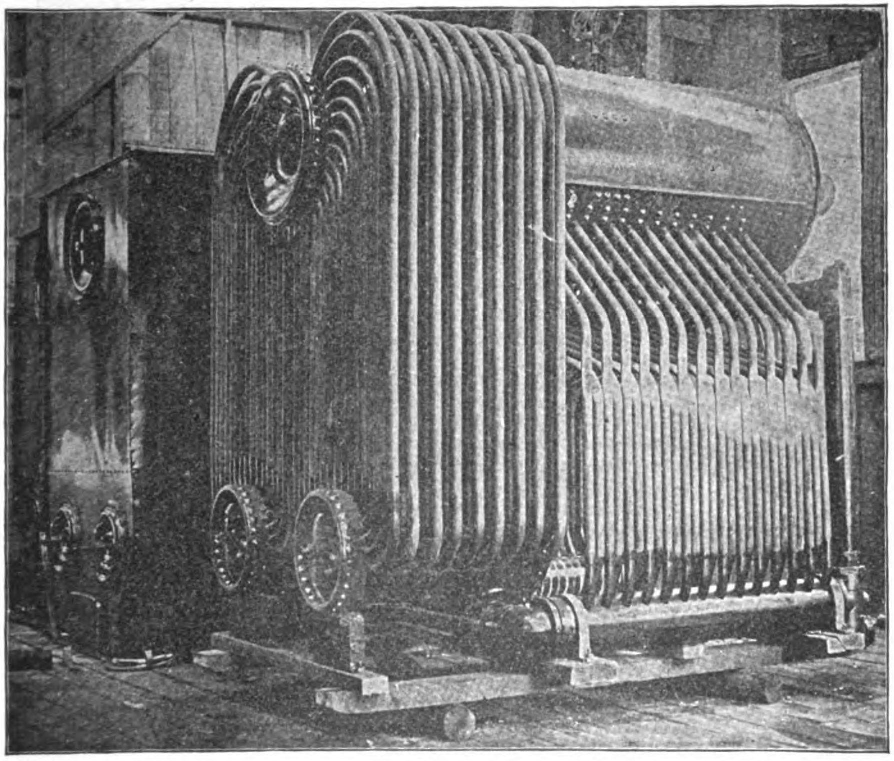

Fig. 2.—The Cowles Water-Tube Boiler.

The Cowles Engineering Co. (foot of 43d street, Brooklyn, N.Y.), claim that it is impossible to injure the boiler by unequal expansion or overheating, and that it is far safer with a working pressure of 200 lbs. than the old style of shell boiler with its 100 lbs. pressure.

CROCKER-WHEELER ELECTRIC CO.

Although there is to be no regular exhibition at the Buffalo Electric Light Convention, the Crocker-Wheeler Electric Company will have a number of motors set up and running at the office of their Buffalo agents, Messrs F. P. Little & Company, adjoining the Broezel House. Messrs. Otis Bros. will also have one of their celebrated pumps operated by a ½ h. p. C. W. perfected motor, and their latest Crocker-Wheeler automatic switch.

ELECTRIC HEATERS ON THE OMAHA STREET RAILWAY.

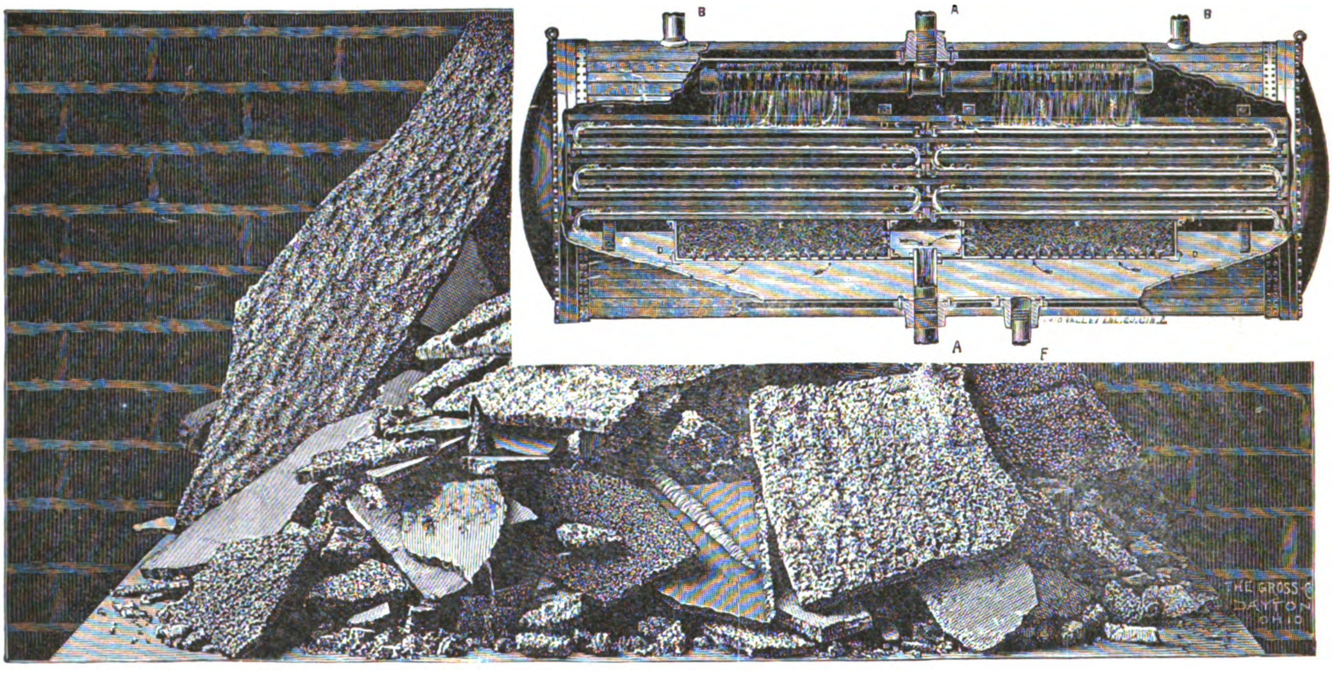
We have recently received some interesting figures in regard to the use of electric heaters on the electric cars of the Omaha Street Railway Co. It appears that per set of 4 Burton heaters to the car, 2 h. p. is required in the shape of current, or 4 lbs. of coal per h. p. hour, or 144 lbs. of coal per day of 18 hours. Coal costs the company $1.75 per ton, making 1 lb. cost .00087 dollar, or 144 lbs. cost .12528 or 12¾ cents per car per day. The company's experience with coal stoves has been that they cost them 25 cents a day.

Mr. Robert C. Hull, formerly of the Thomson-Houston Works, at Lynn, has accepted a position in the engineering department of the Thomson-Houston Electric Light Company, at Philadelphia.

STILWELL'S PATENT LIVE STEAM FEED WATER PURIFIER.

In many instances it is for various reasons impracticable to use an exhaust steam heater, and to meet emergencies, the horizontal live steam purifier, shown in the accompanying illustration, was expressly designed by the Stilwell & Bierce Manufacturing Co., Dayton, O. In mode of operation it is similar to the upright live steam purifier, but its mechanical construction is quite different.

As will be observed, it is a horizontal cylinder, made of best steel boiler plate, and may be placed in any convenient locality above the boilers to be supplied and with which it is directly connected. The cold water, or water from exhaust heater, is introduced at A through a pipe connected by a tee with a horizontal pipe inside the shell. Both ends of this horizontal pipe are perforated with many small openings, through which the water escapes in the form of a shower. Live steam is admitted at B B, filling the purifier with steam at boiler pressure. The water falls from the induction pipe through a body of steam into the top of two series of shallow iron pans, each pan being one-half the length of the purifier shell. These pans are provided with openings in the bottom at alternate ends, and the water is compelled to traverse their entire area in a thin sheet. As the heat and pressure in the purifier is the same as in the boilers, the water, in its passage over these pans, is subjected to the same chemical change as in ordinary boilers, and is relieved of all scale-producing impurities, which are precipitated upon the surface of these pans from which they can be quickly and easily removed. After passing the circuit of the pans, the water drops into the large settling chamber D D, in the bottom of the purifier, where the non-crystalized impurities deposit in the form of slush or mud, and are blown off at frequent intervals through the blow-off F. To complete the work of purification, the water passes through the filtering chambers E E which are filled with coke or other suitable material, into the pure water chamber, and thence into the boiler through pipe A.



Stilwell Purifier and Impurities Retained by It at Dayton, O.

It is claimed that the feed water is then absolutely pure, and at substantially the same temperature as the water in the boiler, thus effectually preventing the deposit of sediment in the boiler, and the strain upon it incident to the introduction of water at a low temperature.

Each end of the purifier is provided with a heavy head fastened in place with cap screws. The depositing pans slide on ways which are fastened to the shell and can easily be removed through either end of the shell for cleaning, and any impurities which may attach to the bottom of the purifier shell can readily be raked out, as removing the head exposes the entire inner structure.

A forcible reminder of what impurities are contained in ordinary feed-water for boilers is afforded by the engraving of a heap of lime deposits retained in a Stilwell live steam purifier in use on the boilers at the City Water Works, Dayton, Ohio.

Mr. H. T. Bierwirth, city electrician at Lincoln, Neb., has resigned to accept a similar position at Omaha.

COBB, DANBY & KNOTT; CHANGE OF FIRM NAME.

The resignation of Mr. Danby from the firm of Cobb, Danby & Knott has necessitated the changing of the firm name. The new style will be Cobb, Smith & Knott, Mr. Eugene M. Smith having taken a place in the firm. This gives the company a complete electrical and mechanical force.

Cobb, Smith & Knott have been awarded the contract for furnishing the entire electrical outfit for the Edison Illuminating Co., of Coney Island. Mr. Cobb has been appointed consulting electrical engineer and Mr. Knott consulting superintendent of construction. The plant to be installed is to consist of a Wood system 200 arc light machine and a 4,000 incandescent light Edison plant.

THE GRAPHITE LUBRICATING COMPANY.

The Graphite Lubricating Company, of Bound Brook, N. J., have completed a desirable and well-equipped factory in this thriving town of Central New Jersey. With their increased facilities they are now in a position to accept and turn out on shortest notice, all business in their particular line with which they are entrusted. They are in receipt of large orders for their dry Graphite lubricating trolley wheels for electric cars. A special feature in their new trolley wheels is the invention of Mr. Bache, superintendent of the factory, and consists of a specially cast hub into which the grooved bushings are placed. The hub is cast with a chamber surrounding the bushing. In this space is placed powdered graphite which feeds through very small holes directly onto the shaft, keeping an automatic feed of dry lubricant on the shaft at all times.

The company have their own well-appointed brass foundry where all castings for their special work are made. They are at present turning out a large number of specially constructed bearings for street car motor armatures with special graphite feeders. These bushings are used entirely by the Detroit Electrical Works and are giving excellent satisfaction. The shafting of the entire factory runs in the graphite lubricating bushings and, in some cases, has been running continually since the 1st of July, 1891, without change or the use of a particle of lubricating oil.

A LAVA SHIELD FOR ARC LIGHT CARBONS.

Mr. D. M. Steward, of the D. M. Steward Manufacturing Company, of Chattanooga, Tenn., is now on a trip North, and while in this city recently showed us among other interesting pieces of lava insulation, an arc light carbon shield. It had been in use continuously upon a carbon for thirty hours, and during part of that time may be said to have been actually around the upper portion of the arc. It was fractured on being taken out, but appeared likely otherwise to last for an indefinite period. With such wonderful material as this lava as a shield single carbon lamps ought, to put it paradoxically, to burn longer than the double.

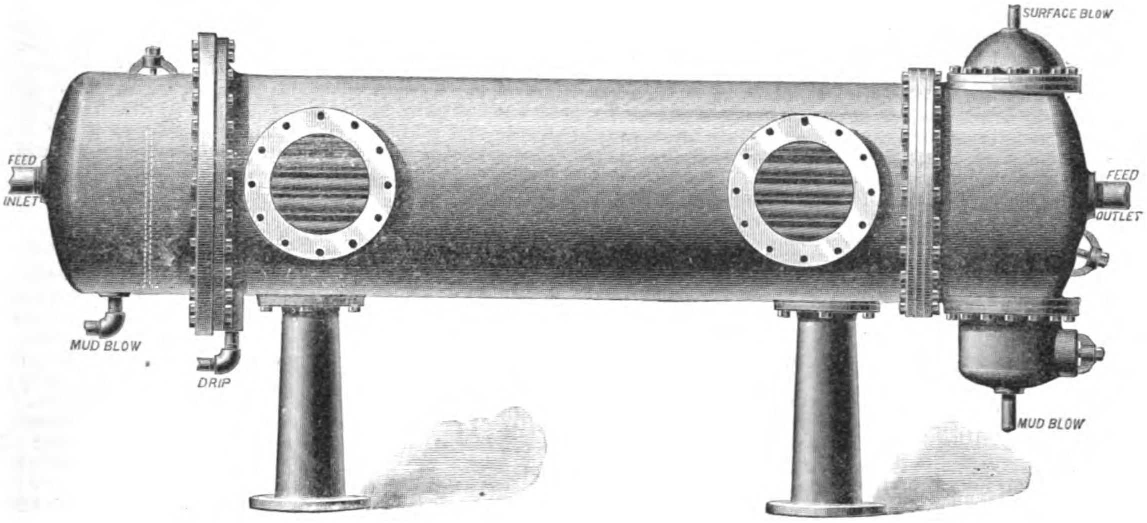
THE GOUBERT HORIZONTAL FEED-WATER HEATER.

The Goubert Manufacturing Company, of 32 Cortlandt street, have lately introduced a new horizontal feed-water heater, shown in the accompanying illustration. It is designed to meet the difficulty of insufficient head room often encountered where the cellars of city buildings have to be utilized for the location of the steam plant.

This horizontal heater is also specially adapted for use in connection with condensing engines, as the steam nozzles can be placed in any position required; the inlet nozzles may be directly under the engine exhaust and the outlet nozzle bolted to the top of the condenser. This arrangement practically taking the place of the exhaust pipe, making a very neat connection.

The heater is shown on the engraving as resting on a pair of columns, but it may be provided instead with lugs or bolts, or straps, to be hung from the ceiling; or it may be supported by beams or saddles.

The manufacturers have preserved in the horizontal heater all the advantages of construction that have made their regular vertical heater so successful.



The Goubert Horizontal Feed Water Heater.

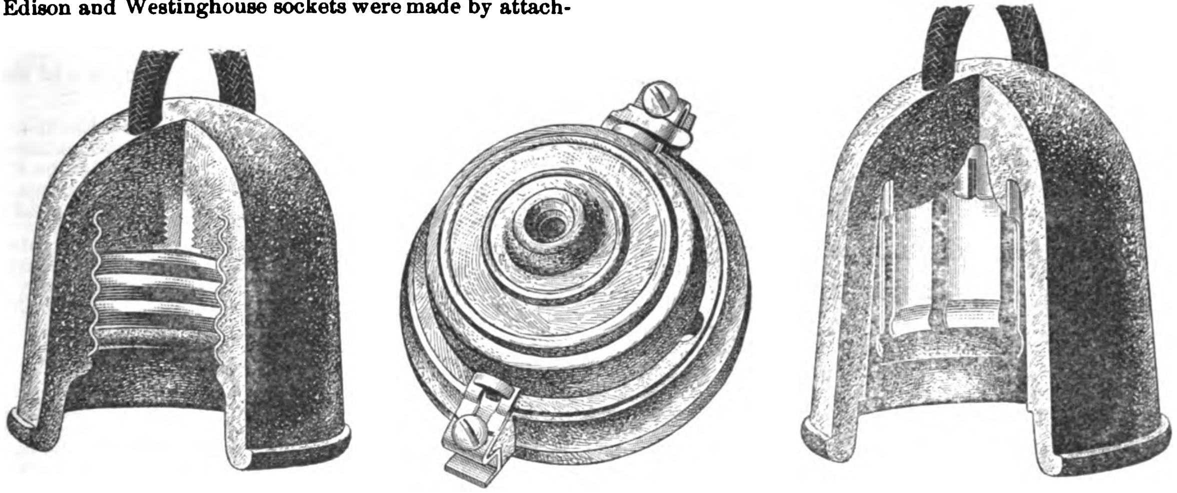
GOULD & WATSON SOCKETS.

The Gould & Watson Co., of 35 Hartford St., Boston, have just completed improvements in their keyless waterproof sockets. Formerly Edison and Westinghouse sockets were made by attaching extensions to the Thomson-Houston socket, which did not produce a waterproof article, although otherwise satisfactory. The success in the Thomson-Houston sockets has led this firm to bring out an Edison and a Westinghouse socket, which are so constructed that, by the introduction of a rubber washer, lamps may be burned under water with perfect safety. This is an interesting improvement, and one which is likely to meet with general approval. The sockets as now made are compact, and the brass parts are moulded entirely within the socket.

The wires are also changed in their mode of attachment so that there is considerable space between them, and this prevents the gathering of moisture and rotting of the wire at the point of entrance into the socket. All these points will be readily appreciated, and the attention of visitors to the Electric Light Convention is called to the exhibit of these goods, and also to the Smith rosettes manufactured by this firm.

In the accompanying illustrations, Fig. 1 shows the Edison, and Fig. 2, the Westinghouse socket, both of which are designed to carry shade holders. Fig. 3 shows the Smith rosette, the price of which has been reduced so that they are claimed to compare favorably with any rosette in the market. The wiping joint at the point of attachment is also of valuable consideration.

Mr. Edward P. Sharp will be in attendance at the Convention, and will be pleased to show samples of these goods, and explain their features.



Figs. 1, 2 and 3.—The Gould & Watson Waterproof Sockets and Rosette.

THE SAMSON CORDAGE WORKS.

The Samson Cordage Works of Boston are building some new braiders for the manufacture of the Samson arc light cord, as the demand for this article has been greater than their capacity to supply. The new machines are of somewhat different pattern from the old ones and are considered quite an improvement. This cord is made from the very best cotton stock, free from waste, and its tensile strength has been shown by careful tests to be very high. Its durability is considerably increased by the waterproof finish which the manufacturers apply at a slight additional expense, and it is much the most desirable cord for hanging arc lamps, as well as for trolley cord and magnet cord. The manufacturers are glad to send samples of the various sizes, and full catalogue with discounts.

Mr. John Earles, manager of the Kaukauna, Wis., Electric Light Company is to sever his connection with the company at the end of this month.

THE KNUDSON CUTTRISS WIRE CO., "LIMITED."

THE above company has been organized under the laws of the State of New York. It is the owner of patents granted to A. A. Knudson and Charles Cuttriss for a new insulated *fibre* wire. The points in its favor over other wires of this class are claimed to be as follows:

1st. A new and simple method of applying the cotton in its raw state, thereby saving the difference between the price of the raw, and the yarn, at the start, and, also the difference in the time and labor; as one process only is needed, against several of braiding in order to get the required amount of cotton on the wire.

2d. An insulating material which, while being cheaper than the most that is used on the ordinary so-called weatherproof wires, tests very high. Samples which have remained under water from three to six weeks show a resistance from 100 to 200 meghoms per mile.

The cost of manufacture, therefore of this wire will be less than that of other fibre covered wires, it is claimed, while its excellent insulating qualities should commend it to the trade. Other features of excellence are low inductive capacity, non-abrasion, and resistance to atmospheric changes. A cheap and excellent cable for telegraph, telephone and other uses can, it is said, be made with this process. Any information regarding rights to manufacture under the patents controlled by this company can be obtained by addressing Mr. John F. Zebley, president, Rooms 37-38 Drexel Building, New York.

THE WASHBURN-MOEN COMPANY.

A RECENT special feature at the factories of the Washburn-Moen Company, Worcester, Mass., has been the putting in of a special plant for the insulating of all sizes and grades of wire. This department is now in full working shape and the company are prepared to accept and fill all orders promptly.

THE ENGINEERING EQUIPMENT CO.

AMONG the more important February announcements is that of the contract made between the Engineering Equipment Co. of New York and the Gould & Watson Company of Boston. The former have become, under exclusive privileges, the sole sales agency in the East for "G. & W." line materials. Purchasers of these materials will find the Engineering Equipment Co. prepared to give manufacturers' terms, as on the other lines they handle, and to fill orders from stock without delay. New designs, added to standard styles now selling largely, offer to roads and contractors an attractive variety of materials of this well-known make and samples are now shown which none interested should fail to see. Mr. W. F. D. Crane, M. E., has charge of this department at the Engineering Equipment Co.'s New York offices, 143 Liberty street; and at 126 Pearl street, Boston, Mr. F. A. Magee, M. E., represents the company on all their lines of electric railway materials.

"THE PENNSYLVANIA LAMP."

THE manufacturers of this lamp are convinced that they have an excellent article, and are now busily engaged in converting the rest of the community to the same belief. A description of the lamp, together with some results of a recent test, was given in the last issue of THE ELECTRICAL ENGINEER.

NEW YORK NOTES.

MR. H. C. WHITNEY, late of the Consolidated Electric Storage Company, and previously with the Crosby Electric Company, has just closed with the Union Electric Company of 45 Broadway, to represent them in this city. Mr. Whitney's experience in the battery business has been thorough and extensive, involving thousands of miles of travel for the companies with whom he has been connected, and incidentally giving him the advantage of a wide and intimate acquaintance with the trade. With the acknowledged future which awaits storage batteries in general and the special merits of the battery manufactured by the Union Electric Company, Mr. Whitney's success would seem to be assured.

THE completing of arrangements whereby the price of the Security insulator has been very much reduced and the manufacturing facilities increased, has had the effect of bringing in large orders. Mr. Brown, the manager of the company, is receiving some exceedingly congratulatory letters from those who have used the insulators. The offices are located in the Electrical Exchange Building, this city.

BALTIMORE NOTES.

MR. ELIAS E. RIES, president of the Ries Electric Specialty Company of Baltimore, Md., will make his headquarters at the Iroquois during the Convention, and an opportunity will be offered to the central station men, etc, to see the Ries regulating socket in operation, and to receive a full explanation and all details relating to the many advantages offered to the general electrical public by the Ries regulating socket for alternating current incandescent lamps. It would be well for every visitor to the Convention to look this exhibit up, so as to become familiar with the Ries regulating socket, as it is certainly destined to play an important part in the incandescent electric lighting system of the present and future

The Ries Electric Specialty Company will shortly increase their capital stock to $150,000. Some very valuable specialties have been lately acquired by this company, and in order to increase their facilities to meet the rapidly increasing demand for their goods, it was decided at the last meeting of the board of directors to issue stock to the above amount, of which $50,000 will be preferred and will bear interest at the rate of 6 per cent. Most of the new issue has been already subscribed for, and there is no doubt but that the balance will be speedily taken.

WESTERN NOTES.

THE ELECTRIC MERCHANDISE COMPANY, Chicago, has the past week filled an unusually large order for its own insulating tape. Being of an extra heavy weight and having unusual strength, it is found especially well adapted to street railway needs. Appearances at 11 Adams street, the head-quarters of the company, tell the tale of another season's advent, apparently a lively one. Large lots of all manner of electric railway supplies for use upon all the different systems are being added to its stock, placing the company in an enviable position for the opening of the spring business. Owing to the tendency of street roads to use heavier equipment, additional strength has been given to many of the devices furnished by this company with a view to furnishing, as heretofore, material first-class in every particular.

THE POND ENGINEERING CO., owing to the increase of business in their Chicago office, have found it necessary to move from the offices 427 and 429 the Rookery, which they have occupied for the last three years, and are now to be found in Room 8 the Rookery. This is one of the best offices in this well-known office building, and the Pond Engineering Co. are having it fitted in an elegant manner, with a view to the best accommodation of themselves and their patrons. Room 8 extends from the rotunda to the Rookery court; the front part will be devoted exclusively to office use, and the rear for drawing-room, shipping, etc. The many friends of the Pond Engineering Co. will doubtless be pleased to learn of their new move, and visit their new quarters.

MR. THOS. G. GRIER has published in pamphlet form a nice little set of tables for wiring for motor circuits. The first table is arranged to show the amperes per motor at certain efficiencies for various horse powers and voltages. A separate table shows the minimum size of wire for motor services and a final table designates the wiring for various losses, giving horse power, ampere capacity, safe-carrying capacity, diameter, gauge, number, etc., and full particulars for determining any size of wire for any required motor circuit.

MR. WILLARD W. LOW, president of the Electric Appliance Company, has just returned from an extensive business trip, and reports that while he finds business rather quiet, he did not let a single day go by without sending in something substantial in the way of an order, and had on the whole a very successful trip.

THE STEARNS MANUFACTURING CO., of Erie, Pa., are installing two "Woodbury" engines of 75 h. p. each for running the electric lights in the B. & O. depot at Pittsburgh. They also put in two 100 h. p. engines at the Brighton Hotel, Atlantic City, electric light plant.

SOUTHERN NOTES.

DALLAS, TEX.—Mr. Chas. Q. Harris, so long known in the Southern electrical field as a consulting and contracting electrical engineer is again actively engaged in business. He will represent the National Elec. Mfg. Co.; the Consolidated Elec. Mfg. Co.; the Electric Merchandise Co.; Holmes, Booth & Haydens; Geo. Cutter; Peru Glass & Carbon Co.; the Electric Gas Lighting Co.; the Ernest L. Clark Co. and others.

THE
Electrical Engineer.

VOL. XIII. MARCH 2, 1892. No. 200.

ALTERNATE CURRENT MOTORS.[1]

BY WM. STANLEY, JR.

It is not my purpose in the present paper to enter minutely into the details of the various attempts that inventors have made to produce an operative motor. As far as I know, the first work on alternate current motors in this country was undertaken at Great Barrington, 1886 and 1887, when I designed and built a synchronous motor, and a motor acting under the repulsive currents obtained by periodically short circuiting armature coils, while they were under the induction from the field. One of these motors was designed in January, 1886. Professor Thomson, in 1887 and 1888, also produced motors of this type, and, what was of still more importance, he read a paper before the American Institute of Electrical Engineers memorable for the clearness with which he treated the subject.

The various plans suggested by inventors and by engineers may be classified into three types, they are: First, motors operating in synchronism with the current alternations, having a field magnetization, produced by continuous currents with alternate currents applied to the armature circuits, a type originally demonstrated by Hopkinson in 1883; second, motors actuated by the inductive effects of a rotating field upon closed armature circuits, first suggested by Mr. Tesla in 1887; and, third, motors operated by alternate currents, in both field and armature, constituting one of the types investigated by Mr. Kelly and myself.

While many inventors were eagerly following their various lines of investigation for the purpose of producing an operative motor, Mr. Tesla had quietly worked out a new solution of the problem on an entirely novel basis, by inventing the rotating field, that is, the field produced by shifting magnetism, and producing it by alternate currents. Mr. Tesla's motor is so simple and so beautiful in theory that many have doubtless wondered why it has not been brought into general use. If I correctly understand the subject, it has not been commercially adopted because of the difficulties in operating it at the frequency generally in use in this country, viz., 130 ∼ p. s., and especially because thus far special generators and circuits having phase differing currents must be employed; there have been attempts to subdivide alternating currents into two or more currents differing in phase. Special arrangements of condensers for producing phase differences from a single source of supply have been worked out by M. Leblanc, in France, and by Mr. Kelly in this country. As regards the motor itself, there are two drawbacks to its use which have not thus far been entirely removed; they result from the inductive effects of the currents upon themselves and upon each other.

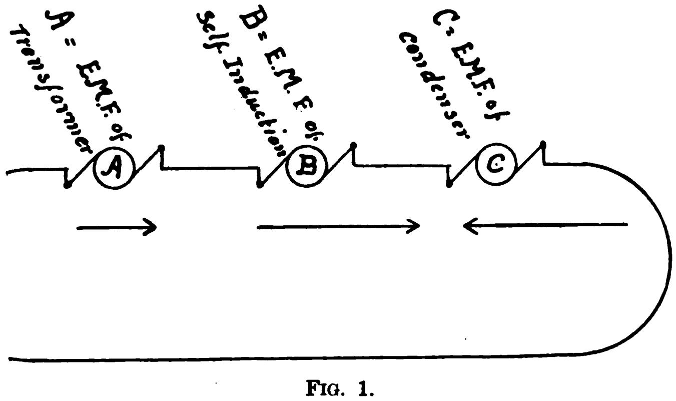

FIG. 1.

Mr. Kelly and I have invented what we call a "condenser motor," which differs radically from either of the above mentioned types. The problem which we have had in mind was to construct a motor which should be operated by existing alternate currents in exactly the same manner that we operate an ordinary motor when supplied with continuous currents; to do this, it is necessary to construct a motor whose circuits do not possess (effective) self-induction, or, to put it in another way, it is necessary to take away from the alternate current circuits the effects of the E. M. F. induced in them by their own currents, which render unavailable a considerable part of the E. M. F. applied.

I will attempt to explain our shunt motor without the use of formulæ, illustrating the results obtained as best I can.

Our motor has a laminated sheet iron field, and may be made in any of the multipolar or bipolar types. The field winding is connected in series with a condenser to the secondary of a transformer, which, when fed from the station, furnishes the source of supply. The armature of the motor, although wound with a special winding, is substantially the same as a continuous current armature, and is surrounded by closed copper bands whose function I will describe later. The theory of the motor is, that, given the necessary magnetization and armature current, the motor will operate as well with alternate as with continuous currents. Returning to the field circuit, let us glance at the function of the condenser. If the field windings were connected directly to the transformer or source of supply we should have two E. M. F.'s in circuit, combining to oppose the E. M. F. applied by the transformer.

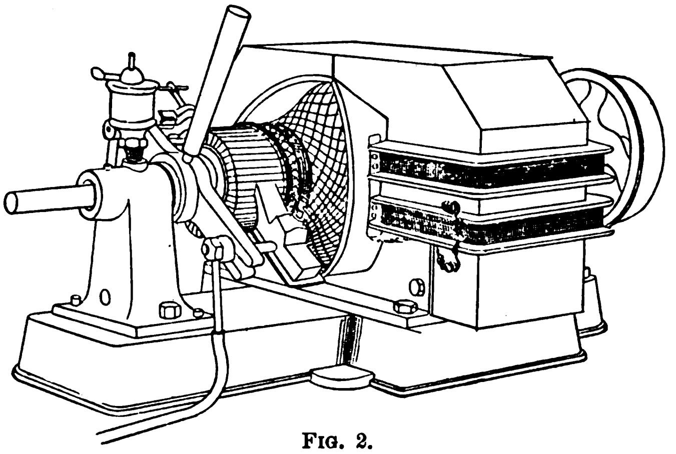

FIG. 2.

This may be made simple by considering the resultant effects produced by a number of alternators coupled in series, Fig. 1. Let A, B and C be these generators; let them be all rigidly coupled to the same shaft, A being set on the shaft so that its armature generates an E. M. F. 90 degrees away from that of B and C, while B and C are coupled to produce the same voltage at the same time and have their terminals opposed; then B and C will exert no effect upon the circuit, for they will always neutralize each other. The E. M. F. of A corresponds to the transformer E. M. F.; the E. M. F. of B to the E. M. F. of self-induction on the field coil, and the E. M. F. of C to the E. M. F. on the condenser. In this way we obtain the necessary current to magnetize our motor unrestrained by the E. M. F. of self-induction.

Had we a reliable means of dividing an alternate current into two currents having the proper difference of phase, Mr. Tesla's motor would be made available and would be of great commercial value. Mr. Kelly and myself have found an entirely novel and complete solution to the problem. As far as we can discover, it has never been attempted by any other experimenters. By the use of a very simple invention, we are able to draw from a single transformer secondary two phase-differing currents, having any differences of phase we elect. These currents maintain their phases, that is to say, times of flow, independent of the amperage of the current and of each other. We can apply our invention at the station, splitting the primary current from the dynamos into two phase-differing currents, or we can lead the primary current through a transformer and split the secondary into two components.

I regret that I am unable to disclose the methods we adopt, but I hope to be able to publish our results shortly. Our method will then allow us to run the Tesla motors from the same circuits and by the same generators that we now employ in incandescent alternate current lighting. The Tesla motor for the past five years has been waiting for one thing only to develop it, viz., a current splitter, and we have found one.

---

[1] Abstract of a paper read before the National Electric Light Association, at Buffalo, Feb. 24, 1892.

The next difficulty to clear up, in order to operate our motor, is to get rid of the external resistance in the armature circuit. In order that a motor may operate economically and regulate properly for changes of load and current, it is desirable that the armature resistance should be very low; the principal resistance offered to alternate currents in an armature is, as before stated, due to the work outside of the armature wire in the iron core; these losses in the iron are occasioned by the alternating magnetization developed by the armature current; to remove this loss of energy we have had to destroy most all of the armature magnetism in the following manner:

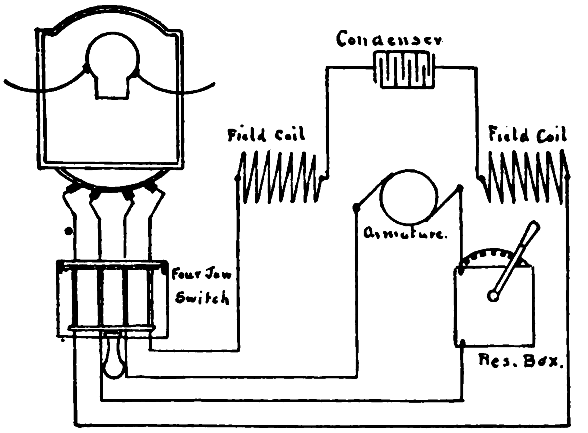

FIG. 3.

You are all aware that if a magnet core is wound with two equal coils in opposite directions and is connected with a current source, the resulting magnetism will be only that due to the difference of the winding displacement, and will be practically negligible. About our armature, see Fig. 2, we place close circuited copper bands or wires, so disposed as to be parallel to the direction of current flow in the armature conductors; the currents flowing in the armature windings induce oppositely directed currents in the stationary bands, and, consequently, the armature core is surrounded by two sheets of current during each wave of current flow, the sheet of current on the armature flowing in one direction, whilst the current in the stationary bands flows in the opposite direction, thus practically preventing any magnetizing effect, and thus, also, preventing any loss by hysteresis and eddy currents in the core. Now, it can be shown that the work lost in the copper bands will be very small, provided the resistance of these bands be kept low, and we have found that this loss can be made as low as one-third of the inside or ohmic loss, a result which enables us, by proper designing, to make our armatures almost as efficient as those of the best direct current type, with small additional expense.

One other point of advantage obtained by the use of the compensating bands should be mentioned. As the cross magnetization of the armature is practically destroyed, there is no change of lead under variation of load as there is no distortion of the field magnetism by the armature current. These results are eminently satisfactory. In our motor 96 to 98 per cent. of the voltage applied to the armature is available, while the operating conditions are identically the same as found with a continuous current motor. It is not to be understood that the motor has an efficiency of 96 to 98 per cent. Far from it. In our small motors the losses in the field and armature will aggregate 30 to 40 per cent. In the larger types of from 2 to 5 h. p. the loss will not exceed 25 per cent., whilst in the still larger sizes the losses will be much less. The problem of the efficiency of the motor is almost the same as the efficiency of the transformer and depends in large measure on the care and skill of design.

To operate our motors it is necessary that the speed of the dynamo should remain constant; as constant as possible. If the stations will give us a definite number of alternations, and will maintain that number, our motors will behave beautifully; if the alternations change, the condenser electromotive force will no longer exactly oppose the lagging electromotive force of self-induction and the field current will change and lag either positively or negatively; mere change of electromotive force will not interfere with the operation of our motors more than it would with any continuous current motor.

Fig. 3 illustrates the general design and arrangement of the motor system. The condenser is placed either upon the wall or under the motor in the base; the E. M. F. applied to the field is about 150 volts; the armature E. M. F. is either 50 or 100 volts. The E. M. F. on the condenser is, approximately, 750 volts; while this E. M. F. may appear excessive at first sight, there is no real danger from its use, as a contact across the terminals would instantly reduce the potential and accidental contact is easily prevented by properly insulated wires.

There is one other type of motor to be mentioned; the series wound motor. When operating a motor by alternate currents, the magnetism in the field should coincide with the E. M. F. applied to the armature, or else there will be a false current in the armature circuit; the condenser accomplishes this desired result in the shunt type of motor. In the series wound motor the magnetization necessarily coincides with the armature E. M. F., because they both accompany the same current. Fig. 4 represents a motor having its field and armature connected in series, while *c* is a condenser also connected in series; the distribution of the E. M. F.'s is given in the diagram. In my judgment, this type of motor will be of great practical use; not only will these motors successfully handle all constant load problems, such as pumping, blowing, etc., but they will be exceedingly useful in crane and elevator work, while their service in propelling cars can hardly be estimated. In all cases where hand control is required, they can be operated as successfully as continuous current motors.

The most serious question we have met in pursuing this problem has been that of finding a suitable condenser. It may be well to state that none of the ordinary types of condensers, viz., those made of paper, paraffine, glass, mica, etc., are of the slightest use. We have found that the residual charge in all the above-mentioned substances absolutely prevents their acceptance; this residual charge seems to depend upon the non-homogeneity of the dielectric and upon the want of an absolute contact between the plates of the condenser and the dielectric surface. When glass is used as a dielectric and a potential of 1,000 volts (average) is maintained upon the condenser, the glass heats rapidly until, finally, it is shattered to pieces. Condensers of glass, when raised to a potential of 15,000 volts, became phosphorescent, rapid flashes of light appeared in various parts of the glass, while they withstood the potential, which was only for a few moments. Vulcanite we find unreliable; metallic chips are always present and for this reason, if for no other, it fails to stand satisfactorily. We have succeeded in producing what we call "films" from .003 to .005 of an inch thick, which will surely stand a potential of 1,000 volts. We believe that these condensers are entirely commercial, that they will not deteriorate, while their cost per microfarad is quite low. So perfect are they, that they show but little trace of residual charge, they do not heat perceptibly when in circuit for a long time, and withstand a potential of from 2,000 to 3,000 volts with a dielectric thickness of .006 inch. The processes of their manufacture will not be made public at present.

Mr. Kelly and I have produced motors which are operative on existing circuits. As we have stated, our motors start at full torque, run to a definite speed and behave exactly like direct current motors under load. So perfectly does our compensating winding eliminate the E. M. F. of self-induction from the armature circuit, that this circuit offers very nearly the same opposition to alternate currents of a frequency of 130 ~ p. s. that it offers to continuous currents; there is, therefore, little falling off of speed due to the self-induction of the armature circuit; in fact, we can over compound the motor by its own load by setting the brushes off the neutral point of commutation, thus changing the flux through the field.

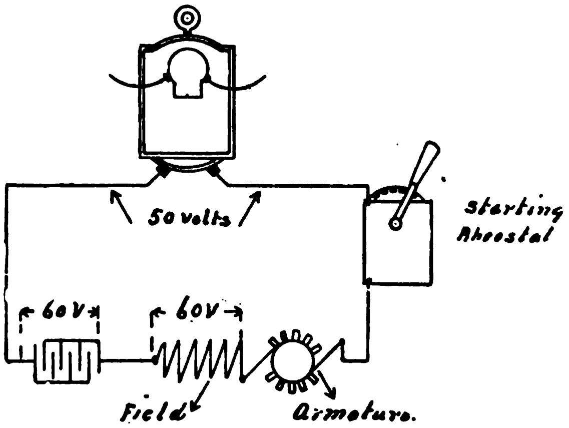

FIG. 4.

I feel convinced that the coming year will place the alternate current motor firmly on its feet, and that before the year elapses many stations represented in this convention will be testing the accuracy of the statements contained in this paper.

UNDERGROUND CONSTRUCTION OF THE BUFFALO RAILWAY CO.[1]

BY J. B. CRAVEN.

UNDERGROUND construction for railroad use brings us many problems to solve. Whilst not using a high tension current, we have one side of our system always grounded, so that between the many miles of cables in use and the earth we have a difference of 500 volts; thus you see at once the necessity of having and keeping up the highest insulation possible. This question of ground return requires that the insulation resistance of a railway circuit be twice that of an arc or incandescent underground system, where you have a metallic circuit; then there are the constant and excessive strains that one does not meet either in arc or incandescent lighting, due to the throwing off and on of the cars. It is almost impossible to figure your feeders to carry the maximum current, so that at any time you are liable to have your cables over-loaded, bringing very heavy strains upon them.

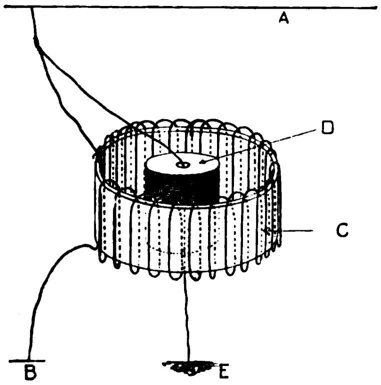

FIG. 1.

Another question is the one of connecting overhead with underground wires. This brings lightning to the field to be guarded against, for the large surface of trolley wire offers an attractive path for lightning, and how to protect the underground feeders and mains has been quite a problem. Lightning has little regard for insulation, seeming to want a path only to earth; this path is offered by the underground cables, so that we have to introduce some arrester at the junction of the underground and overhead wires to give it some other path.

Fig. 1 shows by what means we hope to accomplish this end. A is the overhead conductor, B is the underground cable to be protected, D is a non-inductive path to the ground, C is a coil with an iron core grounded through a fuse. This, you see, will offer two paths to the lightning; one of very low resistance to the dynamo current, but very high resistance to a lightning discharge, due to its self-induction; the other a very high resistance to the dynamo current, but a very low resistance to the lightning discharge.

This arrester is placed inside a water-tight iron box on top of a pole, wherever a tap is made with overhead wires; this box also affords a good place where overhead and underground wires can be connected and keep moisture from the cables; this is accomplished by wiping a three-inch lead cup onto the lead of the cable and filling it with insulating compound.

We have in this city about 11⅛ miles of subways, divided into two trunk lines, which branch off, carrying feeders to the outlying districts. Our conduits are laid in cement, 30 inches below the surface of the street. They are crowned in the center, so that the water will drain to the manholes, which in turn drain to the city sewers, with a bell-trap to prevent sewer gas coming back. Lately, on account of natural gas finding its way into subway and manholes, we have found it necessary to attach a blower at the station, which ventilates the whole system. Manholes we have placed every 400 feet, and have tried to make that distance standard, as pulling a greater distance brings an excessive strain on the cable when drawn in.

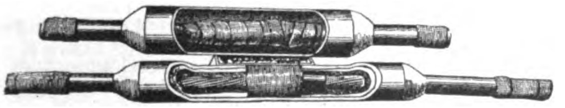

FIG. 2.

After careful consideration before this work was started, we decided to depend on our cable for insulation, not on conduits made of insulating material. To me it seems impossible to prevent moisture from penetrating the latter system, thereby lowering the insulation. We depend on our ducts for mechanical protection alone. The cables in use here are lead-covered, provided with an exterior fibrous jacket or covering saturated with pitch, the purpose of which is to protect the cables whilst being drawn in the duct. We have some 45 miles of cables, which have been in use since July last. These are of two classes—one for insulation depends on pure Para rubber, the other on a composition, our shortest feeder being two and a half miles in length, some of the longer ones reaching a distance of eight miles; yet the insulation on none at the present day is below 120 megohms, the short ones testing as high as 1,100 megohms. In laying this cable all tests were made in the testing-room at the station; this was made feasible by the use of a telephone circuit throughout the underground system, so that a workman making a joint in a manhole was in communication with the man making the the test and could always find out if his work was satisfactory. The joints made were the standard joints used by the companies from whom the cable was bought. A view of these will be seen in Fig. 2, the lower one being the one used for the rubber covered cable, showing the consecutive layers of insulating tape; the first, which is next to the copper, being a narrow white tape, free from sulphur; then follows a layer of pure Para rubber tape; upon this is wrapped a layer of rubber compound, then a layer of black rubber, and around the whole is wound cloth tape of a sufficient thickness to entirely fill the lead sleeve; the ends of the lead sleeve are then dressed down and wiped to the lead covering of the cable with an ordinary plumber's wiped joint.

The upper view represents a joint as made in the cable, using composition for insulation; the method here employed differed from the foregoing in that the lead sleeve is slipped over the completed copper joint, dressed down and wiped, the sleeve then being filled with compound through two small holes tapped through the top which are afterwards closed permanently with a soldering iron; each feeder, for the purpose of tapping off branches to feed the trolley wire and to facilitate the breaking of cables in case of trouble, is run through a junction box, Fig. 3, every 1,000 feet. The box shown in the cut has eight stubs, which allows three cables to pass through and be broken, and two taps to be taken off for feeding purposes.

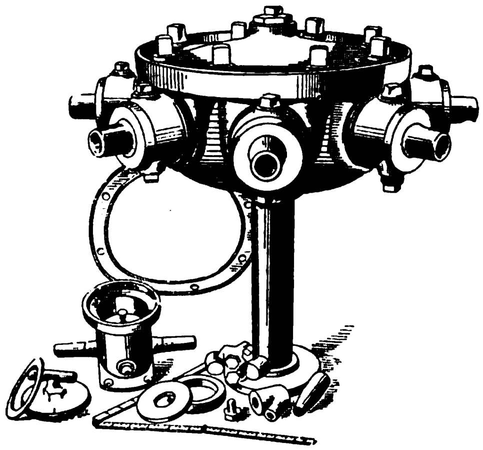

FIG. 3.

A small telephone box is seen at the left. One of these is placed in each manhole, the terminals of which are all in multiple.

A few words in regard to the testing of this system and the difficulties encountered on account of one side being grounded. We are obliged to test at night, when the load can be thrown off one feeder and onto another; then it is disconnected by means of a switch where it connects to the overhead, and the test is then made. It is rather a slow process, but the only one left open to us. The testing-room is equipped with first-class instruments for practical use. The galvanometer, which is of the Thomson reflecting type, is enclosed within a magnetic shield made of wrought-iron pipe, and also suspended by three springs to absorb vibration. The rest of the instruments consist of a chloride of silver battery, standard resistance and shunt and reversing key. It also includes a telephone communicating with the manholes.

Thus far we have looked upon the difficulties and disadvantage of the underground system. No arguments have been advanced in its favor, but I think you will agree with me that it has some. First, it does away with the public objection of disfiguring the streets, obstructing firemen in their duties, and, in the case of high tension currents, a menace to life itself; and then the liability of wires falling, causing a suspension of traffic, and, in case of a storm, causing a delay and loss of thousands of dollars to the companies themselves.

---

[1] Abstract of a paper read before the National Electric Light Association, at Buffalo, Feb. 23, 1892.

THE RELATION OF SIZE AND EFFICIENCY IN TRANSFORMERS.[1]

BY L. B. STILLWELL.

THE designer of a transformer has presented to him alternative paths. He may easily design with reference to a very small loss of energy and relatively high efficiency at light loads, if he is willing to sacrifice regulation. He may design a transformer of little weight and large output, if he is content to work at a very high temperature, which may, perhaps, endanger the lasting qualities of his insulation. The best transformer is not necessarily that which has the lowest leakage or magnetizing current; nor that which regulates most closely; nor that which is lightest and most easily handled; nor yet that which will carry its full load indefinitely with the least increase of temperature; but it is that transformer which best combines as much of each of these desirable properties as is practicable. In comparing various types, therefore, it is necessary to begin with a realizing sense of the fact that the same laws govern all types as to design and performance; and that, under the general laws of physics which have to do with this class of work, extraordinary excellence in one respect is necessarily obtained at the price of sacrificing excellence with respect to other properties equally important.

I propose, without venturing further upon the domain of theory than is absolutely necessary, to glance at what may be called the geometrical relations of transformers of various sizes, and so invite the attention of owners and operators of central station plants to a subject of very considerable practical importance to them.

It is safe to say that a commercial transformer, by which I mean a transformer that can be manufactured at a cost that will make it a commercial or saleable article, cannot be so designed so as to have a loss of less than 20 watts, due to the magnetization of the iron. A transformer twice as large—that is, of 10 lights capacity—is called upon to do precisely the same work and no more in developing counter E. M. F. to oppose that of the dynamo and may quite as easily be designed to work with an iron loss of 25 watts. If the rated capacity of the five-light transformer is 250 watts and of the 10-light transformer 500 watts, the loss in the former will be 8 per cent. and in the latter 5 per cent. A 20-light transformer may as easily be designed to work with an iron loss of 30 watts, and a 40-light transformer with an iron loss of 45 watts; the percentage of loss in these cases being, respectively, 3 per cent. and 2.25 per cent.

One ten-light substituted for two five-light transformers will reduce the amount of energy lost in magnetizing the iron from 8 per cent. to 5 per cent., a saving of 3 per cent. One 40-light substituted for two 20-light transformers will reduce iron loss from 3 per cent. to 2.5 per cent., a saving of one-half of 1 per cent. About the same percentage of saving can be effected by again doubling the size, and 100-light transformers can be furnished in which the iron loss does not exceed 1.7 per cent. Beyond this figure it is easily seen that improvement is difficult and even were it possible, by employing a very large transformer, say, one of 500 lights capacity, to reduce iron loss to 1 per cent., the improvement in efficiency resulting from the substitution of one of this size for five of the 100-light size would be but a fraction of 1 per cent., and, in view of the necessarily greater weight and the obvious objections to putting a large number of eggs in one basket, the advisability of such substitution would be doubtful.

Thus far we have considered only the loss in iron when no current flows in the secondary circuit, and it will be sufficiently accurate for our purpose to assume that this iron loss remains constant under varying loads of the transformer. The loss of energy due to the resistance of the copper when no current flows in the secondary is negligible, since the magnetizing current in the primary is very small, but this load increases as the load on the transformer is increased, and the increase varies as the square of the current flowing; that is to say, the copper loss is four times as great when two amperes flow in the secondary circuit as when one ampere flows in that circuit. In the transformer without load we have a certain loss of energy designated iron loss, while in the transformer fully loaded we have this same iron loss plus the maximum copper loss. For intermediate loads we have, approximately, the same iron loss with varying copper losses dependent upon the amount of the load.

The loss due to the resistance of copper is generally about 2 per cent. This does not vary materially with a variation in size of the transformer, certain considerations having to do with regulation being largely accountable for this fact. If we assume that the loss in copper at full load for every size is 2 per cent., and that the iron loss is constant, irrespective of the load, the following table will, with sufficient accuracy, indicate iron and copper losses and efficiencies at full load. The table does not represent actual measurements of selected transformers, but is intended to fairly represent the proportionality of losses in transformers of various sizes. Actual tests will show results as good as, or even better than, the figures given in the table.

Capacity in 16 c. p. lamps.	Loss in iron.	Loss in copper.	Efficiency at full load.
5	8 per cent.	2 per cent.	90 per cent.
10	5 "	2 "	93 "
20	3 "	2 "	95 "
30	2.5 "	2 "	95.5 "
40	2.3 "	2 "	95.7 "
60	2.1 "	2 "	95.9 "
80	1.9 "	2 "	96.1 "
100	1.7 "	2 "	96.3 "
300	1.5 "	2 "	96.5 "

It will be seen that for sizes of less than 20 lights capacity the falling off in efficiency as we go down the scale of sizes is very rapid, while, on the other hand, the gain in efficiency of transformers larger than that of 20 lights capacity is much less marked. The exact significance of the table will, perhaps, be better shown by putting it in another form. Let us compare the losses at no load and at full load in 1,200 lights capacity of converters of each of the several sizes, and let us express the loss in each case in terms of the number of 16 c. p. lamps, which the energy so lost would be sufficient to supply. We then have the following:

Transformers used.			Loss at no load.	Loss at full load.
240	5-light	capacity.	96 lamps.	120 lamps.
120	10	"	60 "	80 "
60	20	"	36 "	60 "
40	30	"	30 "	54 "
30	40	"	$27\frac{6}{10}$ "	$51\frac{6}{10}$ "
20	60	"	$25\frac{2}{10}$ "	$49\frac{2}{10}$ "
15	80	"	$22\frac{8}{10}$ "	$46\frac{8}{10}$ "
12	100	"	$20\frac{4}{10}$ "	$44\frac{4}{10}$ "
4	300	"	18 "	42 "

These figures plainly show that to supply any number of lamps up to 100 it is desirable, on the score of efficiency, to use a single transformer of the required size rather than two or more of less capacity.

For sizes of a capacity above 100 lights the improvement in efficiency is necessarily little, and although the argument on the score of efficiency is still in favor of the use of the large sizes, that argument is by no means as strong as it was before we passed the 100 light limit.

In favor of the use of large sizes is the very practical argument of reduced cost per lamp capacity. In giving proper weight to this consideration the purchaser should assure himself that the manufacturer has not effected a reduction in cost at the price of an excessively high limiting temperature, which may endanger the lasting qualities of the insulation.

Transformers of 300 or 500 lights capacity are naturally large and difficult to handle; or if they are not very large it will be well to again note the temperature.

An investment in a 500-light transformer is large as compared with an investment in one of 100 lights capacity, and the chances of accident, such as may be caused by lightning, are quite as great in the case of the former as in the case of the latter.

It is extremely improbable that a static discharge from the line caused by lightning will damage more than one of a group five transformers which may be connected together in multiple arc, while a discharge which may break down the insulation of one of these will be quite as likely to damage a 500-light transformer.

THE ALLIED POWERS.[1]

BY D. ASHWORTH.

AFTER a few words of introduction, in which the forces of steam and electricity were compared with the Allied Powers of Europe, the speaker continued:

This subtle and all-powerful agent, electricity, this reinforcement and seemingly inseparable hand-maiden of the older agent, steam, will be left for those whose lines of thought and action have been concentrated thereon; those among you who have been and are continually developing its hitherto unknown resources and powers; to you is relegated the pleasant duty of presenting its claims to an enlightened and appreciative public while we present to them the older one, that of steam and the steam engine.

There is a very notable feature in the development of the steam engine, as relates to James Watt, to which I invite your attention, and that is, that all the principal features so essential to economy of fuel, regulations and benefits to be obtained by expansion were fully considered by him. He was fully cognizant of the insidious losses by condensation, so that, after all, the marvelous progress that has been made in this direction has been in the refining of well-known existing conditions rather than the profundity of philosophical though tbestowed uponit by Watt in its early stages. The gradual perfection of mechanical appliances in the form of tools, etc., again contributed to the still greater success, until at length it seemed that the acme of excellence had been attained in workmanship.

It is not our purpose to enter upon any description of the many devices which ingenious and fertile minds developed during these periods, but it is generally acknowledged that the drop cut-off valve, invented by George Sickles, embracing as it does the tripper and dash-pot, giving an instantaneous cut-off, gave the keynote for further and more thorough steps in this direction. This was followed by the Corliss system of valve motions, producing results which attracted the attention of not only the engineering world, but the vast body of steam consumers.

[1] Abstract of a paper read at the Buffalo meeting of the National Electric Light Association, February 24, 1892.

We now reach a point that may be worthy of attention—at all events, may lead to an idea; since the advent of electric lights and motors the refinements of the steam engine in every respect to meet the requirements have more than surpassed those of the half century preceding.

It may be said, without exaggeration, that during this period the finest intellects have been taxed to their utmost in research of principles to meet the exacting demands of the electrical requirements.

In the matter of steam or fuel economy, a general survey of the field in this direction reveals results of a marvelous character. Looking back to the period antedating the advent of the electric power, the majority of cases were well content with a result of four or five pounds of coal per horse-power per hour. With the advance in the adoption of the compound system, one and a half and two pounds are attained in practice.

As has already been stated, the results in regulation and economy in engine practice to-day would seem to fill the round of desires or expectations at least. There yet remains much to be done in the direction of design with a view to durability, embracing within itself those qualities which, in a machine of continuous operation, would reduce the wear and tear to a minimum or scarcely appreciable amount.

In the matter of economy in the adoption of early points of cut-off and rates of expansion, it has been conceded that the positions of pure theorists, governed by the laws of thermodynamics, when brought into the actual school of practice and measured by the searching light of commercial conditions, were at variance. A halt upon this important point was the result, and now these theories are rapidly being modified and brought into close relation with accurate and first-class practice.

The numerous types and systems of steam generators brought to our notice constantly give ample testimony to the continued interest manifested in this important direction. Strength to resist pressure, durability, facility of access to clean and repair, are imperative. For economic results an abundance of steam capacity is requisite to produce the quantity of steam and, what is of equal importance, quality of same. The latter is receiving close attention, indeed, so much as to receive favorable commendations from our compeers abroad.

We are prepared to hear it said that these are but common truisms and are like twice told tales. We know it, but at the same time, they are such as will bear repetition. No attempt is made to describe any of the marvelous points of mechanism or to demonstrate with mathematical precision the unerring laws which, when formulated, reveal the very foundations of the principles by which these mighty results are achieved, the object being simply to point out the various causes of friction frequently introduced between these two powers like unto the welding heated surface to join, foreign particles prevent a perfect union, our desire being a cementing together, an harmonious working.

THE TRANSMISSION OF ELECTRIC ENERGY BY ALTERNATING CURRENTS AND ITS UTILIZATION BY CONTINUOUS CURRENTS.[1]

BY H. WARD LEONARD.

After a few introductory remarks in regard to the relative merits of continuous and alternating systems for the transmission of energy, the speaker continued;

The high tension alternating current says:

"How easy it would be to get there if somebody could only utilize me." And the low tension continuous current says: "How easy it would be to use me for any application if somebody could only get me there."

I stand here to make the claim that the transmission of power over great distances necessitates the use of both the alternating and continuous currents, and that by the combined use of the systems the result is commercial to-day over any reasonable distance, and for the transmission of any amount of power.

I arrive at this conclusion, as follows: The economical use of electric energy with automatic control of the speed and torque demands that the voltage be varied as the speed, and the current as the torque. It will be evident that for merely transmitting electric energy from a prime motive power of constant speed there can be nothing simpler or better than the synchronous alternating current motor of constant potential. But nearly every application of the transmitted power demands not only a variable torque, but a variable speed, as will be evident when we consider hoists, locomotives, pumps, ventilating fans, etc. The synchronous character of the alternating current is therefore unsuited to such work.

It would seem, therefore, that both theoretical and practical considerations demand that we should transmit our energy over the great distances demanded for commercial applications by means of the alternating current, and that we should then convert it into a continuous current in order to best utilize it. Under this plan we shall be able to undertake the transmission of power at any distance and on any scale by apparatus manufactured by half-a-dozen companies to-day.

Let us suppose, for example, that we have a water-power at a distance of twenty miles from a mine where it is desired to utilize 2,000 h. p. for various purposes.

Let us start with 10,000 volts and lose 22 per cent. in the conductor. The cost of our generator, conductor and synchronous motor will be about $90 per horse power at the point of work The synchronous motor will drive the necessary continuous current generators of 500 volts and less to supply hoists, pumps, locomotives, ventilating fans, air compressors, incandescent lights, arc lights, crushers, mills, etc. If the total power installed be 2,000 h. p. the cost of the working motors will be $50,000. With 2,000 h. p. installed, the maximum demand for power will not exceed 1,500 h. p. The cost of continuous current generators and conductors for this service will be about $52,500, and the cost of the synchronous transmission system about $135,000. Allowing $42,500 as an average cost for the development of the water-power and the construction, we have a total cost of plant of $280,000 or $140 per horse power represented in the electric motors at the point of work.

The starting up of the synchronous alternating current motor without load can be readily accomplished by any one of several simple methods, such as the use of a small storage battery supplying current to one of the continuous current dynamos and operating it as a motor to drive the alternator up to synchronism, or the utilization of the energy of a weight upon a hoist in its descent to operate its motor as a generator which in turn will drive the continuous current generator as a motor and thus bring the alternator up to its synchronous speed.

It seems to me that we should install a plant at the mine exactly as though we were going to drive it by a steam engine, and, instead of doing so, use the synchronous alternating current motor for this purpose, and utilize as our original source of power the distant water-power. In many instances, this method will be of especial value where it may be necessary for a few weeks in a year to fall back upon expensive steam power on account of the temporary failure of a distant cheap water-power.

If one comprehensive plant be installed of this alternating and continuous current type, I believe an enormous development in this line will immediately follow, and luckily the apparatus required can be turned out rapidly from any one of several large works without the delays incidental to the development of new apparatus and methods.

THE OPERATION OF HIGH-TENSION CURRENTS UNDERGROUND FROM A PHYSICAL AND FINANCIAL STANDPOINT.[1]

BY E. A. LESLIE.

In presenting this paper, I shall endeavor to confine myself strictly to my own experience and observation, submitting only such data as I may have been personally able to collect, and leaving it to you to decide whether, it having been determined that the successful operation of high-tension currents underground is physically possible, the financial aspects of the case will permit its general introduction.

CONDUITS.

The underground conduits in New York City for high-tension currents are owned by the Consolidated Telegraph and Electrical Subway Company, who lease their ducts to the various electric lighting companies.

The prevailing type of duct is of iron pipe, mostly three inches in diameter, running along the sides of the streets into manholes about 275 feet apart. These are the so-called "trunk ducts." Over the trunk ducts are superimposed from two to four distributing ducts, with four-way handholes about 50 feet apart. Many of these handholes are brought to the surface of the street and are covered over with an iron plate, which is easily removable, giving ready access to the wires in the distributing ducts. In many places, however, the handholes do not approach the surface, and, in order to get at the wires to make changes or connections, it is necessary to dig up the street. Again, on some of the prominent streets no distributing facilities whatsoever have been provided and the companies are compelled to make long and expensive house connections from manholes. This is particularly true of Sixth avenue above Eighteenth street and Broadway above Thirty-fourth street.

---

[1] Abstract of a paper read at the Buffalo Convention of the National Electric Light Association, Feb. 24, 1892.

[1] Abstract of a paper read before the National Electric Light Association, Buffalo, Feb. 25, 1892.

The Subway Company have also a number of miles of a system which is made up of sectional iron castings and so framed together as to combine in one conduit both trunk and distributing facilities. These conduits have no surface handholes and, in order to make changes or connections, it is also necessary to dig up the street. The manholes are about 275 feet apart as in the case of the iron pipe. There is also a small amount of conduit in use, which is composed simply of cement-lined iron pipes, running from manhole to manhole, of about three inches inside diameter.

The cost of the New York conduits is an unknown quantity. The Subway Company guard the secret well, and, beyond the general statement that they have cost, on an average, nearly $5,000 per mile, per duct, no reliable information can be gained. In these figures, however, are doubtless included the expenses of years of legislation and long and costly litigation. It is the universal opinion among electric light men in the city that the actual average cost should have been less than $3,000 per mile of duct.

CABLES.

The companies with which I am connected use, principally, cables insulated with a rubber compound, although we also have in use 35 or 40 miles of cable, the insulating material of which is fibrous. Perhaps the best description of cables I can give is to embody herewith a copy of our specifications, which, with slight modification, are in general use by the New York companies.

SPECIFICATIONS FOR UNDERGROUND CABLE.

Wire.—No. ——— B. & S. (solid or stranded) must contain no joints or splices.

Lead Covering.—To have an alloy of from four to five per cent. tin. Thickness of lead, $\frac{3}{32}$.

Insulation.—Outside diameter, ——— 32ds (usually $\frac{5}{32}$ to $\frac{7}{32}$ all around the conductor). Resistance of insulation without lead covering, after at least 48 hours' soaking at temperature of 75 degrees Fahrenheit, 1,500 megohms per mile. Resistance dry test with lead cover and without lamp connections, 1,500 megohms. Resistance of insulation after three years' use to be up to the standard required by the Board of Electrical Control, which is not less than five megohms per mile, per 100 volts of current employed up to, for example, 3,000 volts, *i. e.*, 150 megohms.

Copper.—Conductivity of copper, 98 per cent. To be medium hardness; that is to say, a mean between hard drawn and soft copper.

Diameter.—Outside diameter of cable, including lead covering ——— 32ds (depending upon the size of the wire).

Electrical tests of insulation to be made at factory by company's representative. If insulation is taped, outside diameter of cable to be ——— 32ds.

Capacity.—Cable shall be capable of carrying an alternating current of ——— volts and ——— amperes; or continuous current, ——— volts and ——— amperes.

Laying and Connecting.—The cable to be laid and connected by the ——— Electric Light Company under the supervision of the manufacturers, who shall carefully supervise the work, and, after accepting the same, shall be liable under the guarantee in the same manner, and to the same extent, as if they (the manufacturers) had themselves laid and connected the cable.

It is usual for manufacturers to guarantee their cables for a term of three years, and a special form is provided therefor.

The cost of lead-covered cables, such as the above specifications call for, varies considerably according to the size and manufacture. Roughly speaking, however, No. 4 cable ranges from 15 to 20 cents per foot, or, from $792 to $1,056 per mile. No. 2, from 25 to 30 cents per foot, or, from $1,320 to $1,584 per mile. No. 00, from 37½ to 45 cents per foot, or, from $1,980 to $2,376 per mile. No. 0000, from 55 to 65 cents per foot, or, from $2,904 to $3,432 per mile. In other words, underground conductors cost from four to five times as much as overhead conductors, which is a matter to be carefully borne in mind.

LAYING.

The manner of laying cables is simple. It is first necessary to draw a rope through the duct to be occupied. To do this, rods about three feet in length are used, having brass male and female screw attachments, one at each end. The first rod is inserted in one end of the duct; then another is screwed into it and pushed forward, and this process is continued until the first rod emerges into the manhole at the other end and you have an unbroken line of connecting rods through the duct. A rope is then attached to the last rod, and, as the rods are pulled forward and unscrewed in the manhole at the distant end, the rope is gradually drawn through. Unless a large number are to be drawn into a single duct, they can be drawn by hand without any special machinery. If, however, it is desirable to draw in as many at one time as the duct will hold, it is necessary to use a winch or windlass, or, in lieu of either, a snatchblock with a rope and tackle, and enough men to pull the mass. Great care should be observed not to allow the cables to twist in the duct, as, if this occurs, it is next to impossible to withdraw any given conductor thereafter without removing all conductors in the duct. In cutting the cables to fit given sections, about 12 feet should be allowed for slack between manholes, for racking around the sides of manholes and for metallic joints. The cost varies considerably. To draw in two cables in a duct would cost in the neighborhood of from 2½ to 3 cents per foot of cable; but to draw in four or six, or even eight, as has frequently been done, the cost diminishes and will not average over two cents per foot, or even less, assuming that the men in charge have had experience and understand their work thoroughly.

JOINTING.

The proper jointing of cables is a matter of paramount importance. Unless the joints are made by an experienced person, it is almost impossible to secure a joint which will give the same insulation resistance as the cable itself, and yet, unless the joints are so made, the object of securing immensely high insulation in the cables proper is entirely defeated and a large proportion of the original investment practically wasted.

The New York Subway Company, in its early inception, framed a set of rules governing the operation of underground conduits. Among them is one which has always challenged my admiration and the man who framed it either built wiser than he knew, or was a remarkably gifted person. This rule at first was considered absurd and impossible of compliance, but to-day I think I am safe in saying that every electric light company governed by it will acknowledge its wisdom and admit that, by having enforced a high standard of insulation from the very outset, a large amount of subsequent experiment and waste of money has been avoided. I quote the rule:

> *Section* 4, *Electromotive Force.*—"All conductors drawn into and operated in the conduits, and intended to convey currents of an electromotive force exceeding 100 volts, shall have at the temperature of 75 degrees Fahrenheit, an initial insulation resistance of not less then 15 megohms per mile per 100 volts electromotive force of current in the circuit. Whenever the insulation resistance of a conductor as aforesaid shall prove to be less than five megohms, per mile, per 100 volts, the use of that conductor shall at once cease, unless the actual electromotive force in its circuit be reduced so as to re-establish the foregoing ratio."

You will observe that the initial tests of cables laid by any of the companies in New York city must show an initial insulation resistance of not less than 15 megohms per mile, per 100 volts of current used. This means that, with an alternating current of 1,000 volts, the cable must show, before the current is turned into it, an insulation resistance of not less than 150 megohms per mile; with an arc circuit of 2,500 or 3,000 volts, or even 4,000 volts, initial insulation resistance must not be less than 375 megohms, 450 megohms and 600 megohms, respectively. Taken into consideration with the fact that on an ordinarily humid day, overhead circuits will not show an insulation resistance of more than from 200,000 to 500,000 ohms per mile, the above requirements seem altogether impossible of attainment and to be ideal rather than practical, but this is not the case. On the contrary, it is rare, indeed, that the initial tests of cables laid in New York city, do not show from three to four times the initial insulation resistance required by the rule, and, of the hundreds of miles of cable actually in operation at the present time, and which have been in operation from two to three years, and with which I am personally familiar, I do not believe that there is one that will not show, under like conditions, nearly, if not quite, the same high degree of insulation, as when the original test was made. In fact, I have proved this to be true many times, and will cite one of our latest tests.

Initial Test, November 17, 1889.—Weather, clear; temperature, 60 degrees Fahrenheit; constant, 33,000. Leg No. 1: Length, .95 mile; deflection of galvanometer, 25 divisions; total insulation resistance, 1,320 megohms; insulation resistance per mile, 1,259 megohms. Leg No. 2: Length, .95 mile; deflection of galvanometer, 20 divisions; total insulation resistance, 1,650 megohms; insulation resistance per mile, 1,567 megohms.

Last Test, February 5, 1892.—Weather, fine; temperature, 25 degrees Fahrenheit; constant, 33,000. Leg No. 1: Length, .9 miles; deflection of galvanometer, 12 divisions; total insulation resistance, 2750 megohms; insulation resistance per mile, 2,475 megohms. Leg No. 2: Length, .9 mile; deflection of galvanometer, 10 divisions; total insulation resistance, 3,300 megohms; insulation resistance per mile, 2,970 megohms.

It is, of course, apparent that the conditions under which this last test was made were much more favorable than in the case of the initial test, but I think it is also apparant that the insulation resistance of the cable has suffered little or no deterioration after more than two years of constant use.

This would be impossible with poorly insulated joints. The first cable laid by the Manhattan Electric Light Company on Broadway was insulated with rubber compound and the joints were made by contract, on the representation of the contractor that his men were professional jointers. After the cable was connected throughout, a test showed less than a megohm of insulation per mile, and this bad condition of things was quickly shown to be in the joints; every one of them had to be cut out and our lesson was well learned. Since that time we have never allowed any but our own men, specially trained and educated for the purpose, to make joints on rubber compound cables. The cost of joints will run from $2 to $3 apiece and any manufacturer can give proper directions how to make them and what to use, both as to metallic contact and insulation; but, in the case of the rubber compound cables, the difficulty lies more with the man than with the method. Men whose hands are naturally moist cannot make a good joint, *i. e.*, a joint which will test "infinity."

TESTING.

We are required to test all underground circuits at least once per week. For this purpose a portable reflecting galvanometer is used. Where the cables enter the station a test-room, free from the jar of the building, is usually provided in which to set up the instruments; but, in cases where the cables are reached from the station by overhead wires, it is customary to rent a quiet room adjacent to the junction-pole and connect by a well-insulated "lead" for permanent use. The total insulation of a circuit with all converters or arc lamps connected, will generally fall below the requirements of the rule above quoted, but, unless it is shown to be less than say one megohm per mile of cable, its condition, as a "completely connected circuit," is usually accepted. But, as a general rule, when the insulation falls below this standard, what are termed "ex-converter" and "ex-lamp" tests are called for. These require, in the case of incandescent circuits, that every converter installation be cut out, the cable ends freed from all contact, and test of cables only be made to ascertain their exact condition. The arc circuits are similiarly treated by disconnecting all lamps and switches. Unless the results of such tests come within the limit prescribed by the rule, the circuits are not allowed to be operated until the defect has been removed and the insulation brought back to the required standard. Fortunately, defects are rare, and tests of this character are not now called for with sufficient frequency to prove burdensome.

HOUSE CONNECTIONS.

House connections are built by the Subway Company at the expense of the electric light companies; but the Subway Company claims not to relinquish ownership therein, and will not allow their joint use by two or more companies, except by special arrangement. The cost of house connections in New York City is appalling to the man of exclusively overhead experience. I will quote a few selected at random:

On upper Sixth avenue:

To No.	House Pipe.	Cable and Labor.	Total.
888 Sixth avenue............	$108.57	$59.93	$168.50
527 "	141.96	79.06	221.02
1011 "	78.51	54.10	132.61
846 "	155.08	88.56	243.64

Many of the streets have subways upon one side only. House connections from handhole boxes to the opposite side of the street are long and expensive, for instance:

To No.	House Pipe.	Cable and Labor.	Total.
1860 Third avenue............	$124.67	$43.60	$168.27
1995 "	124.59	50.60	175.19
2401 "	118.54	61.66	180.20
1666 "	153.65	47.60	201.25

Distribution to side of street on which conduit is laid, or where there are distributing facilities on both sides of the street:

To No.	House Pipe.	Cable and Labor.	Total.
1924 Third avenue............	$24.82	$25.42	$50.24
2102 "	24.54	16.00	40.54
666 Eighth avenue...........	31.03	22.47	53.50
728 "	21.84	23.84	45.68

The cost of connections to city lamp posts, including pipe, cable and labor, averages about $110 per post.

You will observe that, in some cases, the cost of these connections exceeds the gross revenue derived from an arc lamp for an entire year, but, unless we resolve not to develop the particular territory in which these cases occur, we are obliged to invest our money and take chances for the future.

Fortunately, it often happens that one house connection will serve for two or three different installations, and, in this way, the average cost per installation or per arc lamp, is very largely reduced. For instance: In the fall of 1890 our arc lamp connections cost us, on an average, only $43; in the spring of 1891, an average of about $30; the ratio of new connections to new installations or lamps being as one is to two. In other words, for 100 installations or lamps we were required to make but 50 house connections. This ratio could be largely and safely reduced were we allowed by the authorities to use more than 100 feet of overhead wire with each underground connection.

SOME FEATURES OF UNDERGROUND OPERATION.

It is a fact worth knowing that the underground service is more reliable than that of the overhead. Storms, blizzards, sleet and wet snow have little or no effect upon it, and neither has lightning, where the circuits are entirely underground. In consequence, cases of interruption are rare; crosses never occur; grounds but seldom, and open circuits are unknown, except when a break occurs at a lamp or a switch. The number of "burn-outs" in the subways is small, and thus far, after three years' experience, not a single instance of burn-out has occurred in our "rubber" compound cables that has not been directly attributable to some imperfection of manufacture, which originally escaped detection, or to mechanical injury after the cables were laid. And these have not amounted to more than 10 or 12 all told. We have, however, had several instances with the "fibrous" compound, but whether due to accidental abrasion of the lead covering, which is fatal to that form of insulation, or to some inherent defect, we were unable to determine, as the intense heat of the escaping current destroyed all evidence in each case.

On wet nights we have an occasional case of trouble in a leaky switch-box, or, at an exposed joint, where the wire running to the lamp is connected with the cable. These joints were at first covered with ordinary tape, but after a few months' exposure the tape would invariably leak under the high pressure and sometimes convey the current to the lead covering and result in a burn-out. In the case of rubber compound cables, we now simply cut back the lead a few inches, strip off the taping, make an ordinary metallic joint and then slide over the bare metal a floor insulator, open at both ends, and standing upright so as to allow the rain to run through the lower end; the insulator resting upon the rubber compound, not upon the lead covering of the cable. This, of course, refers only to lamps where switch-boxes cannot be used, such, for instance, as city lamps. Where fibrous cables are used, a regular insulating joint of pure rubber is made, connecting to a short piece of specially insulated wire. The joint is immersed in boiling hot paraffine and the specially insulated wire is then connected in the ordinary way to the wire running to the lamp. This is done to protect the insulation of the cable from moisture and also to facilitate connecting and disconnecting with the lamp, which the regulation tests frequently render necessary.

In laying cables it has been found desirable to place both "legs" of incandescent circuits in the same duct. When they are separated into different ducts great loss results from self-induction.

The use of the subways makes it possible to employ much heavier single conductors than could be used overhead. There are in some of the ducts conductors having nearly, if not quite, 500,000 circular mils area, and such sizes as No. 00 and No. 0000 are quite common. The conductor being composed of small wires stranded, affords sufficient flexibilty for all purposes; but in sizes up to and including No. 2 B. and S., the conductor is generally solid.

In the matter of public safety, the records of the past three years show but one death to have occurred from the current conducted underground, and that particular case occurred on top of a city lamp-post on a wet night, the victim neglecting to use his gloves.

The arrangement of the underground system is exceedingly cumbersome; that is to say, it requires much greater time, as compared with overhead methods, in the construction both of trunk lines and house connections. Under the old overhead system an order for an arc lamp, for instance, could be executed within two or three hours after its receipt and the whole cost of hanging was not to exceed anywhere from $8 to $12; now, however, in order to hang an arc lamp and connect therewith, it is necessary to make formal application to the Subway Company for the house connection, and this requires, on their part, anywhere from three to ten days' time. After receiving due notice that the house connection has been built, we are then required to apply to the Board of Electrical Control for a permit to hang the lamp and connect it with the underground conductors. This requires additional time, amounting to from three to ten days, often two weeks and even longer; and, in a number of instances, before we were finally permitted to fill the order, the prospective customer had become disgusted with the delay and canceled his contract. The Subway Company have also to apply to the Department of Public Works for a permit to open the street and must receive the same before they can proceed with the work, making in all three distinct applications to three different bodies for each house connection. Again, the underground system rigidly circumscribes the territory in which current can be distributed to the streets through which subways are built. Lights cannot be served 200 or 300 feet off the line of the subways without a long underground connection, the cost of which would, in nine cases out of ten, prove prohibitive.

I recently read an article in a Western paper, to the effect that the wiring of the plant located in the city in which the paper was published, was all overhead, because the underground systems in New York City and elsewhere had proved to be a failure on account of gas explosions, which were so serious and frequent in their nature as to make the operation of high-tension currents underground infinitely more dangerous than dynamite. Now, as a matter of fact, although it is true that the earth beneath the street pavements of New York City is completely saturated with gas, but very few explosions have actually occurred and those not at all serious in character. Only one interrupted our business, and, in that case, only for a few hours and on but two circuits. The Subway Company use a system of blowers, which keep the subways reasonably free from gas, and this source of danger or interruption, at least so far as the city of New York is concerned, may be wholly disregarded. Nevertheless, without the blowers it might be reasonable to apprehend danger.

THE FINANCIAL ASPECT.

A good system of underground conduits fairly covering the electric lighting territory of a large city, will, in my opinion, cost on an average from $2,500 to $3,000 per mile, per duct, but, in the case of a single duct in a trench, the latter figure is likely to be exceeded, depending largely upon the character of the digging and the engineering difficulties to be overcome. For the purpose of comparison, however, let us assume $3,000 to be the cost of one mile of distributing duct and then consider the cost of one mile of construction for one arc and one incandescent circuit, by both underground and overhead methods, as follows:

UNDERGROUND.		OVERHEAD.	
Duct	$3,000.00	50 poles prepared and set at $12.00	$600.00
11,000 ft. No. 4 cable at 20 cents, laid	2,000.00	11,000 ft. No. 4 wire, at 4½ cents	495.00
11,000 ft. No. 2 cable at 30 cents, laid	3,300.00	11,000 ft. No. 2 wire, at 7¼ cents	797.00
40 house connections at $75.00	3,000.00	40 house connections	480.00
Total	$11,500.00		$2,872.50

Hence, from these figures, it must be assumed that the initial investment for an underground system will exceed by about five times the cost of an overhead system, and the fixed charges on this very expensive feature of investment in a central station plant must be correspondingly increased.

But in New York City, as before stated, the underground conduits are owned by a subway company, who have an exclusive franchise and who lease their ducts to the various electric light companies upon the following schedule of rentals:

Distributing ducts,		$1,000	per mile	per annum.
Trunk ducts, 3	inch,	900	"	"
2½	"	800	"	"
2	"	700	"	"
1½	"	550	"	"

These rates have the effect of increasing the usual and ordinary expenses of a central station enormously, and, although some overhead wires are still in service, and our field of operation is almost wholly confined to the more important streets and avenues, *the amount of the duct rental already equals the combined cost of coal, water, oil, waste and the salaries of chief engineer, engineers, firemen, coal handlers, boiler cleaner and oilers employed in the engine department.*

The development of electric lighting territory is, consequently, much restricted, and streets which would offer fair inducement for overhead wires cannot be considered at all from an underground standpoint. A case of this kind occurred in our last bidding for street lights. A certain company bid for the lights on Fifth avenue, between Twenty-third and Forty-second streets, about fifteen in all, at the rate of 60 cents per light per night. This was 20 cents above the ruling price. Being called upon to explain, the company stated, First, That there was no commercial arc lighting to be had in that locality whatsoever, and they must rely solely upon the street lights for revenue; Second, That there were subways on both sides of the street and that, as the lights were distributed on both sides of the street, they would be obliged to lease a duct on each side; Third, That, therefore, the duct rental *on Fifth avenue alone would amount to 32 cents per light, per night.*

There is another onerous feature which discourages the extension of territory, and that is, that the Subway Company requires us to execute a bond agreeing to pay rental for a term of five years on all new ducts constructed and this bond must be secured by collateral of unquestionable value. This ensures the return of their capital, even at their own estimate of cost, but it imposes a heavy burden upon the electric lighting companies.

And right here it seems pertinent to remark that I have long been convinced that it is a matter of paramount importance to an electric light company to own the subways it occupies and to possess the right to extend the same as the development of its business may require. While I have no complaint to make against the Subway Company of New York, I know that the subways could be operated by the companies for much less money than they are now required to pay, taking into full consideration the matter of interest on capital investment, cost of maintenance and operation, and every other charge which can be justly considered. Therefore, for those to whom opportunity is yet given, it might be wise and prudent to at least secure the right to construct underground conduits, even although they may not adopt their use for some time to come.

As to maintenance, our experience with cables has not been sufficiently great as to give us a definite idea as to their possible life. Aside from this, however, it costs no more to maintain the cables than it does to keep overhead wires in good order, say, from $15 to $20 per mile per annum—probably not quite so much; but, unless the cables last at least 20 years, the cost of maintenance is also likely to be far greater.

Finally, summing up the whole situation, the following conclusions may be fairly reached:

First. The underground service is not only a physical possibility, but an established fact upon a very large scale.

Second. It is less liable to interruption than overhead wires.

Third. It is less dangerous to human life.

Fourth. Its cost is enormously greater.

Fifth. It is cumbersome to a degree and lacks, to a considerable extent, the flexibility of overhead wires.

Sixth. Its cost precludes its extension to sparsely lighted districts, which must either be reached overhead or permanently abandoned.

TRANSMISSION OF POWER WITH SPECIAL REFERENCE TO THE FRANKFORT PLANT.[1]

BY CARL HERING.

This lecture was one delivered with special reference to the proposed transmission of power from Niagara Falls to Buffalo, and its feasibility as illustrated by the recent work at Frankfort with the transmission from Lauffen. Mr. Hering presented a very interesting statement of the general conditions of the problem, and then described the manner in which the experiments at the Frankfort Exhibition were carried out. He also explained in an admirably lucid and simple manner the nature of the three-phase rotary current used and its difference both from the two-phase current and from the ordinary oscillating current generally used in alternating work.

Mr. Hering closed his lecture with the following passage:

"The Oerlikon Company gives the following figures regarding the cost of the plant: Assuming that 300 h. p. is developed at Lauffen, and that all the energy received in Frankfort was converted into light, the cost of the plant per effective horse power measured at the terminals of the lamp will be about $282, of which $236 is for the line alone. These figures appear high, but it must not be forgotten that in this particular plant there were conditions which would not be likely to occur in practice, namely, relatively small power on the one hand, and exceedingly great distance on the other, both of which factors naturally increase the cost per horse power.

"It may be of interest to add herethat Mr. Dobrowolsky of the Berlin firm states that he would be willing to bid on the contract to transmit 1,000 or 5,000 h. p. from Niagara to Chicago, a distance of about 500 miles. He proposes to use 40,000 to 50,000 volts and claims that an efficiency of 60 to 75 per cent. could be obtained without difficulty."

He also added the following:

"I received this morning a letter from the Zurich people, the Oerlikon Co., who you may know have put in a bid for the transmission of power from Niagara Falls to Buffalo. They propose that the current generated at the Falls is to be such that both motors and lamps—arc lamps as well as incandescent lamps—shall be used. That is, the current shall be fit for motors, arc and incandescent lamps. They say the Drehstrom (that is, the rotary) current is at present, and will be for a long time to come, the only practical form of current to run large motors of a fair efficiency. They propose to use 50 periods in place of 40 which were used at Lauffen, because they say that 40 is too low to run arc lamps. Fifty is said to be the lowest at which arc lamps will run satisfactorily. The generating station would be composed of units of 5,000 h. p. each. The dynamos must therefore be of 5,000 h. p. According to the wishes of the turbine designers the number of revolutions has been fixed at 250 per minute. The diameter of the armatures has been fixed at 3¼ metres, that is about ten feet. The armature is to be drum wound. I suppose that means the drum winding on the surface of the cylinder, that is, not across the ends as we usually wind drum armatures here, but wound as they very often do in European multipolar machines. The currents are to be 2,000 amperes in each of the three circuits, and the voltage 600 to 700. It has been found advantageous to revolve the armature instead of the magnetic field, in order to have a minimum weight on the vertical shafts. The weight on one of those shafts, by the way, is something very great. The shafts are 20 feet long, and the weight of the shafts together with that of the armature and turbine is a very great weight, and must therefore be considered. The generators will have 24 poles.

---

[1] Abstract of lecture delivered before the National Electric Light Association, Buffalo, February 23, 1892.

They will be separately excited. The efficiency will be in the neighborhood of 96 per cent., that is the efficiency of the dynamo including exciting power. There will be two transformers, as it was not found practical to build a single transformer of 5,000 h. p. The transformers will be artificially ventilated, and only the high pressure coils will be placed in oil. These transformers will raise the potential to 25,000 volts.

"This" they say, "is no longer to be looked upon as an experiment. The cost of the line will be about 100,000 francs, that is, $20,000, an almost trifling part of the whole, for the total distance. It is a simple pair of copper wires, that is, three pair of copper wires on poles; the cheapest kind of a line.

"As to the line, we propose not to carry any more than one or two units of 5,000 h. p. on one line, of poles for a number of reasons. A 5,000 or 10,000 h. p. can be conducted on wooden poles at a very moderate initial cost of plant. The lines would terminate in one or more step-down transformer stations that would supply current of 1,800 to 2,000 volts for municipal and street lighting in the shape of alternating currents to be transformed down to the suitable lamp voltage, as is the case in the present transformer systems. The cost of the electrical part of the proposed plant, including the generators, exciters, and transformers at both ends of the line, would be about $180,000 for each unit of 5,000 h. p., with an efficiency of 84 per cent. at the low pressure terminals of the secondary transformers. This reduces to $36.00 per horse power. The cost of the line is about $4.00 per horse power, which is about 10 per cent. of the whole."

At the close of the lecture, Mr. Hering showed a number of magic lantern slides illustrative of the Frankfort-Lauffen apparatus, line, exhibition, etc.

Prof. Elihu Thomson followed in a most interesting address, in which he expressed himself not only as greatly in favor of the three-phase method, but as perferring an underground line, for which purpose he suggested an iron pipe filled with oil. Then the higher they ran their potential the less danger would there be from lightning. Their plant would be constructed to withstand a moderate phase of lightning, and it would then take considerable to break it down. With sufficient oil, they could easily run up to 100,000 volts.

Mr. H. Ward Leonard then read a brief and well-put paper[1] arguing for the necessity of a combination of the alternating transmission with a direct current distribution. He said, too, that all the problems could be solved with existing apparatus and methods embodying it.

Mr. L. B. Stillwell remarked that the work done abroad had been carried on with Government help, and was practically paid for by three States. There certainly were manufacturers here ready for any kind of work, with such a guarantee of payment. As to the technical side of the matter, there seemed to be reasons for thinking that a two-phase, 90 degree system, was preferable for combination work, *i. e.*, where more than one motor was run or where motors and lights were run together. With regard to a synchronous plant at Telluride, mentioned by Mr. Hering, he said that the current was transmitted 2¾ miles at 3,300 volts, with the intention of going eight miles to other motors. The present motor was running 24 hours at least six days in the week. Mr. Stillwell also said that he failed to see the necessity for step-up and step-down transformers for any distance of less than 10 miles. Moreover, in some places oil insulators could not be used, owing to the fact that the line was set at all angles, so that the fluid was spilled. At Telluride, ordinary glass had been used successfully all through the winter.

Mr. C. S. Bradley spoke of his pioneer work in rotating fields, and expressed his preference for three-phase methods.

Dr. Louis Bell discussed the whole question in an eminently shrewd, practical manner, showing that while something had been done there was still much to be learned, especially with regard to the relative values of the methods employed.

"In the present situation it does seem to me that a great deal of the discussion between the defects of the various systems ignores for a moment that much of what is to be done in the next year or two must be done under the conditions where we are working now. Much of it must be done with existing apparatus, and the man who will make the most thorough success of the transmission of power in that field is he who will attack each separate problem, doing the best he can with the apparatus which he can get, and not tying himself up absolutely to either continuous or direct currents, to two-phase, three-phase, or any phase motors, but seizeing the opportunities for transmission of power as they come, and making the best of the situation with the best apparatus that that particular moment commands. It is this practical, commercial side of the problem that I think one is half apt to forget in the glory of electrical pyrotechnics."

At this point a discussion arose as to cost of the plant and line, Mr. Carl Hering having given figures which were generally considered to be too low, namely, $36 per horse power for the entire Niagara-Buffalo plant, including dynamos and all, up to 2,500 h. p., with $4 per horse power for the line. Mr. Leonard remarked

(*Concluded on page* 221.)

OVERHEAD CONSTRUCTION.[1]

BY E. F. PECK.

In view of the great interest taken at present in underground construction, it would seem almost incongruous to agitate the well-worn subject of overhead construction. Still, as the majority of electric lighting companies in this country will have to contend with this method of construction for some years to come, it may be that the subject will still be debatable. In order to bring out a discussion that will, I trust, prove both interesting and instructive, I will outline some recent work that has been done under my supervision in Brooklyn.

We had reached that point where further patching was out of the question, and reconstruction became a necessity. The first point of attack was our switchboard. This was the old style plug, socket and cable board, with wooden framework, originally designed for 36 circuits and 36 dynamos, but now, due to the increase of our business, handling 53 circuits and 42 dynamos.

The switchboard that I have planned is arranged to manipulate 80 circuits and 66 dynamos, divided into three units, which I will describe as sections A, B and C—circuits and dynamos in each section being interchangeable—section A to provide for 32 circuits and 22 dynamos, and sections B and C each providing for 24 circuits and 22 dynamos. Each section consists of two rectangular slate slabs, placed five inches apart, supported on a suitable framework of steel I beams and channel bars, occupying three sides of a square. Into these slabs are fitted rows of metal bushings which are properly connected together by copper strips, so that the horizontal rows of bushings on the front board are connected to the dynamos *via* single throw jack knife safety switches, while the vertical rows on rear board are connected to the circuits and also to an extra row of bushings on the bottom of front board. This extra row is used to connect two or more circuits together by means of cables and plugs, the connecting of dynamos to circuits being done by means of an ordinary plug of brass tubing, provided with an insulated handle. Above the switchboard proper, which stands about five feet high, slate slabs extend to the ceiling of the room in which the board is located, providing space for necessary lightning arresters, combined ammeters and polarity indicators, to be used on each circuit.

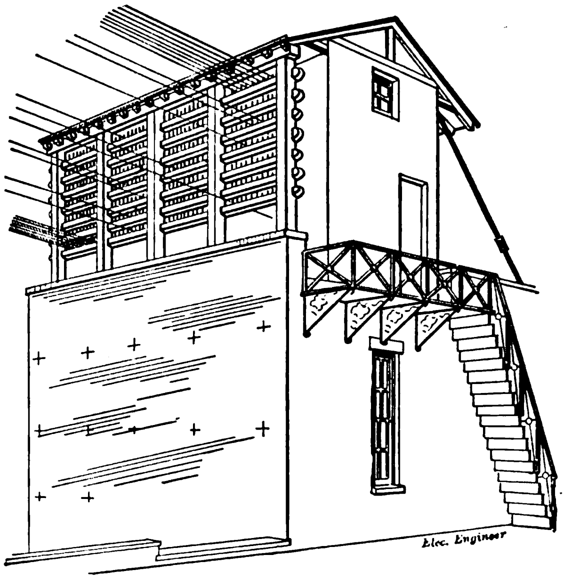

FIG. 1.

The next improvement which became necessary was the building of a suitable wire tower. The wire tower of a central station is an unknown quantity and a problem that is hard to solve. The first question is as to its shape. Shall it be rectangular, octagonal or circular? This can only be answered by one having a thorough knowledge of the situation of the station and the directions which the circuits are to take after leaving the same.

While at Montreal, I saw a very pretty arrangement of a wire tower on the new station of the Royal Electric Company. It was octagonal in shape, each side being about 10 feet wide, with a rectangular section of slate framed into each section. This permitted the introduction and insulation of wires without other precautions, and, owing to the shape of the tower, provided for a lead for the circuits in eight directions. In our Brooklyn station, it was necessary to have the wires leave the tower in one direction only; so it was built rectangular in shape (see Figs. 1, 2 and 3). The tower is built directly over the switchboard and is 23 feet long and 10 feet wide. The framework of the tower,*inside wire rack and outside wire rack, are all framed and bolted together, and guyed to the roof in the rear of the tower by means of wrought iron rods, provided with turn-buckles. The front, or side through which the wires enter, is made up of two thicknesses of two-inch plank laid diagonally to each other and fastened together with wooden pins. This was done to insure sufficient strength without framing and to permit the promiscuous boring for glass bushings. The inside finish of the tower is of hard oil varnish, and the outside of three coats of insulating and fire-proof paint. The roof is of slate, the eaves of which extend over the outside rack, thus, to a certain extent, sheltering it from the weather. At the bottom of the inside rack of the tower is an auxiliary slate switchboard of very simple construction, consisting of two rows of metallic bushings and binding posts. By the use of plugs and cables on this board the tangles and cross connections, incidental to all central stations are confined to this particular point. This arrangement also permits the transferring of circuits to any one of the sections of the main switchboard, thus adding to the flexibility of the entire system. From the outside rack, the wires are carried to a distributing pole (see Figs. 4, 5 and 6) of Norway pine set directly opposite the center of the tower. This pole is 92 feet long, 30 inches in diameter at the butt, 18 inches in diameter at the top, and is set 12 feet in the ground to insure stability. This height was necessary to allow wires to clear a three story building to be built in front of the wire tower. On this pole are fitted 11 double sets of eight pin arms, and 11 double sets of 16 pin arms, a total of 44 arms, providing for 176 wires, or 88 circuits. The 16 pin arms are set parallel to the arms on the tower rack, and the eight pin arms are at right angles to same, to enable wires to run north and south. These arms are of the best quality of long-grained oak of the following dimensions: Eight pin arms are eight feet long, three and three-quarters inches by four and one-half inches, pins nine inches between centers—excepting pins nearest the middle of arm, which are three feet between centers, to allow a man to pass between wires when ascending the pole. Sixteen pin arms are ten feet six inches long, four inches by five inches, with pins six inches between centers. The pins used on these arms are of selected locust, one and one-half inches in diameter, and the glass insulators are of the deep grooved double petticoat pattern. The bracing and fastening of the arms can best be seen by referring to the sketch.

---

[1] Abstract of a paper read before the National Electric Light Association, Buffalo, Feb. 24, 1892.

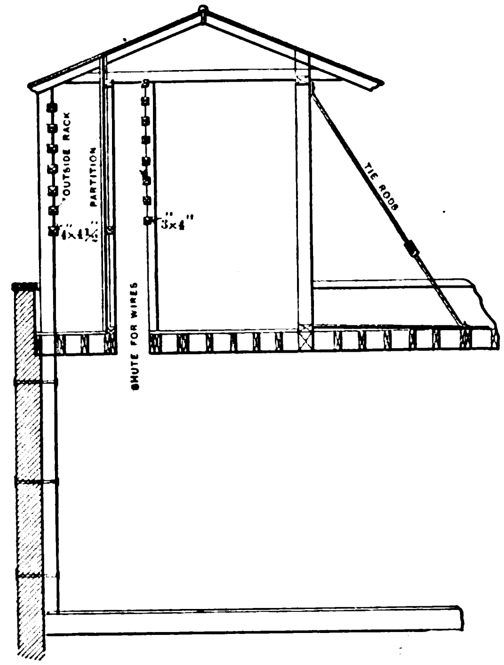

FIG. 2.

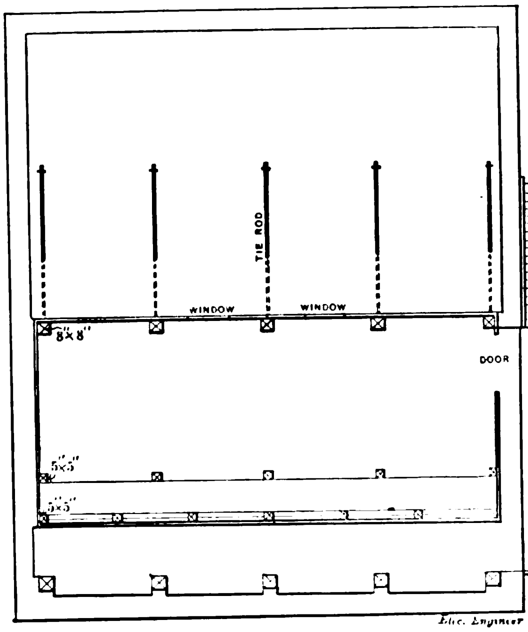

FIG. 3.

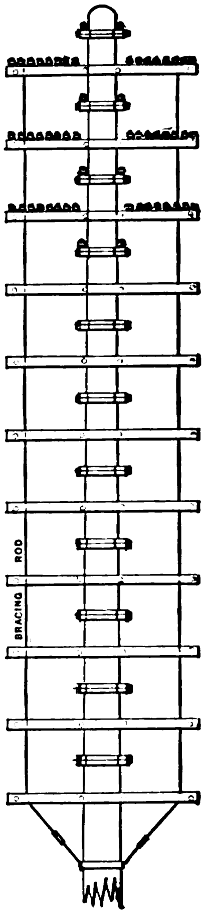

FIG. 4.

From this point the poles gradually decrease in length until a height of 50 feet is reached, which height is maintained on all our main lines. On lines carrying from eight to sixteen wires octagonal chestnut poles are used, 35 feet long, 10 to 12 inches at butt and six to eight inches at the top. Lamp poles are of the same material and shape, 24 feet long, eight inches at butt and six inches at top.

Particular attention is paid to the guying of poles where necessary; and we are using for this purpose four No. 6 B. & S. galvanized iron wires twisted together to form one strand, and introducing turnbuckles on all main guys. This wire is purchased made up in this manner, and we find it a great improvement and saving over the old method in vogue, of allowing linemen to waste their time in making up guys as needed.

While on the subject of poles, I wish to call attention to what I consider an erroneous method of treating poles to preserve them which is practiced by many companies. Pitch or tar is applied to the butt, thus confining the sap, which ferments and hastens decay. There are many different ways of treating poles, but I know of no method which is successful unless applied to the entire pole. The well-known creosoting process is objectionable on account of the dirt and the unpleasant odor connected with it, as well as the fact that the creosote does not penetrate to a sufficient depth. The same objections apply to the Burnettizing and Kyanizing processes. My attention has been recently called to the Haskins process, which seems to be highly successful. This process consists in the placing of timber in an air-tight retort and subjecting it to the heavy pressure of superheated air, which permeats the whole section, thereby accomplishing the same result as a charring process, without altering any of the chemical properties of the wood.

In regard to the character of wood to be used for poles, the choice is limited in the vicinity of New York, those obtainable being chestnut, Norway pine, Princess pine, cedar, yellow pine, spruce and white pine. The Princess and Norway pine, although not as durable as chestnut, are the most desirable for the heavier poles, on account of their straightness and size. For lighter work, I prefer hewn or sawed chestnut poles to all others, and they are still obtainable in lengths up to 40 feet. Cedar poles are excellent as far as life is concerned, but too crooked and knotty to be useful for first-class work. My experience with yellow pine, spruce and white pine has been very discouraging, the life of each being short and uncertain.

The next step in the way of improvement which suggested itself was a better method of hanging commercial lamps. It has always been a source of surprise to me that more attention has not been paid by lighting companies to this important matter. The small additional expense necessary to ornament these fixtures certainly ought to warrant an improvement. I have in use a fixture adopted by us which is not expensive, but neat in appearance, and it allows of a subtantial method of wiring without the use of other appliances. The fixture is made of wrought iron pipe, excepting the flange or T, which is of cast iron.

The scroll work in an ornamental fixture has been arranged to permit the introduction of the initials of the firm in front of whose store it is placed. The scroll letters are gilded, while the remainder of the fixture is black. The effect is both pleasing and attractive.

Last in the line of improvements came the wiring. It was only a question of rubber covered wires *versus* weather-proof.

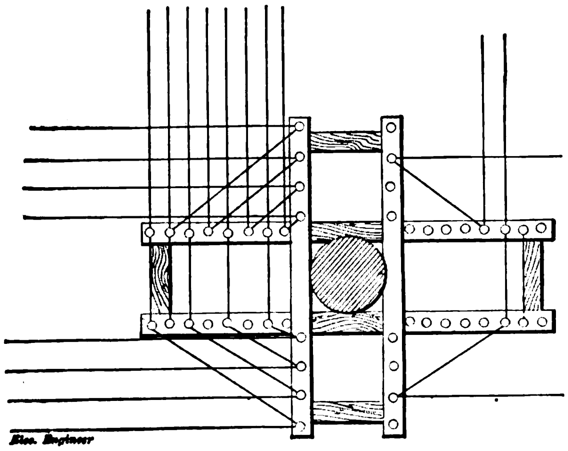

Fig. 5.

We compromised the matter by using the best grade of rubber covered wire for all leads from the switchboard to the main poles, and on all lines crossing under telephone and telegraph or uninsulated wires. For the balance of the reconstruction the best grade of weather-proof wire was used. It will be noticed that I have used the term "best grade" for both classes of wire. This term is a little ambiguous, as I am reminded each day by our friend, the wire salesman, who claims that his brand of wire is the best and that all other kinds are not in it. So it remains for the purchaser to judge for himself as to the respective merits of the different brands in the market.

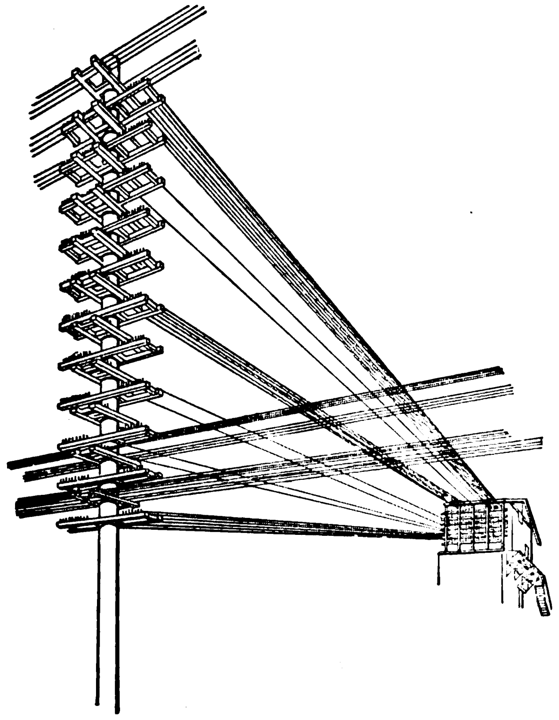

Fig. 6.

On some of the loops to buildings, where two or more circuits were necessary, we have used, with great success, duplex cables, thus doing away with a complicated and unsightly network of wires and fixtures. All wires are run on deep groove double petticoat insulators, the use of rubber hooks and porcelain knobs being avoided. It would be difficult to formulate rules for this branch of construction, it being simply a question of judgment and experience. However, a few suggestions may not be amiss. Great care should be used in the stringing of wire, for the insulation of a whole circuit may be ruined by the carelessness of linemen in handling. Joints should be soldered on all electric light work when possible. I have found that wrapping a joint with tin foil, and then covering with a good rubber tape, makes an excellent substitude for soldering, and is easily applied. Keep wires on the same relative pins to the end of the line, thus avoiding confusion, and making it an easy task to locate trouble.

Diagrams of principal poles, showing location of circuits, should be kept in every central station, for they are often the means of preventing serious trouble. Do not leave loops up that are out of service, expecting to pick them up again, as they may become a menace to your live wires. If more attention were paid to overhead construction by the electric lighting companies, substantial, neatly-painted poles being used, with well insulated wires kept taut and thoroughly inspected, the everlasting hue and cry against the "deadly" electric light wires would soon change to one of commendation and praise.

DISCUSSION ON MR. HERING'S PAPER.

(Concluded from page 219.)

that such prices were impossible in this country. Mr. Martin also doubted the statement as to a periodicity of 40 or 50 per second having been attained, and said that he understood it had ranged below 25. This was confirmed by Mr. Bradley, who said that it seemed difficult to get above 28. Mr. Martin also questioned whether it could fairly be said that the losses had all followed Ohm's law; the static conditions of the line had been abnormal and severe. He suggested that perhaps the Standard Oil Co. might lend them for experiment one of their pipe lines.

Mr. Stanley—It may interesting to the members of the Association to know that there is a line of 15,000 volts in operation in this country. We have constructed a small line at Pittsfield using 20 h. p. and fed by the station currents, the line starting at the outskirts of the town and making quite a little circuit. We find that there is practically no difficulty whatever at that potential; 15,000 volts, however, is a very different matter from one, or two, or three, or five, or ten, or twelve thousand volts. The striking distance at 15,000 volts is apparently two or three times what it is at 10,000 volts. For instance, if a wire hangs down from the line within an inch or two of the ground there is a most delightful aurora borealis between the ground and the wire; and if a dry board be interposed in the circuit—an ordinary pine board—it does not seem to affect the resistance of the circuit a particle. It goes right through it. We are making these tests at Pittsfield to become familiar with this question from a commercial standpoint, and have undertaken to transmit 400 h. p. for lighting purposes a distance of 28 miles in one place in this country. The delightful lecture given by Mr. Hering does not, however, give us some of the points which as engineers and as practical men we need in examining and testing the merits of the various devices. For instance, Mr. Swinburne wrote me the other day that from information he had received the Dobrowolsky motors—two horse power motors—required 4,200 watts to run at no load and 14,000 watts, or 10 times its rated capacity to run it at its full load, I do not mean that 14,000 watts are expended in the circuit, but I do mean that of the current apparently applied, viz., 14,000 watts, but 1,500 are actually useful. If this is an example of the engineering practice on the other side, I am very certain that my friend Mr. Stillwell can tell us that it is far below that obtained by Tesla. If I understand them correctly, the Tesla motor uses about .6 of its full load current to run it empty, .7 of which is usefully applied. That is to say, about .7 × .6 × the total energy, is required to run the motor empty. The synchronous motor has certain very beautiful applications, but it has a very serious defect in my judgment; that is, that when the motor is overloaded beyond a certain point, the motor not only stops, but it goes to pieces—burns up; or it is very liable to burn up. I do not see how any commercial system of distribution of power can be made when we have to start our apparatus by a weight as suggested by one gentleman; or by another motor, as suggested by another gentleman; or by three special circuits which will not work in multiple, except they work alone, the plan suggested by Dobrowolsky.

In the case of the transmission of power between Niagara Falls and Buffalo, I am quite certain that 15,000 volts could be loaded on the circuit between that place and this, but I am equally certain that no large amount of power can be transmitted successfully by the present apparatus. I mean with commercial success. If we are going to bring Niagara Falls to this city—or a small portion of Niagara Falls—we have got to adopt some scheme radically different from anything that has been presented up to the present; such as the scheme that Prof. Thomson suggested, and lay our wires at 100,000 volts pressure in an oil pipe. I cannot see that there is any half way solution of the problem.

Mr. M. C. Sullivan has been appointed New York agent of the New Process Raw Hide Co., with offices at the Electrical Exchange, 136 Liberty street, this city.

Modern science affords the best, the highest, and the most useful school of intellectual culture.—W. Mattieu Williams.

THE BUFFALO ELECTRIC LIGHT CONVENTION.

It is seldom that we have the opportunity to speak of a convention in such terms of praise as we feel inclined to use about the recent meeting of the National Electric Light Association at Buffalo. The reception accorded to the body by Buffalo and her citizens was most generous and cordial; the work done was of a high class right through, and there was a remarkable absence or suppression of "axe grinding," for which, presumably, we must thank a vigilant executive committee. The Association stands higher to-day in esteem and in results than ever before, thanks to the felicitous manner in which President Huntley has discharged the duties of his position; and he hands over to the competent hands of Mr. Ayer, of St. Louis, an organization in which central station men cannot but find a bulwark and a means of practical improvement.

A number of most excellent papers and addresses were delivered, and the advanced standard set by Mr. Huntley, in his address, and by Mr. Carl Hering, in his lecture on the Frankfort transmission, was maintained to the end. Mr. Stanley's paper on alternate current motors was an excellent exposé of the principles underlying the operation of these machines and of the difficulties encountered in their construction. Mr. Stanley believes that the reason why Mr. Tesla's motors are not more in use in this country is owing to the fact that the periodicity employed in alternating systems is too high; but the cause which we believe is the more probable one, is the fact that these motors require a special generator and at least three wires to produce the necessary phase difference. Messrs. Stanley and Kelly have set themselves the task of obtaining this difference of phase by a current splitter, which avoids the special generator and allows them to obtain any desired difference of phase. Their new type of alternating motor appears to resemble very closely the continuous current machine, in which special provision has been made to avoid currents flowing in the armature core, which they effect by a special close circuited winding directly enclosing the armature. The losses in the small motors of this type appear to be large, but they are in fact not much, if any, larger than those of the continuous current machines, although we believe it probable that larger sizes of alternating current motors of this design may not quite equal those of the continuous current type. Nevertheless it is apparent that if they can be placed upon the alternating current circuit they would have an unlimited field of usefulness, since efficiency alone is but one item in the many that go to make up a practical machine.

Mr. L. B. Stillwell's paper on "The Relation of Size and Efficiency in Transformers" is one that should be carefully studied by station managers. It has taken some time to develop the fact that the use of a large number of small converters is uneconomical, but exactly to what extent this is the case is now well shown in tables prepared by Mr. Stillwell. He shows that on account of the high loss in the iron in small transformers, coupled with the fact that the loss in the copper remains practically constant throughout the load, it is more economical to use a single transformer to supply any number of lamps up to one hundred in preference to a number of small ones of equivalent capacity. The discussion which followed Mr. Stillwell's paper brought out a remark from Prof. Thomson that in the ideal transformer the iron ought to be hot and the copper cold in order to obtain the highest efficiency, while Mr. Stanley inclines strongly to believe that the transformer of the future will have no perishable insulation whatever, so that it may be run at the most economical point, independent of its temperature.

The discussion on the amendments to the wiring rules showed that there are still questions to be solved in this field, notwithstanding the fact that much has already been done to tabulate the results of the best practice. The remarks of several speakers went to show that in more than one detail improvements in both the methods and the apparatus of distribution are still possible, and will have to be effected before they can be considered to fill the requirements of a safe apparatus.

Mr. E. A. Leslie's paper on the operation of high tension currents underground from a physical and financial standpoint and the discussion to which it led was one of the principal contributions to the work of the Convention. The paper itself was one of the best which has ever been presented at any meeting of the Association, and places in a clear light the enormous difficulties which have to be contended with in high-tension, underground work. Mr. Leslie shows the paramount importance of good joints and good laying, and we think it well to freely admit, as he does, the success of such underground cables when properly installed. His frankness in this regard we think would bring conviction with it to those who might otherwise stand aghast at the figures given in another part of his paper relating to the cost of underground work. Mr. Leslie showed that the cost of connection to city lamp posts, including pipe, labor and cables, averages no less than $110 per post, and to this initial cost must be added the enormous cost of the rental of duct, cost of cable, etc. This he shows, as compared with the overhead system, to be five times as expensive for the same service. The enormously increased difficulties of earning dividends under such circumstances, and the restrictions which a company forced to go underground would suffer thereby, ought to be sufficient to awaken to a sense of responsibility those who blindly advocate burying all wires irrespective of the conditions involved.

One of the most encouraging features in connection with the Buffalo Convention, and one which the members were not slow to acknowledge in words of appreciation, was the fact that such men as Prof. Elihu Thomson, Mr. Wm. Stanley, Jr., Mr. L. B. Stillwell and others attended all the sessions and freely gave to the members their experience on the numerous points involved which were brought out in the discussions. The value of the presence of men who have created the apparatus employed and who know its character, perhaps better than any one else, is so apparent as to require no further pointing out on our part; and we consider this one of the most hopeful evidences that the Association commands the attention of electrical workers and engineers as well as that of the central station men, thus illustrating the fact that success achieved by the one means the success of the other.

Owing to the fact that no paper was presented at the meeting bearing specifically on the subject of steam engineering in connection with electricity and its distribution, this subject received no attention whatever. This is somewhat to be regretted as the marked changes which have taken place in this direction would have been sufficient to form the basis of an interesting discussion. Notwithstanding this, we think, without seeking to make any invidious comparison, it may be truthfully said that in the point of practical information as regards the papers and discussions, and in the interest manifested by the members throughout, the Buffalo Convention was the best, thus far held, in the history of the Association. This meeting has demonstrated the fact, if such demonstration was still required, that the Association has a *raison d'etre*, and what is more, that it has a mission to fill the importance of which is increasing day by day.

ELECTRIC LIGHTING FROM A FINANCIAL STANDPOINT.[1]

BY ERASTUS WIMAN.

HAVING in the process of time developed a large demand for light, evidences of which are seen on every hand; having at the same time gone through a most unusual experience in not only creating that demand, but in the production of the article for its supply, a review is in order as to the present position of electrical securities and the prospect of profit. It may as well be admitted that there has been a serious and costly struggle, and that, taken as a whole, the results in the shape of a total profit on the total investment in electric lighting is not to be seen in the shape of dividends. There are, however, happily, exceptions to this general statement, and in the returns sent to me from all parts of the country, there are a considerable number of companies whose career has shown that in electric lighting there resides the potentialities of a profit, equal to that of any legitimate enterprise. The successful companies illustrate what it is possible to do, and though they may not be numerous in comparison with others whose record for profit is small or who report a loss, yet that money can be made continuously and rapidly out of electric lighting is clearly demonstrated. In order to cite an example of steady growth in revenue, and also to show the corresponding ratio of expense, I append the figures for seven years, from one of the most successful companies in the East, whose management has been characterized by the highest ability, and whose location and name it would hardly be proper to disclose. The figures are authentic, and show a record of which any man might be proud.

EARNINGS OF AN ELECTRIC LIGHT COMPANY.

For 1885—Receipts	$30,768.70
Expenses	24,901.54
Net earnings	$5,867.16
For 1866—Receipts	$47,613.76
Expenses	34,700.83
Net earnings	$12,912.93
For 1887—Receipts	$57,750.71
Expenses	34,691.85
Net earnings	$23,058.86
For 1888—Receipts	$75,734.14
Expenses	46,235.83
Net earnings	$29,498.31
For 1889—Receipts	$135,254.08
Expenses	94,178.69
Net earnings	$41,075.39
For 1890—Receipts	$199.195.72
Expenses	150,195.48
Net earnings	$49,000.24
For 1891—Receipts	$247,679.88
Expenses	187,092.77
Net earnings	$60,587.11

The company commenced to pay dividends January 1, 1887, at the rate of 8 per cent., payable in quarterly dividends of 2 per cent., and have continued the same up to date.

Before closing the books December, 31, 1891, there were charged off from the earnings of 1891, for depreciation, $10,000 from the steam plant. and $30.000 from the electric plant. On January 1, 1892. capital stock $800,000, surplus $90,000.

The above figures speak for themselves, and in the progress shown in receipts and profits there is contained a hopeful sign for many another company whose career up to this time has yielded an inadequate return. Indeed, to present a totally different picture, here is an extract from the letter of an esteemed Western friend that shows the ruins of a senseless competitive struggle and the folly of low prices:

"I am the president and manager of five electric light companies in this city, but *three* of which have actually survived financial pressure and bankruptcy. One of these three, with a a capital of $150,000, fell behind nearly $100,000 in seven years, and last year the stockholders voluntarily came up with an assessment of $60,000 to save it from bankruptcy. Another, working under the strictest economy, is but barely able to meet operating expenses. Still the other, a foundling of the Gas Company, is, under exceptionally favorable conditions, and paying no salary to its executive officer, making a little money; after 18 months' operation, it last month declared a dividend of 3 per cent."

With such an experience it is no wonder that the gentleman writes as follows: "I am aware that books can be kept so as to show an earning, but this is in many cases at the expense of a constantly depreciating capital investment."

As a matter of course the profitableness of any undertaking depends upon the prices obtained. In my judgment electric light projectors are themselves to blame for loss of profit through false representations as to the economy of operations. If the truth had been told, and contracts refused except upon a paying basis, the electrical business throughout the country would now be upon a much better footing.

The promoters of electrical enterprises, and the sellers of electrical apparatus and appliances are rapidly killing "the goose that lays the golden egg" by falsely representing the great economy of operation, and consequently the great profits of such undertakings, thus falsely educating the public into the belief that anything like a reasonable price is extortionate. The true policy of the friends of the electrical industry should be directed in just the opposite course to that which you propose pursuing, namely, to show that electrical undertakings upon the basis of the present prices *are not profitable*, and if they expect perfect service they must pay better prices, prices that have prevailed because the companies themselves have not heretofore appreciated and understood the cost of operation, and the great loss due to accidents and rapid depreciation.

---

[1] Abstract of a paper read before the National Electric Light Association, Buffalo, February. 24, 1892.

FROM THE TANNERY TO THE DYNAMO.[1]

BY CHAS. A. SCHIEREN.

It may be of interest to engineers, and the electric light fraternity in general, to learn something of how leather is tanned, and the various processes through which a hide passes before it is tanned and curried ready to be put into belting. Naturally, the first question will be, "Where do all the steer hides come from?" Principally from Chicago, because within its city limits there are four large slaughtering establishments where thousands of cattle are slaughtered daily, the hides of which are carefully taken off and assorted for whatever purpose they are best suited. The hides which are heaviest and most perfect in point of freedom from cuts, brands and other blemishes, are selected for belting leather. These hides are put up in bundles, packed into a freight car, and shipped to the tannery.

We propose to follow one of these freight cars loaded with belting hides to its destination. After a journey of about 600 miles, the car arrives at the little station of Adamsburg, Pa., right in the mountain region, a spur of the Alleghenies, where the tannery is situated.

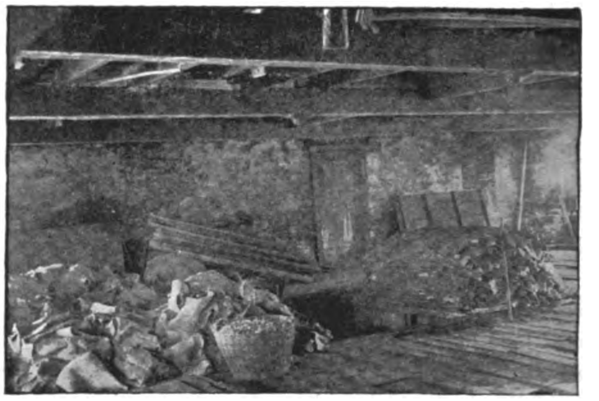
Oak tanneries are generally placed near the bark region of the mountains, where the rock oak tree predominates, the bark of which is universally conceded to be the best for making the finest grade of leather. It is interesting to watch the mountaineers fell the huge oak trees, and skin the bark from the same. This is generally done in the springtime, and tanners have to purchase their year's supply during the bark peeling season, which is from the middle of May to about the middle of June, according to the condition of the weather; the season seldom lasts over six weeks. If the sap rises into the leaves the bark cannot be taken off, and, therefore, oak trees are only cut down in that period.

The peeling of the bark is done wherever the trees are felled; the bark is gathered together in small stacks and covered to protect it from getting wet, because the strength of the tannic acid is lost by the bark getting wet; it must also be carefully guarded against mildew. Mountain fog is very damaging to peeled bark, therefore the mountaineers load the bark in wagons and deliver it as quickly as possible to the nearest tannery or railroad station.

UNHAIRING HIDES.

However, our car of belting hides has arrived at the station, and we will watch the process of tanning. The hides are examined and weighed, and put into the shed; an equal number of hides are taken out daily (whatever the capacity of the tannery may be), and placed in a large vat of pure cold water, generally good spring water. After the hides are thoroughly soaked and the dirt washed out, they are laid across a beam and, with a blunt fleshing knife, the surplus fat or meat still remaining is taken off; then they are placed in a vat of weak lime water, and are hauled up daily and the lime strengthened until the hair gets loose, which action takes about eight days. After this the hides are cleansed once more in pure water and placed over the beam and, with a blunt knife, the hair is removed; this part of the work is done in what the tanners call the beam or lime house, and very much depends upon the successful liming process in making good leather.

After the hair is off, the hides are washed again and thoroughly cleansed and purified, to remove every particle of lime, after which process they are taken into the handlers. These are composed of large vats, about seven by nine feet, and six feet deep. The hides here are laid across sticks side by side, as close as possible, and hung about three inches below the top of the vat. These vats are generally connected so that when the first vat is fed the tannin liquor will pass through every vat until they are all filled, and cover the hides completely. In the handlers the hides receive their first bath of tannin liquor, which is very weak at the start, and gradually strengthened. During this first stage of tanning the hide plumps up, and is prepared for the lay-aways; this process also opens the pores and swells the hide, which gives thickness and firmness to the leather. If the hides cannot be made thicker at this period of the tanning, they will never be made heavier afterward; this is the critical point and has to be watched closely. Much depends upon the character of the tannic acid; if too strong, it tends to make the leather brittle and harsh; if the tannic acid should be too sour, it tends to make the leather soft and flabby.

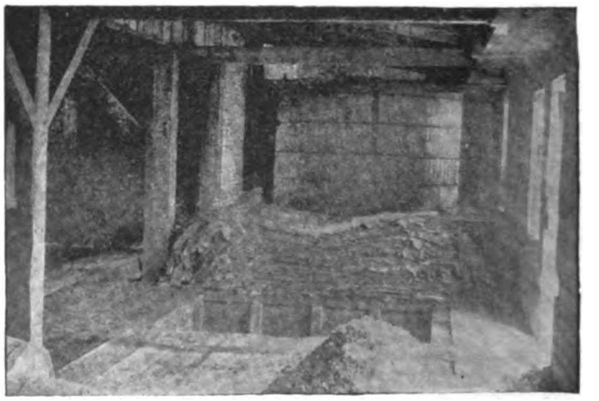


TRIMMING HIDES FOR LAY-AWAY VATS.

Some tanners use a rocking process to keep the hides in motion, thereby opening the pores of the hide quicker to receive the tannic acid; however, opinion differs as to the utility of the rockers, some claim (and justly) that the rocking motion loosens the fibre of the hide, and softens the leather too much. The best process is to simply hang them in the vats and cover them with the tannin liquor, and raise them a few times during the day, or draw the liquor through them, which some tanners are now doing with success.

The tannic acid in the handlers generally has a strength of from five to fifteen, very seldom over twenty degrees. The hides remain in that process from ten to twelve days; they are then taken up and, if they are to be used for belt leather, the flanks (bellies) and heads of the hides are cut off and tanned separately; the remaining butt part receives an extra layer of bark to tan it more thoroughly and make it firmer.

From the handlers the hides are packed away in vats, called lay-aways; these are large vats seven by nine feet, and six feet deep, having a capacity of from fifty to seventy-five hides each. The vats are not connected with each other, but only with the pump to change the liquor. The hides are laid nicely one on top of another, and loose ground bark spread between each hide, and when the vat is full it is filled with tannin liquor of from twenty-five to thirty degrees in strength. The hides intended for belting receive at least six layers of bark, or in other words, are changed six times in the lay-aways; the first time they are changed after lying ten days, and then five days are added after each layer, so that the hides in the last or sixth layer will take forty days to absorb the tanning liquor and penetrate the leather. Each time fresh ground bark is spread between the hides and then covered with tannin liquor.



TAN PITS AND FEED TANK.

The leaching and grinding of the bark is an important factor in a tannery. The large pieces of bark taken from the oak tree are thrown into a hopper-shaped mill or grinder, which resembles a coffee grinder on a large scale. The ross on the outside of the bark creates a great deal of dust, and contains little or no tannin, but it cannot be severed from the rind which really contains the acid; from the bark mill the ground bark is elevated into large tubs which have false bottoms, or receivers underneath to take up the tannin liquor. After a tub is filled with ground bark, a rotary sprinkler is set in motion to saturate the bark with a spray of water or liquor, which percolates through the ground bark, and on its way to the bottom catches up the tannic acid contained in the bark; at times warm water is used to facilitate the operation, also weak tannin liquor is used sometimes with good effect; however, old school tanners prefer cold water, which they claim makes purer and sweeter tannin liquor. After the receivers at the bottom of these tanks are filled, the contents are pumped into large supply tanks, from which the liquor is distributed through the tannery as required.

---

[1] Read before the N. E. L. A., Buffalo, Feb. 24, 1892.

The leaching process is the most interesting and valuable operation in the tannery, and upon its skillful management depends the financial success of the business; opinion differs very materially as to the best method. The large round leach tubs, such as described, are the most popular now in use; however, many tanners still adhere (and some with success) to the old square passed leach tubs, in which the ground bark is simply soaked or steeped in water and left for a length of time, until the tannic acid is extracted from the bark. Opinion also differs as to using steam or hot water; however, all have their merits.

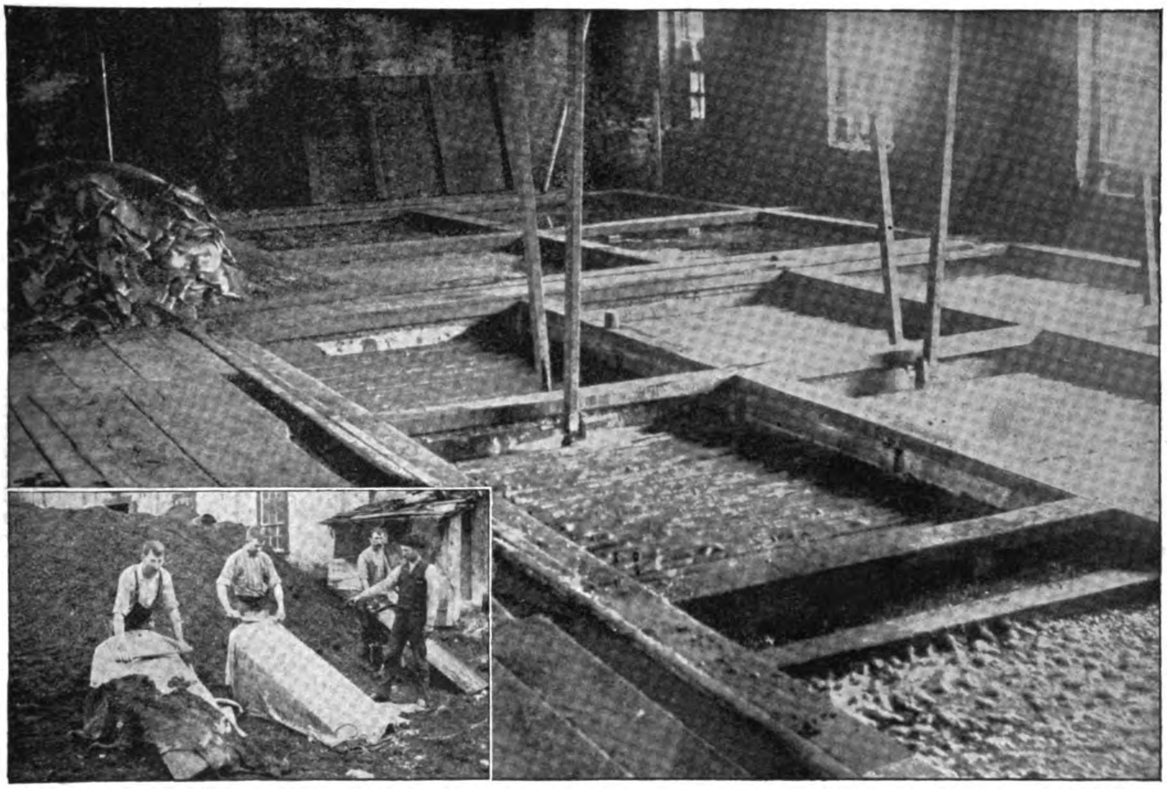
Very strange and erroneous ideas prevail among those who use leather, and have no knowledge of the art of tanning; certainly it is an art, and one of the oldest handed down to us. The general opinion prevails that leather made in "ye olden time" is superior to ours of the present time, but such is not the case; in fact, the fundamental process of tanning to-day is precisely the same as that of a thousand years ago, except that we enjoy improved machinery and appliances which further the process and improve the material. What took our forefathers from fourteen months to about two years, we accomplish in from four to six months, and the quality of leather is as good, if not superior to the leather made a hundred years ago; with the aid of steam and power we can facilitate the process and shorten the length of time to produce the leather. The "olden time tanneries" had the lay-away vats in the yard exposed to the elements, and in rainy and inclement weather, as well as during the winter, the tanners could not do any work, and left the leather lying in the vats, generally to the detriment of the stock. In our present improved and model tanneries everything is done under cover, even the bark is put under sheds to keep it dry, and good leather is tanned within four months; however, belt and prime harness leather generally takes six months.

When the leather is taken from the last layer of bark, it is oiled on the grain and hung up in a darkened room to dry; to obtain a nice clear russet color the place must be kept at an even temperature, and very little heat used. After the leather is thoroughly dried it is put up in rolls containing five butts (hides) each, and whenever a carload is ready it is shipped to New York; here it is again examined and weighed, and all butts not suited for belting are thrown out and finished into sole leather for shoe purposes.

The perfect hides for belting are soaked in warm water, and the centre part cut out and used for prime belting; the waste or offal is finished and rolled for shoe purposes. When the pieces are thoroughly scoured and cleansed they are oiled on the grain and hung up to dry, and when in a semi-dry condition, they receive a coat of stuffing made of equal parts of cod oil and beef tallow. This is done to preserve the leather and make it pliable for the transmission of power. After the stuffing has entered the pores, which takes about twenty-four hours, the leather is subjected to great strain in large stretching machines; great care and good judgment must be manifested in this part of the process. Each piece of leather must receive an equalizing strain because of the peculiar formation of the hide, the fibres being very fine and closely knit together on the back of the animal, and running coarser and thicker towards the flanks. It is of the highest importance, for belts intended for electric light plants, to have an equal tension over the entire surface of the belt; therefore, the stretching process of belt leather needs the utmost care, and should receive the closest attention. After the pieces of leather are thoroughly stretched, they are worked smooth on the grain side, and both by hand and machine labor are set down as solid and compact as possible; then they are put into a drying room and thoroughly dried. Afterwards one edge of the pieces is straightened, and they are then cut into whatever width of belt they are best suited for; the pieces of each width are matched accurately as to thickness, and then the laps (joints) are cut by a machine, the edge of the laps are feathered, and the joints cemented (glued) together, and pressed under a hydraulic press, which pressure is considered the best by all first-class belt makers.

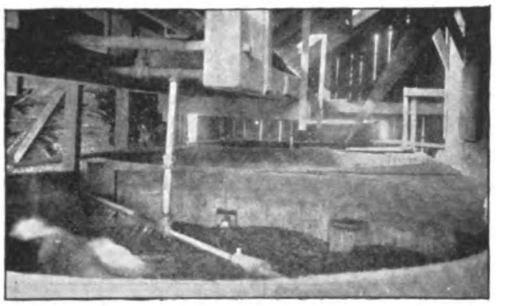
Rivets are now rarely put into belts; a double belt well cemented is good for all ordinary purposes, and rivets are superfluous; however, certain fastenings, such as endless copper wire screws, which do not obstruct the surface or unnecessarily stiffen the belt, are a benefit; especially when the belt comes in contact with water or too much oil, this fastening prevents the belt from coming apart, and holds the leather firmly together.

All main driving belts over forty inches in width have to be



HANDLERS AND FLESHING HIDES.

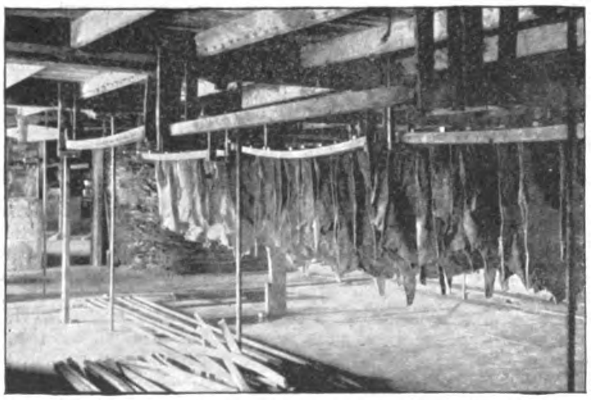
made in sections, consisting of two or more pieces of leather cemented together; the average hide for belting does not contain more than forty inches in width of solid leather suited for belting, very rarely over that; therefore, wide main belts are made in sections. Ordinarily the pieces are not lapped parallel, but simply butted. For example: A sixty-inch double belt receives two thirty-inch pieces for the first layer, laid side by side, and a thirty-inch piece over the centre of the two lower pieces to break the joint, and two fifteen-inch pieces on top of each edge of the lower layer to complete the width; thus the belt is cemented together.



Leeching Bark.

However, for electric light plants where belts are run at high speed and with variable power (which produces sudden strain), the seam of these butted joint belts, in several instances, broke, doubled up and destroyed the belts completely. To guard against such a calamity it is considered advisable to make wide main driving belts with parallel joints. For example: A sixty-inch double belt will be made of two thirty-three-inch pieces joined parallel, with a three-inch lap, making one solid piece sixty inches in width, and on the upper part put a thirty-three inch piece in the centre, and two eighteen-inch pieces on the edges, all joined with parallel laps; this cemented together will make a sixty-inch double belt with unbroken surface, and as one solid piece of leather having a uniform tension and able to withstand an equal strain over the belt transversely as well as parallel, and thus will prevent such large, heavy driving belts from collapsing at the parallel joints. Every one must admit that main belts made on this plan are superior, and more reliable, and would come into general use if it were not for the additional cost of labor and material in making them.

Leather being by nature an absorber of moisture, belts must be guarded against exposure to oil. In electric light and power plants much mineral oil is used, and the great velocity at which the belts are run seems almost imperceptibly to suck or draw the oil from the journals of the engines and dynamos, and allow it to be absorbed by the belts, which get completely saturated with oil. This in a short time rots and destroys the fibre of the leather. Various methods have been used to overcome this difficulty. One of the most successful is a certain composition or belt dressing which is rubbed over the surface of the belt, and closes the pores of the leather. No foreign substance can penetrate a belt treated with this compound, and the belts last much longer and give better service. With perforated belts this compound does not seem to be so effectual, because the perforations naturally expose the inner part or the heart of the leather, which is very porous; however, the surface of the belt being covered it shields that part of the leather which comes in contact with the pulleys, and the current of air passing through the perforations protects the belt to a certain extent, and that class of belt runs smoother, with less friction and is more reliable.



Drying Loft.

And now, gentlemen, we have reached the point where another curious and erroneous idea prevails among many engineers, namely, that belting should be made of pieces only four feet in length; as if all hides were of the same length and texture; it will surprise these men to learn that there are no two hides alike, they vary in some particular point. Hides exist which will make almost six feet of sound solid leather below the shoulder, and again some hides will not make four feet of solid length; the only safeguard is to specify belting made of leather cut below the shoulder of the hide, irrespective of length.

Now, gentlemen, I have endeavored to show you, in this paper the various processes and changes to which a hide is subjected in its travels from the "Tannery to the Dynamo."

HOW TO FIRE A BOILER.[1]

BY R. HAMMOND.

It has been said that the waste of fuel due to improper firing is often of more consequence than any other loss which is produced in the operation of a steam plant, but in a great many cases the waste of fuel cannot be entirely charged to improper firing, as there are other causes by which a waste of the evaporating power of the fuel is produced. The principal of these are: First, the improper construction of the boiler in relation to grate surface, tube area, heating surface and combustion chambers; unless these proportions are properly worked out, it matters little whether the firing be done by mechanical means or by the more intelligent fireman, waste of fuel must necessarily follow.

A great many contrivances have been placed on the market, such as mechanical strokers and other means by which coal and air can be supplied to the furnaces of steam boilers for the purpose of obtaining good combustion without producing a waste of heat by allowing too much air to pass above the grates or an insufficient supply below the grates; by this statement I do not mean that any particular method of firing will produce any more heat from a pound of coal than Nature put into it; just as good results can be obtained from hand firing as have been obtained by the best mechanical means.

It is often the case that firemen are paid insufficient wages for the work they are expected to do. We should be as particular to have good firemen in charge of our boilers as we are in having good engineers in charge of our engines; a good fireman should be just as capable of manipulating the furnaces of his boiler so that his steam recorder and his coal and water records will show just as good cards as the engineer can show in the manipulation of the steam he uses in his engine. If we paid the same attention to all the details of the construction and setting of our boilers and their economical use of fuel as we do to our engines our steam plants would be far more economical; everything is "*shined up*" about the engine. Engineers go into all the details of its construction and management and the greatest care is taken in the figuring out of its proportions so that it will have the very highest possible initial steam pressure and temperature and the very lowest possible terminal temperature and pressure; all endeavoring to get the greatest horse power from the pound of coal, thus securing the greatest economy. These very same highly educated individuals, who designed these engines, forget that all the power comes from the pound of coal and pay little attention to how that power is transmitted from the coal pile to the engine. It is just as essential to good economy that the boilers should have the very highest initial or furnace temperature, and the highest possible steam pressure, and the lowest possible chimney temperature, as it is for the engine to be economical under similar conditions of high initial pressure and temperature and low terminal temperature.

Experiment has proved that bituminous coal requires 150 cubic feet of air per pound of coal for good combustion; an excess of air results in a waste of heat which it carries into the flues and chimney and often a greater loss in an insufficient supply to produce good combustion.

In my experience for steam plant boilers carrying 80 to 160 lbs. of steam, I find that at least 20 lbs. of bituminous coal should be burned per square foot of grate per hour, and the air spaces of the grates should not be less than 50 per cent. of the grate area, and the draft pressure not less than one-half inch of water; if the grate surface is so large that only 10 lbs. of coal is consumed, it would be more economical to reduce the grate surface and burn not less than 20 lbs. with good draft, thus securing a good combustion. The same weight of coal burned on a large grate would not be as economical on account of the low temperature; the temperature of the furnaces should not be less than 3,500 degrees, and the ratio of the draft area through the tubes or flues should not be less than one-sixth, nor more than one-fourth, of the grate surface, and the proportion of heat surface to grate surface should be at least as 35 to 1.

---

[1] Read before the National Electric Light Association, Buffalo, Feb. 25, 1892.

Under the conditions just stated, boilers should be fired very economically whether done by mechanical means or by hand. I have noticed in firing marine boilers on the great lakes that the firemen spread their coal evenly over the entire grate at each firing, and they produce steam very economically, while firemen on coastwise steamers will pile up the coal just inside the furnace door and as it becomes coked will rake it back over the incandescent fire and grate with equally as good but no better results in the way of economy than obtained by the lake firemen; both of these ways of firing are equally good, but in all cases the grate bars should be entirely covered, and the amount of air required above the grate should be admitted from above instead of below the grate.

Different grades of bituminous coal require different methods of firing, and by a little experiment the experienced fireman soon finds out and adopts the best method of firing, and in all cases he should keep his flues and tubes clear of ashes and soot, as well as his fires and grate bars. In firing anthracite coal, the coal must be spread evenly over the grate in all cases, and like bituminous coal must be burned at a high temperature with good draft.

Steam users should see to it that all parts of their boilers and settings should be of equally as good proportions for strength and economy as their engines; employ good, intelligent firemen as well as engineers, and see that both produce good indicator cards. By a little attention in this direction steam users will themselves soon become experienced firemen and engineers and can readily tell whether the firemen and engineers are doing their duty.

THE CONSTRUCTION, SAFETY AND OPERATION OF SWITCHBOARDS.[1]

BY M. C. SULLIVAN.

THE manager, who has seen his station grow from a mole hill to a mountain, who has been compelled to add on dynamo after dynamo to satisfy the demands of the maddening crowd, now has a problem on his hands to equip a switchboard that will not only handle the service of the present time, but what is in store in the future. He knows from experience that what may be called the "skeleton board" with spring-jack connections, will not suffice for this, and he must look about for another method. In thus casting about for the proper assistance, the manager is unfortunately thrown upon his own resources. A great source of the trouble are the cables, or flexible conductors, used for making the cross-connections from one part of the board to the other. While we may exhaust every means to make the operator safe from contact, the use of these cables cannot very well be eliminated. It is possible, however, to construct a board on which any combination can be made without cables, but it would be so large and cumbersome as to become practically inoperative, in fact would be a very complicated affair. It is nevertheless practical to equip a board for arc service so that every part of the live circuit would be entirely insulated from the front. For large composite stations, embracing arc and incandescent lighting, of both high and low tension, and power generators for street railways, condensation is one of the vital features, not in the sense of crowding anything, but of utilizing every inch of space to install the apparatus necessary to do the work required. A most effective way to build a switchboard for stations of this character is to have it arranged in the form of a square so that one side could be devoted to each division of the service.

Stations occupying a large open floor with high ceiling present the opportunity for building the ideal switchboard. This could be raised above the floor a sufficient distance so as not to occupy any valuable floor space. For this matter it might be suspended from the ceiling. The wires from the dynamos could run directly to the left, thence through the switchboard, and from the latter to the cupola, arranged as nearly over the switchboard as possible. This arrangement would give us a central starting point for our lines, enabling us at once to trace every wire of the system. However desirable such an arrangement as the above may be, the conditions are such that we cannot always do as our best judgment dictates, but rather have to make the best of things as we find them.

The prime object to be secured in switchboards for high-tension service is safety, not only to the attendants, but to the station. This can be accomplished by having every part of the board over which current is transmitted insulated in such a manner that contact from the front is impossible.

The prime necessity of switchboards in railway power stations is facility for rapid manipulation whereby any part of it can be reached in the shortest space of time. Here also the indicating instruments must be within plain sight so that the movement of the current, with its rapid vibrations, can be readily noted.

We now come to the most important feature of the whole question; what material should be used for our switchboards? As it must be fireproof, the use of wood is entirely prohibited. We must therefore look for something entirely different. Various efforts have been made to make wood fireproof. This has been accomplished to a limited degree, but the element of doubt still remained. Slate, as many of you know, is the best thing that Nature has yet offered us. For strength, lightness and insulation it is the only material in sight. Unfortunately, however, slate is an alluvial deposit of a laminated character and often contains metallic substances which destroy its insulation, making short circuits and other disagreeable elements. When in the rough stone it is hygroscopic to a considerable extent, and when it becomes saturated with moisture makes surface leakage possible. Great care should be consequently exercised in selecting slate for switchboards, and only that which possesses absolutely no metallic properties be used. This can be determined by the well-known rules of electrical testing.

The drawbacks met with in slate have determined some manufacturers in using marble for this work. This has only one-fifth the breaking strain of slate, and where it is used in the place of slate this must be taken into account. Marble presents the same hygroscopic elements as slate, and there is some metal in it, but owing to its peculiar formation, this metallic substance is not present in any great quantities as it is between the laminations in slate.

Iron should be used for the framework of all switchboards, and in the case of high-tension circuits a wire should be run from this framework to the ground, which is entirely insulated from the circuit, so as to prevent the board from becoming charged and discharging through a person who happens to be near by. Complete plans and specifications should be perfected, so that when an order is given to the manufacturer to make a board, you will know whether it is his fault or your own if things do not turn out as you desire. This may require more time and attention than you wish to give this branch, but if you have experienced the inconvenience some people have suffered, you will feel very much different.

MUNICIPAL FRANCHISES FOR QUASI-PUBLIC CORPORATIONS.[1]

BY ALLEN R. FOOTE.

I BELIEVE that an American economic system is as necessary to American industrial independence as was or is, an American political system to American political independence. The particular feature of foreign economic systems to which objection may be incidentally made in this paper, is State or municipal ownership of industries. Those who advocate such a policy in this country are wrongly educated foreign socialists and college professors who have been educated abroad.

A franchise is the title deed upon which quasi-public corporations are founded. A perfect franchise should legally contain every provision that is essential in a deed to real estate, every provision that is required to establish the rights of property, every provision that maintains the rights of free labor.

The production, transmission, subdivision and cost of mechanical power determines the number of persons who can use such power *with a profit*. The number of persons such users of power are able to employ with a profit, determines the number who can enjoy *the rate of wages* the utilization of mechanical power enables such employers to pay. Cost of power is the determining factor. The lower this cost, the better the opportunity for making a profit. The more certain a profit becomes, the greater will be the number of persons employed. The larger the number of persons employed, the smaller will be the number of the unemployed. The smaller the number of the unemployed, the better will be the wages of the employed, and the smaller the tax on the employed for the support of the unemployed, the greater will be *the profit of labor*. The greater the profit of labor, the greater is the prosperity of individuals, municipalities, States and nations. While every person has a vital interest in the settlement of questions affecting industrial prosperity properly to secure the greatest economic advantage, those most interested are the wage-workers and the unemployed.

Properly to supply these needs, it is necessary to create quasi-public corporations, and grant to them franchises giving them the right to construct, maintain and operate the necessary works, and to construct, maintain and operate through the streets and alleys, the necessary street and service connections to enable the service to be supplied to every building in the municipality. The importance of the organization and facilities granted to such corporations will be quickly appreciated if any citizen will ask himself what the industrial, commercial and social advantage to his municipality would be if it were true that all these services were there rendered at a less cost to the user than in any other municipality in the world. No one will have to think long or closely on the subject to become overwhelmed with his conception of the vast magnitude of the value of such advantages. How properly to secure such advantages is a question requiring clear perception, broad views and an entire absence of prejudice, or interests that tend to sway the compass needle by so much as a hair's breadth from the true point of direction, and a calm, unyielding judgment. Men so dishonest as to be willing to divert, by force of legal enactment, a portion of the profits of industry from those who incurred to those who have not incurred a risk in their production; men so incapable of a correct judgment as to denounce rent, interest and profits as robbery; men so prejudiced against monopolies that they regard them with fear and hatred; men so full of sympathy with the sufferings of the poor that they are blind to the cause of their sufferings, are not safe guides for public opinion.

---

[1] Abstract of a paper read before the N. E. L. A., Feb. 25, 1892.

[1] Abstract of a paper read before the National Electric Light Association, Buffalo, February 25, 1892.

A means of producing light, heat and power for public and private use, distributed from a central station, is a perpetual municipal need. The best interests of its users demand that such means shall be abundant, wholesome, reliable and safe, and that it shall be furnished at the lowest possible price. That these requirements may be properly satisfied, true economic conditions demand:—

First. That a corporation organized to supply a perpetual municipal need shall have the exclusive right to perform the service perpetually.

Second. That the service shall always be supplied by the best methods known to science that are made commercially available by the best practices known in the art.

Third. That all accounts shall be honestly and correctly kept, that economic thrift be insisted upon in every department and that charges be so fixed from time to time, by a competent and disinterested tribunal, as to yield a revenue sufficient to pay all fixed charges, expenses of administration, operation and maintenance, and a reasonable per cent. dividend annually upon the investment.

A comparison of these economic conditions with the conditions fixed by the laws on this subject in all States will quickly show how blindly the blind have been led in efforts to secure the greatest good for the users of the services supplied by municipal franchise corporations. Had laws governing the organization, management, and control of municipal franchise corporations been enacted in accordance with the requirements of true economic conditions, instead of in compliance with the dictates of an unintelligent self-interest or prejudice, how great the change in their wording and meaning would be. There would have been no reference to a particular source, force or instrument, such as gas, telegraphs, telephones, electricity or horses. *The character of the need to be supplied, not the character of the method of supplying it, would have determined the designation of the work to be done.* The sovereign law of labor and property would have protected the right to work.

So rapid and so radical have been the industrial changes wrought by a growing intelligence, encouraged by the acknowledged freedom and dignity of labor, facilitated by the right of private initiative, driven by the energy of hope, inspired by the certainty of owning the profit for the risk incurred, that in a single decade the methods in use at its commencement become obsolete before its close. As a result, the strongest barriers to progress that now exist are the limitations placed on municipal franchise corporations by legal specifications defining the methods to be employed instead of the character of the need to be supplied. The wisdom of the Fathers was not equal to our own. All such barriers must be brushed away.

What would be thought of persons who would undertake to secure improvements for a city in the form of buildings of the largest dimensions, employing the most durable material and the best style of architecture, by offering a title to real estate on which the buildings were to stand, that did not guarantee exclusive possession, and perpetual tenure? The moral and economic sense of the community would be shocked by such a proposal. Yet there are persons in every community who will contend that works costing more than the best buildings in the city which, if operated under true economic conditions, will inevitably enhance the value of all inter-municipal real estate more surely than any other factor of modern civilization, shall have no better title than the one indicated.

How supremely ludicrous a city council would appear that should vote that a street railroad company might use horses to draw its cars but should not use the best horses it could buy. How strange it would seem if a State Legislature should enact a law that a company might generate and distribute gas for the purposes of light, heat and power, but that it should not adopt the best gas-making methods. These things are all as consistent as laws providing for the supplying of municipal needs by mentioning the methods to be used and thus limiting municipal franchise corporations to the use of the methods named, instead of requiring them to adopt the best known methods at the time of incorporation or that may thereafter become known. How strange it appears in the light of the requirements of true economic science that municipalities have supposed they could obtain a supply for a perpetual need, requiring expensive plants, conductors through all streets, service connections to make the supply available in every building, and have the service wholesome, reliable, safe and rendered at the lowest possible price, in the way in which they have undertaken to secure these advantages. They have limited the right to do business to a comparatively short term of years. They have allowed others to build, as it were, on the same piece of real estate. They have limited the methods to be used, so that, when the discoveries of science and invention have made better methods available, existing corporations could not use them, thus compelling the organization of other corporations and a duplication of plants. They have created unnecessary uncertainties by limiting the contract for public service at a fixed price to one, five or ten years, instead of making the contract perpetual and the price adjustable so that it shall always bear a fixed relation to the cost of production.

The services rendered by municipal franchise corporations are assistance to industry, promoters of comfort and inducers of prosperity. Any unnatural restriction placed on them is as fatal to the welfare of society, as an unnatural obstruction to the inhaling of air or taking of food is to the health of the physical body. Any tax levied upon them is as fatal to the best interests of industry, as the extraction of blood is to the physical strength.

A consideration of vital importance to wage-workers, in the discussion of a question of this kind, that cannot be urged upon their attention with too much force, is the fact that every time an industry is removed by legislative enactment from the list of profit-producing industries and placed in the list of non-profit-producing industries operated under government ownership, an avenue to industrial independence is closed. Profit-producing industries are avenues to industrial independence and economic freedom for all who are engaged in them. For the wage-workers, more than any others, the self-interest of the individual, the moral interest of society, the group interest of the municipality, State, and nation, demand that *all avenues to industrial independence and economic freedom shall be kept open.*

PROCEEDINGS OF THE FIFTEENTH, ANNUAL, MEETING OF THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

FEBR. 23, 1892.—MORNING SESSION.

THE meeting was opened by PRESIDENT HUNTLEY, who introduced Mayor Bishop, of Buffalo, and who welcomed the Association to the city.

PRESIDENT HUNTLEY then delivered the following address:

PRESIDENT HUNTLEY'S ADDRESS.

In behalf of the National Electric Light Association I am glad to welcome to our meeting to-day those who represent the city and public of Buffalo, and as a citizen of Buffalo and president of this body, I am not less happy in adding my own welcome to those which greet the visit of the Association to this, the Queen City of the Lakes, a city far enough West to have all the bustle and energy of Chicago, but still far enough East to exhibit the dignity and solidity of New York.

As becomes one who fills this chair, there are certain topics of immediate interest and importance that I will venture to call your attention to, and if I do not touch all the questions that affect our great industry, it is because I made allusion to them at Montreal last September, or expect that you will get enough of them before you go home.

The meeting of this Association so near to Niagara seems to afford a fitting opportunity for discussion of the problem which is attaining great importance day by day, namely, the electrical transmission of power. Whether we are engaged in the distribution of electric light by arc or incandescent lamps, or in generating current for stationary or railway motors, or for heating, we are essentially engaged in generating, distributing and converting power into its various forms; hence any method by which the initial power can be obtained in a manner or from a source of greater economy, deserves our most serious consideration.

The question may, therefore, naturally be asked: What would be the effect of the utilization of Niagara or other large water powers, so far as concerning outlying cities? How far will it be possible to transmit this power, not theoretically, or in an experimental way, but commercially, so as to insure a fair dividend to the investor? At what point does it become cheaper to carry current than to carry coal? Now these are large questions. They are, in fact, the largest problems in modern engineering. When you come to deal with such an immense and incalculable source of power as Niagara, our previous plans and methods and successes sink into nothing, as indicative of final results and realizations. Our attitude toward such a taming of Nature is very much the same as that of the first electrical experimenters when they interrogated her with the help of pith balls and little chips of amber. Even the late demonstration at Frankfort teaches us little, for there we had the utilization of only such a water power as a well to-do American citizen puts in his back yard for ornamental purposes; and the experiment was tried in summer time, when winds are light and skies are clear. Moreover, that plant was run as an exhibition, with the Emperor of Germany and other dignitaries lending a patriotic hand and subscribing patriotic dollars. Now, gentlemen, when you and I who operate stations come to use such water powers, or distant coal beds, we shall not be able to fall back on kindly emperors for timely donations. Some of our fellow-citizens will be be quite ready to help us, but with the instinct that is born in every American, they will want the dollar they pay out to bring another back with it.

Our field of work, in short, with its newness and rawness, is one in which experience must always moderate enthusiasm To me perhaps more than to many of my fellow members, this question of long-distance power transmission is fraught with large possibilities and grave responsibilities. It is imperative that I should know the truth and the facts; and if ever the time comes when I can be humbly instrumental in giving Buffalo a sparkling midnight firmament created by yonder Falls, I shall ask no grander task. I have ventured to make this momentous subject one of the leading topics here, and my call for information has been responded to by some of the most authoritative workers and thinkers in this direction. To them I shall leave the exposition of its details, with the conviction that you will forgive me, if under a sense of duty, I have indicated the practical limitations that must govern every man of affairs.

In this connection I cannot help pointing out again that after all, the cost of coal to operate an electric plant is only one among many items, and frequently a small percentage of the total cost at that. For instance, in electric railway work, the cost of coal comes to about 10 per cent. of the total operating expenses, while in electric lighting it does not probably exceed from 15 to 20 per cent. In these days when municipal plants are the subject of frequent discussion, these facts are generally lost sight of, and the cost of electric lights is calculated by reference to the amount of coal burned under the boiler; thus ignoring the fact that firemen, engineers, linemen, trimmers, etc., are required; that carbons require daily renewal, and globes break; that, like all other machinery, engines, boilers, dynamos and lamps are subject to depreciation, require repairs, that the building must be insured, and that a sinking fund must be established for renewals.

Cheap power in itself would therefore influence the cost of electric lighting very little, even if the electric current is distributed in the immediate vicinity where it is generated; while, its distribution to any considerable distance in large power units on a commercial basis seems to be awaiting its demonstration here rather than in Europe. Hence I would recommend a study of the facts pointed out, which ought to make any community falter before investing in a municipal plant simply because it may happen to have what is supposed to be a cheap source of power around the corner.

Municipal ownership is, as I have just intimated, a topic that some of you have to deal with directly. This Association has always been a forum to which new ideas in the industry might be brought, and our efforts have done not a little in clearing away the haze and confusion on the subject of municipal control and operation. I have made a special effort, as evidence of our impartiality, to get together at this meeting some of those who believe in the abolition of private enterprise and in the surrender of all the ideas that make us crave for a home of our own and the accumulation of a few dollars for a rainy day. If we are wrong in the opinion that self-help is the best help and that ten well-to-do citizens count more for the community than twenty superfluous officeholders, it is time we knew it. Some people want the Government to run the railroads and some want it to buy up the telegraphs and telephones. Others want the municipalities to own street railways, gas works and electric light plants. In Boston there is, I am told, a demand that the city shall collect more taxes and put it into public coal yards. I am reminded of my reading as a boy at school, when I learned that the foredoomed population of a great city once sent up a howl for free bread and free tickets to the circus. Now, let me say right here that public franchises are a public trust. In return for them we are to do something or agree to do something that the community wants. In my humble judgment it has yet to be proved that such a way of introducing improvements and benefits is wrong or foolish. I am a busy man, and have been earning a livelihood all my life, but I have had time enough to observe that the whole vast industrial development that has added so enormously to the comfort and happiness of life has come from the investment, under public franchises, of private capital, skill and enterprise. The public has thus been made the partner in all the great works of the age, and has thus gained infinitely more than it could have secured if it had raised an equal amount of money by taxation, and had placed the proceeds in the hands of a vast body of officeholders for the same purposes.

Among the questions that interest us are those that concern the relations between the so-called parent companies and ourselves, the local companies, operating the apparatus that the parent companies sell. I am aware that in some quarters the consolidations that have been effected from time to time are viewed with anxiety, and that in others the cry of bad faith has been raised—not, perhaps, without warrant. But consolidations have their hopeful, better side. At one period our respective territories were practically open ground for thirty or forty competing manufacturers, each of whom had the best system in existence. That fierce and wasteful local competitions should be engendered under such conditions was inevitable, and even to-day the industry is hampered by the central stations that came into being under this unwholesome outside stimulus. We were, I might say, peaceful farmers whose early and promising crops were an invitation to every raider that could reach us. But at the present time the situation is clearing. The various consolidations let us see pretty clearly with whom we were dealing and we know, too, something of the value of the claims made for the apparatus or the patents that protect it. We have also learned that much apparatus essential to good work is free from patent royalties, and that the moment prices go beyond the point of paying a fair manufacturer's profit, a dozen big engineering firms are ready to invest with capital and brains. My esteemed friend and predecessor, Mr. Weeks, has even suggested that we should combine and manufacture for ourselves. But there is no need for that. Dynamo and lamp construction has made a place for itself already as one of the arts, very few fundamental patents are left, and every day brings us nearer to the time when generator building will be as universally practised as engine building.

Meantime, we who run the stations have been learning hard lessons in the school of experience, and that training is as valuable a part of our enterprises as are the franchises under which we have been induced to put our savings into the business of supplying light and power to our fellow-citizens. Unfortunately much of that experience remains a sealed book, and it is with the view of exchanging practical ideas that this Association carries on its work. I never meet one of my fellow-workers in this field but he teaches me something; possibly I give him a little in return. Now, apply that principle on a broad scale, and see how beneficial it must be to find out from each of two or three hundred earnest men their best way of doing things. That means progress, prosperity, perfection. But as long as only a few of us get together; as long as a feeling of apathy is allowed to control, our central station practice will fall far short of what it ought to be; it will not be as near standardization as it should be; and we will not make as much money as we ought. My political and social economy teaches me that the greater profit I can get out of any enterprise, with fair service and due satisfaction to the public, the better citizen I am. The rewards of society are for those who can increase its wealth and raise its degree of comfort and convenience. Now, the central station man who stays home is not doing his share to promote economical operation. I will go so far as to state that if once a year half the central stations of the country were represented in our gatherings, the average dividends would be increased, while not a few stations that now struggle on in dreary debt would reach a basis of solvency. I am very thoroughly in favor of one meeting a year for this Association, and of a systematic, energetic effort to get everybody there. Every member should make it his business to interest his neighbors in the work we are doing, especially the smaller stations.

As an inducement to the smaller stations I would be glad to see the dues somewhat reduced so that they can come in without feeling that they are paying dearly for their whistle. There is no valid reason why the dues should be high, and if cutting them down will bring in the stations most to be benefited, no hesitation should be felt in taking such action. I would like to see our membership ten times larger. As it is, the influence of the Association is by no means insignificant; but with larger membership its deliberations would be so much more valuable, and when it approved or disapproved, the matter would be at once settled for the entire industry.

It is important that we should interest ourselves in the World's Fair. I surely do not exaggerate when I say that every patriotic New Yorker wishes Chicago the biggest kind of success in her great undertaking, and admires the genuine American fashion in which the Western metropolis has sailed in to win. It is not only our duty, but it will be a source of great pleasure to contribute to the importance and success of the Exposition. We ought to meet in Chicago next year. We must go there in a body. The Chicago Electric Club is ready to take care of us, the whole city has a welcome for us, and the electric exhibit will be the finest the world has ever seen.

We have a good programme of papers for this Convention, and I ask you to do the authors the compliment of discussing them exhaustively. If you don't agree with them, tell us why. If you have any local problem, take us into your confidence. You will probably find that others here have laid awake nights worrying over the same matters, and have sometimes found a way out. If you have made some improvement in station practice and operation, ask for the floor; and if it is too good for everybody, we will go into executive session over it. In these and other ways, you will strengthen the hands of the chair, promote the cause we are here to advocate, and make this meeting the best we have ever had.

An invitation was then read from the Delaney Forge and Iron Co. to go through their works. The Postal Telegraph Co. offered the use of their facilities for the delegates to send social messages free. Free use of all telephone wires in the city and also of the Long Distance telephone wires to New York and elsewhere were offered. The California Electrical Society sent a pressing invitation to hold the next convention in San Francisco. Referred to the executive committee.

A committee of three was appointed to draft resolutions of regret respecting the death of Mr. George Worthington, one of the organizers of the Association.

The Report of the Committee on Underground Conduits and Conductors was then read by MR. M. J. FRANCISCO, as follows:

REPORT OF COMMITTEE ON UNDERGROUND CONDUITS AND WIRES.

At the Providence meeting of the Association, a committee was appointed to investigate underground conduits and conductors, and collect data regarding their working. The committee, in carrying out this work decided to send out circulars to all central stations and other parties using underground conduits, asking for information regarding its use and the success obtained. The following circular was printed and mailed:

A committe was appointed at the Annual Convention of the National Electric Light Association, held in Providence, Feb., 1891, to investigate and collect data relating to underground conduits and conductors. In order to secure the full facts, answers to the following questions are desired. Will you kindly answer and return as soon as possible?

1. Mileage of conduit laid? 2. Cost of conduit per mile? 3. Mileage of conduit in use? 4. Mileage of duct laid? 5. Mileage of duct in use? 6. Average hours per diem same is operated? 7. Number of manholes? 8. Cost of manholes? 9. Number of hand-holes? 10. Cost of hand-holes? 11. Number of services taken direct from conduit? 12. Cost of maintenance per mile per month? 13. Cost of repairs per mile per month? 14. Average number of burn-outs and grounds per mile and the cause? 15. Have you found the working of your underground system a commercial success? 16. What is the voltage on each conductor? 17. What is the current, in amperes, carried by each conductor? 18. What is the size of the conductors used? (In answering this question give the number and gauge.) 19. What is the thickness of the insulation? 20. Who is the maker of the cables? 21. Are the cables laid in any form of conduit? 22. If so, what kind of conduit is used? 23. Have the cables worked satisfactorily during the entire time of their use? 24. If the cables have failed to work satisfactorily, to what cause do you attribute the difficulty? (Please answer as fully as possible) 25. Have you abandoned any conduits because they proved failures?

The names of companies or stations will not be made public, but grouped by numbers. We wish this information for the benefit of every member of the National Electric Light Association.

It soon became apparent to the committee that they were treading upon very dangerous ground, nearly every man addressed at once concluding that there was a direct drive being made at him or his business, and the amount of ignorance displayed by parties who had used underground cable, and were supposed to know of its value and practical working, was rather alarming. Then a plan was adopted to secure from the manufacturers a list of parties who had purchased underground cable with the intention of making personal examination of each plant. Here again the discovery was made that, with a few exceptions, the manufacturers did not know to whom they had sold underground cable and were unable to furnish the list. After these plans had failed, it was decided to investigate personally various plans and systems in use, and the chairman of the committee started out on a voyage of discovery.

The committee found that what had answered the purpose in one city had proved a failure in another, owing to local troubles, such as the nature of the soil, gas, steam, and in some cases politics, which had a very peculiar effect upon the conduit itself, as well as the insulalation used, and, in one city, we found that a liquid insulation, passed through the conduit in such a way that the officials could personally examine and test its efficiency and quality, was the only conduit or system they would approve or adopt.

In another city, the central station company placed about ten miles of underground conductor for an arc line, passing the same through an iron pipe, relying upon the insulation of the wire; it utterly failed and they took it out. They then tried another make of wire, drawing it into that same iron pipe; this held for a short time and then began to burn out, and sometimes two feet of the wire would be entirely burned out, and when it was drawn out of the pipe you could blow dry powder in clouds from the pipe, showing that it was not moisture that caused the trouble. Another company tried a conduit made of three-inch tarred planks, using underground cable with $\frac{5}{32}$-inch insulation that was supposed to be first class; through this they passed a 1,000 volt current. As soon as they started they had innumerable burn-outs, grounds and crosses, and finally abandoned it.

One company, using 1,100 volts and 50 amperes, tried passing a cable through pump logs, with wire of $\frac{1}{16}$-inch insulation and were troubled with grounds and burn-outs, and found the insulation was too thin and had to be abandoned. Another company tried conduit made of asphalt, with several makes of wire, using 1,500 volts and ten amperes, but it did not work successfully on account of burn-outs, grounds and crosses, and they abandoned the entire outfit.

In the course of this voyage, a gang of men were discovered trying to locate a burn-out; as this was directly in line with our business, we decided to anchor and devote sufficient time to the case for an examination. The plan adopted was to dig up the pavement and disconnect the iron pipe containing the wires and then test in each direction; this was repeated until fifteen openings had been made in the street at various points and the section burned out discovered, and it was found that, not only had the wires been burned off, but the iron pipe for nearly two feet had been melted, destroying the whole line. This pipe was removed and a new one inserted and connected.

Of course, in many cities where concrete or asphalt pavements were used, it would be impossible to obtain permission to tear up the street in fifteen places to replace one burn-out, to say nothing about the expense. There were five men employed upon this line, and they informed us that their entire time was spent in tracing and repairing burn-outs in their beat, covering about two wards.

In a municipal plant of one city, where the Dorsett system was used, also iron pipe with cement lining and other styles of conduit, it was stated the underground conduit was perfection and could not be improved upon. A little private investigation developed the fact that one underground circuit had been in trouble for six months previous to our visit, and at that time the trouble had not been located; also that the voltage of the lamps varied from 25 to 55 volts; but as it costs nothing to run a municipal plant, this condition of lines and lamps was not considered of any importance.

Various plans were tried for lighting the Hoosac Tunnel. They used 1,000 volts, but the insulation was too thin and would not stand and they had constant trouble, as the tunnel is very wet and in many places the wire was covered with water. They then tried another style of wire, using 1,000 volts, alternating current, lamps in series, twenty in each set, 1,250 lamps in all; since this plan was adopted they have had no trouble, and the same wire has been in use three years, running twenty-four hours per day.

The Electrical Bureau of Philadelphia have about fifteen miles of duct in use for electric lights; they are using 2,500 volts and $9\frac{6}{10}$ amperes. They report six grounds from January 1, 1890, to November 13, 1891, and all, except one, from too thin insulation. In one case the cable was damaged before drawing into the duct. They used the creosoted wood conduit; the cost of this kind of conduit is about $4,500 per mile, including manholes. As they have only been in use about two years, it is impossible to judge of their durability.

In Washington the terra-cotta conduit is used. This is a trough, $3\frac{1}{2}$ by 8 inches, each made of glazed terra-cotta, laid, with a proper cover, about two feet below the surface; these are connected by bracket-shaped pieces, which hold the joints in position and all laid in a heavy bed of cement; each duct is calculated to hold three 2-inch cables, but the size can be varied. The electric lighting company tried conduits of wood, asphalt and iron, but they all failed; they then used the terra-cotta and have found it very satisfactory and reasonable in price, but the cable to be used must be first class.

In New York City the electric companies could have made a success of the underground conduit work were it not for the exorbitant prices charged as rental for use of conduits, which has been $1,000 per mile per annum for a 3-inch distributing duct; $900 for 3-inch trunk, $800 for $2\frac{1}{4}$-inch trunk; to this must be added the heavy cost of cables, joints, labor, etc., with an expenditure of about $24 per mile to maintain them. The companies are then asked by the city officials to furnish all-night lights for about $75 per year; this would leave a very peculiar balance sheet at the close of the year, and, if repeated for a few years, would require the services of an assignee to adjust.

In England many plans have been adopted with varying success. Through the courtesy of the London Chamber of Commerce and prominent English electricians, we have obtained some information regarding the practical working of various systems. Ferranti uses for his high tension 10,000 volt current, his concentric cable, composed of a thick copper tube, upon which is wound a number of layers of paper saturated with an insulating wax; over this is slipped a thin outer tube of copper, for the return current and drawn down close; then he covers the outer tube with insulation and puts a lead tube covering over that and places same in the ground; wherever there is traffic, he adds an iron pipe. Notwithstanding all these precautions, he has had innumerable troubles from grounds, induction, etc.

In Liverpool the mains are laid in cast iron troughs, then filled in around them with bitumen and covered over with Portland cement; these have answered perfectly for the low tension, but they have not used high tension currents long enough to test their efficiency of durability.

In Bath, England, they use a conduit consisting of an iron trough, with iron cover, in which cables with half-inch insulation are laid on wooden bridges about two feet apart, and after cables are placed in position, the whole is filled solid with bitumen and then the iron cover fastened down. On cables laid in this way, they have carried for two years an arc current of 2,500 volts and an alternating of 2,000 volts successfully, only one ground having occurred.

After a careful and extensive examination of nearly all underground work in this country, the fact has been developed that, with very few exceptions, the system and plans heretofore adopted have proved a failure; in some cases caused by improper materials, insufficient insulation, and in many cases carelessness in laying the conduit or drawing in the cable, and in a large majority of cases, from using cable with too thin an insulation. High tension currents can be carried in conduits successfully, if the conduits are properly built and cables thoroughly insulated and carefully drawn in; but it is absolutely necessary that all work and materials should be first class,—no half-way business or effort to scrimp and save expense by thinly insulated cables or poor construction.

Investigation plainly shows that a large number of the troubles on underground cables have been caused by workmen in the manholes, as the employees of all companies have access to same; employees of one company have been extremely careless while working over the cables of a competing company and trouble has followed. This shows conclusively that each company should own and control exclusively the conduit in which their wires are placed. The plan of renting conduits is not productive of good results, unless the Legislatures of the various States pass a law, regulating the charges made for rental, and this should be the aim of the National Electric Light Association to see that laws, properly controlling the price charged for rental and use of conduits, are passed in all the States where same are used.

A serious trouble in underground work has been caused by drawing in the cables. This is a very important part of the business and should only be intrusted to reliable and experienced men, as the least injury to the insulation, while it is being placed in the duct, will surely develop and cause trouble, and many of the burn-outs have been caused in this way. No matter how good an insulation you may have, if it is cut or injured while passing it into the duct, you can depend upon it that this special place will give you notice before long, and in a way that will severely test your ability to obey one of the Ten Commandments.

Some substance must be used for the conduit that will withstand the action of the gases, soil, etc., and also resist the affectionate embrace of the Irishman's pick, used in excavating and repairing streets. Iron is not desirable, as under certain conditions and places it will be destroyed in a few months, leaving your cable exposed; cement alone cannot be relied upon; wooden conduit soon decays, besides absorbing large quantities of moisture. It would seem that glazed terra-cotta, or like substance, set in concrete was the most reliable, and with a cable first insulated with not less than quarter inch of pure rubber, this covered with a heavy braid well insulated, over this a covering of lead, and then a heavy and substantial braid, saturated with a good compound, will give satisfactory results, and can be used with high tension currents successfully and without being troubled with burn-outs or grounds. But this entails a large outlay for conduits and cables.

There is one feature of the business upon which all examinations and reports agree, that is, that the underground plan has been in use for so short a time that it is impossible to gave a fair comparison of the cost of maintaining aerial and underground circuits, but it is conceded that the expense of maintaining underground cables is far greater than aerial; also, that the durability of conduits and cables, in many cases, is mere conjecture, as they have not been used long enough to test their ability to stand the action of acids, gases and various other requirements, which can only be determined after a sufficient time has elapsed.

In cities of less than 200,000 inhabitants, compelling companies to place their wires underground will practically prohibit the use of electricity for lights, and leave the inhabitants of those cities to meander through the streets, guided by the sickly rays of the kerosene lamp, or the feeble flutter of the gas burner, as no electric lighting company can afford the expense that this would incur, unless they could obtain double the prices now paid for lights.

The expense of conduits and underground cables is so heavy that they can only be adopted in a few of the larger cities, thickly settled, and then the electric lighting companies adopting them must be paid a higher price for service, or eventually their company will be bankrupted by the expense and loss entailed. Therefore the taxpayers in any city, who demand that wires shall be placed underground, want to realize the fact that this move means increased cost for lights and larger taxes to pay for same. From data obtained, it is evident that nearly all the cities could be served with aerial lines for the high tension current in a more acceptable manner and at less expense than with underground conduits, and they could be so arranged as to be perfectly secure and not in any way endanger the public or mar the general appearance of the streets. But as this committee were appointed to investigate underground and not aerial circuits, they have not considered it within their province to describe or recommend a plan for aerial lines.

Mr. Nicholls inquired whether the creosoted wood conduit referred to costs $4,500 per mile, per duct, or for the whole conduit.

Mr. Francisco stated that it was the cost for two ducts in the conduit.

Mr. Hering referred to the system of bare conductors used for distribution in Paris and London which were placed on insulators in conduits under the sidewalks.

Mr. Francisco drew Mr. Hering's attention to the fact that all these conductors were for low-tension distribution only, while his report referred to high-tension distribution.

Mr. Wilmerding thought that high-tension underground conductors are perfectly practicable if properly carried out and enough money be invested in them. They had succeeded in Chicago in transmitting currents underground without any trouble. He did not believe in systems of conduit which are recommended as being insulated. The iron pipe for conduits was just as good as a non-conductor, except for the fact that it will rust out and become useless in four or five years. The main point to be considered in the conduit, was to get a certain strength and elasticity, so as to prevent the conduit from cracking with the action of frost and other causes, and yet be easily repaired. He believed that wood is one of the best substances for conduits. In Chicago they had had very satisfactory results with it. We know that any wood that is kept constantly moist, is practically everlasting. It had the further advantage of being very cheap. He had 40 miles at present of a certain cable, with an insulation of $\frac{5}{32}$ of an inch in thickness, which is carrying a potential of 500 volts on a constant potential motor service, one of 1,000 volts in an alternating service, and one of 2,500 to 3,000 volts in arc lighting service, and which have been in service for over two years, and he had not had a single case of grounding, burn-out, or anything of the kind, on 40 miles of conduit.

Mr. Hering stated that at the Frankfort exhibition last summer, there was an underground cable, in which an alternating current of 20,000 volts was carried for a distance of about a mile.

Mr. Francisco thought in regard to Mr. Wilmerding's remarks about wood, that it all depended on the locality. He knew a case of a wood conduit that had lasted less than nine months, while others had lasted 20 years. It depended on the locality and the soil. He inquired if they had not had trouble in Chicago, with conduits.

Mr. Wilmerding thought that was the case with regard to the city plant. He had been told by one of the employees who had charge of the underground circuit, that they had had trouble on one of their underground circuits for about six months past, and had not been able to locate it. Of course, that was a municipal plant. (Laughter.)

Mr. Stanley—When a high potential continuous current is placed in an underground cable there is a great strain on the insulating material, and this strain is all in one direction. As the result of that continued pressure in one direction the constitution of the insulator changes, and after six months—in some cases, I believe, in London, in even less time than that—the entire structure of the insulator changes, so that while the cable had a high specific resistance to start off with, that rapidly fell off in the same cable. In the case of alternating currents in these conductors this deterioration does not take place; in this case the current reverses rapidly, and the work done by the current passing in one direction is quickly undone by the next wave passing in the opposite direction; and thus the effects are neutralized. The effects of the alternating current are more like those of water flowing through a pipe. If we had a long pipe, filled with water, and suddenly turned it on end, the water would rush to the far end, and strike a hard blow, and there would be a water hammer effect. The longer the cable is underground, and the longer the distance, the greater is this condenser effect; and it was so great in the case of the Ferranti main, that it raised the pressure at London a great many volts higher than at Deptford, where the other end of the cable was. I think it can be generally stated that those insulations made from oil-compounds are unfit for a continuous current strain, while they are exceedingly good for alternating currents. In some cases in underground work we found that the cables did not have the capacity they were figured for; the capacity being always reduced. The resistance of the cables for alternating current was considerably higher than it ought to be; in some cases ten per cent. higher, and we were worried a great deal about it. We found that the external resistance in this cable was due mainly to the work that was done in the iron pipe which enclosed the cable, the resistance function outside of the wire, and not inside, and also that the current in the wire was not evenly distributed, a result which had been predicted long ago by Sir William Thomson. These difficulties were overcome by adopting a certain small standard size of conductors and putting in more cables.

Mr. M. J. Perry thought that it would be practically impossible to run circuits under the sidewalks of American cities. The proposition to place wires underground, in the broad sense, was admitted to be practicable, by all the best electricians, provided one is prepared to put a sufficient amount of money in it. To be able to put that money in it, it is necessary to offer some inducement to the investor for the use of his funds. He assumed that probably the main lines of the Buffalo Company represented from 25 to 40 per cent. of its capitalization. To go underground they would first absolutely have to sink that and throw it away, and that was an enormous strain on any corporation. Secondly, one would have to put in three or four times as much money as now invested for distributing purposes. Up to two years ago at least, the gentlemen from Chicago were not prepared to recommend it to investors; they were not, and could not help themselves. He presumed they had gone on and worked the thing out; but you could get no more American capital on the showing made there; American dollars did not go that way; and they did not grow that way. If we could see the books of the Buffalo Electric Light Company, he would warrant that they would not show that they were making extravagant profits, or extorting from this public, anything more than fair and just for the investment and risk of the business. They might possibly be earning a dividend, a fair return on the investment, which a man who invests his money is entitled to; that was only fair and just. The proposition to place wires underground, if carried out and consummated, would necessitate their earning a dividend on at least double their present capital. If the change is made, they will then be obliged to earn two or three hundred dollars per lamp; but they cannot raise the prices! It may be that if public pressure is put on strong enough, they can be made to go underground in Buffalo; it may be that they will be sent into bankruptcy; and it may be, that those who come in on the second deal, may reap a rich reward. He did not believe, however, that that was the province of any city government, and he did not believe that it was the intention of any intelligent public to do this, if they have been fairly and squarely confronted with the question.

MR. WILMERDING did not think it possible for any company which is operating by the overhead system, to afford to do the lighting at the same price by the underground; it certainly could not be done under any circumstances in a city of small population, two hundred thousand or less; it was practically impossible.

AFTERNOON SESSION.

MR. STILLWELL read a paper on "The Relation of Size and Efficiency in Transformers."[1]

In the discussion which followed, Mr. **WM. STANLEY, JR.**, remarked that the most efficient transformer that could be made, he believed, would be the hottest transformer. The problem of building a transformer, was to build a coil of wire and get as much iron in it as one can; that is, to surround a given amount of iron with as many turns of wire as one can; or, to surround a given size or coil of wire with as much iron as possible. He had had occasion lately, to design transformers of very high voltage, as high as 1,500 volts, and he was now designing some to deliver forty thousand watts or fifty horse power each. He found no difficulty in keeping the temperature of these transformers within reasonable limits. If filled with a homogeneous insulator, such as oil or some solid insulating compound, one can use any potential one wants, provided the discharges do not take place that occur in stratified insulation. He thought heat had very little to do with the breaking down of a properly insulated transformer.

PROF. ELIHU THOMSON—I do not exactly agree with Mr. Stanley in the statement that a transformer is better when it is hot. I would rather modify that statement in this way, that a transformer would run best if the iron would run hot and the copper as cool as possible; that is, the hysteresis losses of the iron would be diminished by the heat, and the resistance losses in the copper would be lessened by keeping it cool. If we could insulate the core of the transformer so as to prevent the escape of heat, and let it get hot, and keep the copper cool as possible by ventilating it thoroughly, we should then have the ideal transformer. I hardly agree with the statement that Mr. Stanley made that the insulation would not be injured by being hot. It is our experience that you cannot have a machine, a dynamo or any other electric apparatus run too cool, as regards the preservation of its insulation, provided it does not run so cool as to condense moisture from the atmosphere. The absolute resistance, the dielectric resistance, is highest when the substance is cool; that is, the tendency to puncture insulation is much less if you can keep your insulation cool. If you allow the insulation to heat up, its power of resisting puncture certainly decreases, until at very high heats it becomes a conductor.

MR. STANLEY stated that he did not mean to imply that it would not injure the insulation of a transformer if one had it hot enough. What he did mean to say was, that so far as the efficiency of the apparatus went, it would rather, on the whole, be improved by heating it. He questioned if the transformer of the future will have cotton or any other inflammable material in it. He was making transformers in which, if the coil is cut in two, the copper wires will be found imbedded in a solid dielectric, and the section would resemble the section of a well-constructed cable; there was nothing to burn there. A temperature change of 30 or 40 degrees would hardly affect the dielectric strength, while it would materially affect the efficiency of the apparatus.

MR. STILLWELL thought anything that was done in the direction of reducing the temperature, either in generators or in transformers, by the manufacturing companies was a direct gain to the purchaser; because taking the apparatus as it is built, such a policy tended to prolong the life of the apparatus.

MR. PERRY moved a vote of thanks to Mr. Stillwell, and to those who took part in the discussion. He believed that if by having two Conventions a year they could get two papers a year like this one they could not afford to hold only one Convention. The motion was caried.

The Committee on Safe Wiring, M. D. Law, chairman, then reported the following proposed amendments to the rules on that subject:[1]

Inside Wiring.

Art. 7. Inside conductors must not be laid in plaster, cement, or similar finish, without an exterior metallic protection.

Special Wiring.

In rooms where inflammable gases exist, the incandescent lamp and socket must be enclosed in a vapor-tight globe. This is not understood to include rooms where illuminating gases are used in the ordinary manner.

Art. 2. The word "waterproof" change to "moisture-proof," so that the article will read: Provided with a durable moisture-proof covering.

Interior Conduits.

Art. 2. Interior conduits must not be of such material or construction that will be injured by plaster or cement or other surrounding material, or that the insulation of the conductor will be ultimately injured or destroyed by the elements of its position.

After a brief discussion, the amendments were adopted as read.

MR. ALLEN R. FOOTE then read a report of fires and injuries caused by electric currents during the year 1890, being data obtained from 425 cities in the United States:

Number of members on fire force, regular and volunteer	56,498
Total number of fires for which the force was called out	39,847
Total number of fires caused by electric currents	518
Total number of injuries received while on duty	1,719
Total number of injuries received while on duty at fires caused by electric currents	35
Total number of injuries caused by electric currents while on duty	31
Total number of fatal injuries received while on duty	60
Total number of fatal injuries caused by electric currents while on duty	1

In the brief remarks following the reading of the data above, it was elicited that in the case of the single fatal injury caused by electric currents while on duty, that the man fell from a pole thirty-five feet high; and as there was no autopsy, it could not be learned what was the exact cause of death.

MR. LANE, of Cleveland, O., then addressed the meeting on the subject of lubricating oils. He said that most people were under the impression that it was necessary to use lubricating oils of high viscosity and low gravity in order to get good lubrication on heavy or high-speed machinery. After extended experiments it had been found by him that a light oil, light in gravity and low in viscosity, would give the best satisfaction in the lubrication of both high speed and heavy machinery. The oil recommended by Mr. Lane is an oil of about 32 gravity and 140 viscosity. He instanced the Calumet and Hecla mines, where lard oil was used up to two years ago, but where they now use a mineral oil. Objection was sometimes raised to oils because they produced a gummy substance; but this is usually a scale-making material, which comes from the walls of the cylinder. As a rule, any oil that will produce a gummy substance is a good oil.

MR. D. ASHWORTH then read a paper on "The Allied Powers,"[2] by Mr.

On motion of **MR. SEELY** a vote of thanks to the author was passed.

Invitations from the Brush Electric Light Company, at Niagara Falls, to visit the Falls, and from the Buffalo Railway Company, to inspect its power station and plant, were read. The meeting then adjourned.

WEDNESDAY, FEB. 24.—MORNING SESSION.

The President called the meeting to order at 10.30 a. m., and the first business was the reading of the paper entitled "From the Tannery to the Dynamo,"[3] by Mr. Charles A. Schieren.

In answer to a question by Mr. Stanley, **MR. SCHIEREN** stated that to make a straight line belt they have to use heads with heads, if the belt is made of anything else than centres; in using centres this is not necessary. The centre is perfectly straight, and it is only by the greatest stupidity on the part of the workman that he can make it crooked. He can make it crooked by stretching one side more than the other. "If we had to make all our belts from centres, it could not be done. In making belts of other than centres there is a right and left, and the workman must be careful not to change the relation. Crooked belts often come from the fact that a workman will put a left on a left, and then again a right on a left. The joints should be made shoulder on shoulder and butt on butt."

[2] See page 214.

[3] See page 224.

Mr. Wm. Stanley, Jr. then read a paper entitled, "Alternate Current Motors."[1]

In the discussion which followed the reading of Mr. Stanley's paper, **Mr. Stillwell** inquired whether there was any retardation of the currents behind the E. M. F. in the circuits. Mr. Stanley replied that there was none whatever.

Mr. Stillwell—I would like to refer to the development of the Tesla motor, and to the relation of the false current to the true current, in the operation of that motor. Mr. Stanley's statement, is so far as my recollection serves me, about correct, when the motor is at full load; but the Tesla motor behaves very much like a transformer. The relation of the false current at no load is not, however, proportionate to the energy. In a transformer of the closed circuit type, when no lamps are burning on the secondary circuit, and consequently there are no currents in the secondary coil, we can obtain the true energy in the primary by multiplying the current and E. M. F. by a factor, which, for the types ordinarily used in this country, is about seven-tenths. As lamps are added to the secondary circuit, the phases of E. M. F. and the current in the primary tend to coincide, and at a partial load, comparatively small, they do coincide, practically, so that the product of current and E. M. F. shows the true energy. In the Tesla motor, the same general relation exists, and if it were possible to operate the motor without an air-gap, identically the same relation would exist. As we load the motor, the phase, the applied E. M. F. coming from the generator, and the current, tend to coincide; and while on a motor of 15 h. p., which gives about the best results, at no load we must multiply the current and E. M. F. by two-tenths instead of six-tenths, at full load we would multiply it by eight-tenths or nine-tenths; that is to say, that when a Tesla motor is turning over, the false current is very large, but there is a relatively good regulation as to energy. This does not apply to the efficiency, and the false reading is by no means as much as would be understood from the bare statement. If we were to transmit power from Niagara Falls to Buffalo, and were to use existing apparatus—about as good a method as we could use—we could have two satisfactory methods, one the two-phase or multi-phase system, and the other would be the straight synchronous system, with small starting motors to start the large ones. I think if we were called upon to supply power to Buffalo from Niagara Falls it would be a toss-up between the two methods. It would depend largely upon the amount of power to be transmitted and the potential to be employed. If it were 10,000 volts, it would be sufficiently high for a distance of 30 miles, if we were to deliver not more than two or three thousand horse power. It is probable that we should prefer to use two wires and two sets of insulators on each pole rather than to run three or four wires. The advantage of the latter would be that we could start the motors with torque, so that they could be brought up to their full speed when fully loaded. The disadvantage of the synchronous is simply that starting devices must be used; but that is a small matter, and a small portion of the necessary investment. The multi-phase and the synchronous type, when run at full load, should be operated synchronously. You will remember that the commission of distinguished engineers who considered this matter at Frankfort arrived at the conclusion that the ordinary synchronous motor, started with small torque, and without load, was a practical and sufficiently effective motor for general purposes; and the views of the commission were in favor of the alternating current, even as against the direct current, for a comparatively limited area. The only objection they raised to the system was that there was a certain amount of sparking at the commutator, and as I have seen one of those machines in operation it may be interesting to know how far it has been improved since. At that time Zipernowsky was using copper brushes, and starting the motor at low speed. The product of revolutions and the number of poles of course did not equal the number of phases at low speed, and there was sparking. The Frankfort commission undertook to measure the amount of copper that was detached from the commutator by sparking 100 times. Since that time we have very generally taken to carbon brushes; and the carbon brush applied to that motor practically gets over that difficulty. I have seen this synchronous motor start on a high number of volts, without any sparking that would cut the commutator. There is a slight discharge, but not a cutting spark. I am glad to know that Mr. Stanley believes that the so-called multi-phase motors possess no advantage over the two-phase type devised by Mr. Tesla.

Mr. Stanley—Mr. Stillwell suggested that there was a possible benefit to be derived from using a multi-phase motor system. I do not believe it. Mr. Tesla in the wonderful work that he did early on that subject outlined the exact conditions of the operations of his motor. We do not want more than two currents of 90 degrees of phase to produce a perfectly rotating field.

Prof. Elisha Gray was then introduced and made a brief address, inviting the Association to take an active part in the Electrical Congress to be held in Chicago in 1893 under the auspices of the World's Congress Auxiliary of the World's Columbian Exposition.

---

1. See p. 211.

The report of the World's Fair Committee, Mr. B. E. Sunny, Chairman, was then read by **Mr. Charles W. Price**, as follows:

REPORT OF THE WORLD'S FAIR COMMITTEE.[1]

Everything in connection with the World's Fair undertaking is moving in a most gratifying and satisfactory way. The buildings and grounds are getting into a finished condition with an expedition that promises an absolute completion of the work long before the date for the opening of the Fair. From Prof. Barrett I ascertain that almost double the amount of space available for electrical exhibits has been applied for by American and foreign electrical manufacturers, and that there is apt to be just a little disappointment by parties who will not be able to get the amount of space that they will require. I think, however, that the arrangement for the care of applicants is on such an elastic basis that every one will get about what he wants. Certainly this is the temper of the Fair management.

As has been announced by the papers, the specifications are out for the furnishing of 6,000 arc lights and 92,000 incandescent lights, and 3,000 h. p. in generators for the service of the Fair, and by the middle of March the contracts will be closed, so that the work of installation can go right ahead.

The organization of the World's Fair Auxiliary, under whose auspices will be held the Convention of electricians from all over the world, is going forward rapidly and satisfactorily, under the direction of Prof. Gray, Chairman. The general plan was adopted for the Auxiliary at a meeting of Prof. Gray's committee, and has been published in the electrical papers of a recent issue. The aim of the Committee is to make the undertaking of the gathering of electricians on a comprehensive basis, and with the assistance that is being offered the Committee in every direction, I have no doubt but that the plan adopted for the Convention will be the one best calculated for the advancement of the interests of electricity. The situation could not be any more satisfactory for the prospects of the undertaking than it is.

On motion of **Mr. J. A. Seely**, the report was received and ordered placed on file; it being understood that the Committee was to continue.

Mr. George M. Phelps then presented the following resolutions in behalf of the Committee previously appointed.

Resolved: The members of the National Electric Light Association, assembled at its fifteenth Convention, desire to record their sense of the loss sustained by the Association in the death of Mr George Worthington.

He was the moving and leading spirit in calling together the company of gentlemen who organized this body seven years ago; and so long as health and strength remained to him he was foremost and unwearied in its service. From the first he appreciated the importance of the organization and its possibilities of usefulness. Busy as he was in his chosen field of journalism he found time and opportunity to lend a hand on every occasion of service.

Highly as we regard the memory of his ability and usefulness as a working member of the electrical community, we even more highly cherish the remembrance of his warmth of heart and his unselfish devotion to his friends. No one came within reach of his hand grasp without becoming his friend. If he had an enemy no one ever found it out.

Resolved: That the Secretary be requested to send a copy of this minute to the family of Mr. Worthington.

On motion of **Mr. J. A. Seely** the resolutions were unanimously adopted and ordered to be engrossed and a copy presented to the family of Mr. Worthington.

The meeting then adjourned until 8 o'clock p. m.

FEB. 24. 1892.—EVENING SESSION.

The meeting was opened by the reading of a paper entitled, "The Construction, Safety and Operation of Switchboards,"[2] by Mr. M. C. Sullivan, of New York. The paper was read by Mr. M. J. Sullivan, of Chicago.

In the discussion which followed the paper, **The President** remarked that the question of switchboards was one that came home very close to every man in a central station; and there was probably no point that central station practice was so weak in as in good switchboards.

Mr. Scott stated that they had a wooden switchboard, and according to the paper just read it was contrary to good practice. But he believed it to be fireproof, because it was wired in such a manner as to make it so. He had found that the great danger from fire with switchboards was either from a dirty connection, a loose screw or from lightning. In order to obviate the trouble from lightning he had provided each feeder with a double lightning arrester. He employs two lightning arresters on each leg of each feeder running to separate ground so as to be certain that if one lightning arrester did not act the other would. Then in order that it shall not reach the main plug cut-out to the dynamo, he put a double fuse block cut-out on each feeder, and fused that only to the limit of that feeder, fusing the dynamo cut-out to the limit of the dynamo; so that if any lightning gets past the lightning arrester and comes in it takes the feeder cut-out instead of the main cut out, from which it might arc and destroy the armature. If managers would fuse their feeders less than they fuse their dynamos, provide as good lightning arresters as they possibly can, and have men thoroughly examine the screws

---

1. Abstract.
2. See page 227.

and the connections at stated times, a wooden switchboard he believed was just as good as a slate or a marble one. Mr. Scott did not believe in slatted wooden switchboards. A plain wall of well-shellacked hard wood he thought better than slats, because edges and corners are susceptible of attack where a full board is not so liable to it.

He used one of the wooden Westinghouse lightning arresters and one of the marble lightning arresters on each feeder. He had had some terrific thunder storms, that have come in and stopped the engine, but the arresters have carried them off.

Mr. E. A. Leslie—We have suffered very severely from lightning in our station in New York. On one occasion there was a bolt of lightning came into the cupola and agitated all the lightning arresters, but at the same time burnt out our station. That set us to thinking about a safer board. We then laid the matter before a manufacturing company, and they built for us a rubber board; that is to say, a slate board with rubber handles; and there was rubber all around it. And that burned out one time when there was no lightning; burned out from arcing in throwing over a heavy load from one machine to another. Then we set about building a switchboard on our own account, and we finally devised one which we think answers the purpose and affords us absolute safety. It is made up of slabs of marbleized slate, and the machine connections are run horizontally on the board and connected up by wires running from the machines overhead, and the connection is made behind the board. The line wires do not come into the switch proper at all. There is an addition to the switchboard, on top; that is a peculiar switch, a final switch. This switch is arranged so that it makes a connection on each side of the board. If you throw it up, the positive terminal, let us say, will make connection on the face of the board and the negative will make connection on the back. Both the line wires are connected with this switch, but they are securely insulated from each other, so that there is no possibility of short-circuit there. The result is that we have a throw of about 18 inches, and no arc on any load that we have thrown there yet will follow it, although our lines are very long, and the arcing is very severe. We use the plug system, and the board is arranged in two sections, so that if we are carrying our load on, say, nine or ten machines—we have 20 altogether in the board—we set up the other section with the other machines, so that in case anything happens, just the moment that you throw over those switches you will start the whole load on the other machines. The board is thus always prepared for an emergency beforehand, and lies there in readiness for just the unexpected to occur. The whole success of the board lies in that throw-over switch that I have mentioned, that final switch.

We had bad luck with lightning arresters, so we discarded them, and although we have passed through two summers of very heavy lightning storms we have not suffered any more damage in the matter of armatures than we did previously, when we had lightning arresters.

Mr. Fairbank then described briefly the Thomson-Houston switchboard. In this the lines come into the back part of the board and the machines are connected in the front. Connections are made with a plug which reaches from one board to the other. There were in his board 20 circuits, so arranged that they can couple any line or any machine with any circuit. It avoided all cables, and was perfectly safe. His switchboard is situated in the centre of the station instead of at the side. He could thus get all around it and test all the wires from the back of the board, or from the front. The wires come from each machine under the floor, and come up on the under side. The line wires go out overhead, and before they go to the wire tower they go through the lightning arresters, which are situated right above the board, in plain sight of the dynamo tenders, and where they can be easily reached. He had not seen anything elsewhere that was so entirely safe.

Prof. Elisha Gray then resumed his remarks on the World's Columbian Fair and outlined the work of the Electrical Congress, already familiar to our readers, and urged the participation of the Association.

He also read the following special announcement of the World's Congress Auxiliary :

> While electrical engineering has been included in the scheme for the Electrical Congress of 1892, it was also originally assigned to the department of engineering, for consideration in the congress of engineers. It was thought, however, by representatives of the Electrical Congress that this double assignment would tend to detract from the completeness and success of that Congress. A conference on this point was held between Prof. Elisha Gray, Chairman of the General Committee of the Electrical Congress ; Mr. O. Chanute, President of the General Committee of Engineers, and President Charles C. Bonney, of the World's Congress Auxiliary, and it was mutually agreed that the double assignment above mentioned should be cancelled and the entire subject of electricity remitted to the Electrical Congress.
>
> The importance and the magnitude of the other great interest to be considered in the Engineering Congress made their representatives feel that they could well afford to be generous to their brethren of the Electrical Congress in the matter of electrical engineering. Their courtesy in this regard will certainly be highly esteemed.

Judge Armstrong moved that a committee of three be appointed to whom the matter be referred. The motion to appoint the committee was seconded and carried, and the **President** named Judge Armstrong, Mr. F. W. Cushing, and Capt. W. L. Candee, as the committee.

Mr. Erastus Wiman then read a paper on "Electric Lighting from a Financial Standpoint."[1]

On motion of **Judge Armstrong** a vote of thanks was tendered to Mr. Wiman.

The meeting then adjourned.

THURSDAY, FEB. 25.—MORNING SESSION.

The Second Vice-President, Mr. M. J. **Francisco**, called the meeting to order.
